66-10. A 55-year-old woman presents to your clinic with vague chest pain and dyspnea. A chest radiograph reveals a mass in the right costophrenic angle. CT of the chest suggests a pericardial cyst. Which of the following is *correct*?

A. Pericardial cysts are smooth, thin-walled structures usually filled with pus
B. The recommended therapeutic course is observation of the patient
C. Pericardial cysts are usually symptomatic and tend to increase in size over time
D. The patient's symptoms are likely unrelated to the cyst
E. Percutaneous drainage of the cyst is recommended for asymptomatic patients

ANSWERS

66-1. **The answer is C.** *(Hurst's The Heart, 14th Edition, Chap. 66)* The human pericardium has two distinct layers; the serosa is composed of a single column of mesothelial cells that surrounds all four cardiac chambers and the proximal great vessels and reflects on itself to form the inner surface of the fibrosa, a fibrocollagenous structure (option C). This monolayer of serosal cells covering the surface of the heart and epicardial fat is also called the visceral pericardium, whereas the fibrosa and the reflection of the serosa make the parietal pericardium.

Most of the innervation of the pericardium occurs via the phrenic nerves (C4–C6), which course anteriorly (option D); this is particularly relevant during pericardiectomy. No adverse consequences follow congenital absence or surgical removal of the pericardium (option B). However, the pericardium serves many important (although subtle) functions. It limits distension of the cardiac chambers and facilitates the interaction and coupling of the ventricles and atria (option A). Limitation of cardiac filling volumes by the pericardium may also limit cardiac output and oxygen delivery during exercise.

66-2. **The answer is C.** *(Hurst's The Heart, 14th Edition, Chap. 66)* The clinical diagnosis of acute pericarditis is established when two of four clinical criteria are satisfied (Table 66-1). Acute pericarditis is usually characterized by sharp retrosternal pain (option B) that is aggravated by lying down and relieved by sitting up; its onset is often heralded by a prodrome of fever, malaise, and myalgia. The most specific physical sign can be the presence of a pericardial friction rub (option D), which is identifiable in no more than a third of cases. Within a few hours of the onset of chest pain, typical ECG changes include ST-segment elevations and depression of the PR segment (except in lead aVR), which can persist for hours or days (option A). This is the first ECG stage of pericarditis, followed by normalization of the ST segments (stage 2), T-wave inversions (stage 3), and finally, normalization again (stage 4). This is different from myocardial

infarction, wherein T-wave inversions often begin while the ST segments are still elevated. In addition, echocardiographic identification of pericardial effusion confirms the clinical diagnosis of acute pericarditis (option E). Elevated fever (option C) is a major indicator of poor prognosis but is not a diagnostic criterion.

TABLE 66-1 Definition and Diagnostic Criteria for Acute Pericarditis

Inflammatory pericardial syndrome to be diagnosed with at least 2 of the 4 following criteria: (1) pericarditic chest pain (2) pericardial rubs (3) new widespread ST elevation or PR depression on ECG (4) pericardial effusion (new or worsening)
Additional supporting findings: Elevation of markers of inflammation (ie, C-reactive protein, erythrocyte sedimentation rate, and white blood cell count); Evidence of pericardial inflammation by an imaging technique (computed tomography, cardiac magnetic resonance).

66-3. The answer is D. *(Hurst's The Heart, 14th Edition, Chap. 66)* Treatment of pericardial disease is challenging because there is a paucity of randomized, placebo-controlled trials that identify appropriate therapy and help with clinical decision making. Table 66-2 summarizes the main recommendations of the 2015 ESC guidelines.[1] Colchicine is a first-line therapy to be used as adjunct to aspirin/NSAIDs or corticosteroids to treat and prevent pericarditis, either in acute or recurrent cases (Class I recommendation, level of evidence: A) (option D). Corticosteroids should not be prescribed as first choice in patients with acute pericarditis, given the risk of recurrence (Class III recommendation, level of evidence: C) (option A). The essential indications to drain a pericardial effusion include: cardiac tamponade (therapeutic pericardiocentesis), a suspicion of bacterial or neoplastic etiology, and persistent moderate to large pericardial effusion without response to medical therapy (Class I recommendation, level of evidence: C) (option C). Vasodilators and diuretics are not recommended in the presence of cardiac tamponade (Class III recommendation, level of evidence: C) (option B).

TABLE 66-2 Summary of the 2015 European Society of Cardiology Guidelines on the Diagnosis and Management of Pericardial Diseases

	Indication	Evidence
Acute and recurrent pericarditis		
A triage is recommended to identify high-risk patients who should be admitted to hospital. Low-risk patients can be managed as outpatients.	Class I	Level B
Colchicine is now a first-choice drug to be used as adjunct to aspirin/NSAID or corticosteroids to treat and prevent pericarditis either in acute or recurrent pericarditis (weight-adjusted doses are recommended without a loading dose; eg, 0.5 mg twice a day for 3 months in acute pericarditis and 6 months in recurrent pericarditis; colchicine should be given only as 0.5 mg once for patients > 70 kg).	Class I	Level A
Levels of C-reactive protein are useful to guide the treatment duration and assess the response to treatment in acute and recurrent pericarditis; anti-inflammatory therapy should be maintained until symptom resolution and C-reactive protein normalization.	Class IIa	Level C
Corticosteroids should not be prescribed as first choice in patients with acute pericarditis since it may favor chronicization.	Class III	Level C
Pericardial effusion		
The essential indications to drain a pericardial effusion include: (1) cardiac tamponade (therapeutic pericardiocentesis), (2) a suspicion of bacterial or neoplastic aetiology, and (3) persistent moderate to large pericardial effusion without response to medical therapy.	Class I	Level C
A triage system is proposed also for the management of pericardial effusion and is essentially based on the following: (1) recognize cardiac tamponade and possible bacterial of neoplastic etiologies, (2) exclude concomitant pericarditis or treat as pericarditis, (3) identify associated underlying diseases, and (4) if chronic and large (> 20 mm), consider pericardial drainage to prevent cardiac tamponade during follow-up.	Class I	Level C
Treatment of pericardial effusions should be tailored as much as possible to the underlying etiology.	Class I	Level C
Cardiac tamponade		
In a patient with clinical suspicion of cardiac tamponade, echocardiography is recommended as the first imaging technique to evaluate the size, location, and degree of hemodynamic impact of the pericardial effusion.	Class I	Level C

Urgent pericardiocentesis or cardiac surgery is recommended to treat cardiac tamponade.	Class I	Level C
A judicious clinical evaluation including echocardiographic findings is recommended to guide the timing of pericardiocentesis.	Class I	Level C
Vasodilators and diuretics are not recommended in the presence of cardiac tamponade.	Class III	Level C
Constrictive pericarditis		
CT and CMR are indicated for the evaluation of a suspected constrictive pericarditis as second-level imaging techniques after echocardiography.	Class I	Level C
Cardiac catheterization is indicated only in complex cases when noninvasive imaging does not provide a clear-cut diagnosis or provides conflicting results.	Class I	Level C
The mainstay of therapy for chronic constriction is radical pericardiectomy, but it is acknowledged that there is a need to assess the possible presence of pericardial inflammation (eg, elevation of C-reactive protein, pericardial inflammation on CT/CMR) as precipitating cause in new-onset cases in order to treat with empiric anti-inflammatory therapy.	Class I	Level C
Diagnostic workup of pericardial diseases		
First diagnostic evaluation in a patient with a clinical suspicion of pericardial disease should include: focused history and physical examination, ECG, chest x-ray, and routine blood tests, including markers of myocardial inflammation and lesion and renal function.	Class I	Level C
Echocardiography is the first essential diagnostic imaging tool, whereas CT and CMR are second-level imaging techniques for specific indications.	Class I	Level C
Additional diagnostic testing should be targeted and clinically guided.	Class I	Level C
Main specific forms		
Tuberculosis		
Empiric antituberculous therapy is only recommended in countries where tuberculosis is endemic and the disease is highly probable in the setting of a patient with pericarditis and pericardial effusion.	Class I	Level C
In cases with an established diagnosis of tuberculous pericarditis, standard antituberculous therapy is recommended for 6 months and prevents the evolution to constrictive pericarditis.	Class I	Level C
In patients with tuberculous pericarditis with features of constriction and not responding to antituberculous therapy, pericardiectomy is recommended after 4–8 weeks of medical therapy.	Class I	Level C
Neoplastic pericardial diseases		
The definite diagnosis of neoplastic pericardial disease relies on the evidence of neoplastic cells on cytology of pericardial fluid.	Class I	Level B
Pericardial biopsy should be considered for the final etiologic diagnosis in selected cases.	Class IIa	Level B
Tumor markers in pericardial fluid may be helpful to differentiate a benign vs a malignant pericardial effusion.	Class IIa	Level B
In cases with a confirmed diagnosis of neoplastic pericardial disease, systemic antineoplastic treatment is indicated.	Class I	Level B
Extended pericardial drainage is recommended to prevent recurrent cardiac tamponade and pericardial effusion and to provide a way for intrapericardial therapy.	Class I	Level B
Intrapericardial therapy with cytostatic agents should be considered to treat neoplastic pericardial disease.	Class IIa	Level B

Abbreviations: CMR, cardiac magnetic resonance; CT, computed tomography; ECG, electrocardiography; NSAID, nonsteroidal anti-inflammatory drugs.

66-4. **The answer is A.** *(Hurst's The Heart, 14th Edition, Chap. 66)* Recurrent pericarditis is one of the most troublesome complications of pericarditis, occurring in one-third of cases. The mainstay of therapy for recurrences is similar to that for acute pericarditis: aspirin or an NSAID plus colchicine at the same doses that are recommended for acute pericarditis (option E). Corticosteroids should be considered as a second-line therapy for patients with contraindications for or failure of aspirin/NSAIDs or patients with specific indications (eg, pregnant patients, patients with a systemic inflammatory disease already on corticosteroids, patients with renal failure, patients on oral anticoagulant therapies to avoid interference with aspirin/NSAIDs) (option D). If used, low to moderate doses (eg, prednisone 0.2 to 0.5 mg/kg/d or equivalent) are indicated because high doses (eg, prednisone 1.0 to 1.5 mg/kg/d) are associated with a high rate of severe side effects (up to 25%) with more drug withdrawals, drug-related hospitalization, and recurrences (option A). In more difficult cases, aspirin or NSAID, colchicine, and corticosteroids may be used together as a triple therapy to achieve better control of symptoms (option B).[2] After failure of medical therapy, pericardiectomy can be considered (option C), although it should be performed in centers with specific expertise in such surgery to achieve the best outcomes.[3]

66-5. **The answer is D.** *(Hurst's The Heart, 14th Edition, Chap. 66)* Tuberculosis is a major cause of pericarditis in nonindustrialized countries but an uncommon cause in developed countries with a low prevalence of tuberculosis. Tuberculous pericarditis results from hematogenous spread of primary tuberculosis or from the breakdown of infected mediastinal lymph nodes, with the result that affected individuals generally lack the typical symptoms and signs of pulmonary tuberculosis (option A). Early signs include fever, weight loss, and night sweats. Essentially, all causes of pericarditis can manifest as pericardial effusion. In developing countries, tuberculosis continues to be the predominant etiology, accounting for 50% to 60% of cases.[4] Findings suggestive of pericardial effusion with tamponade physiology (that are nonspecific to tuberculous pericardial disease, however) include an elevated pulsus paradoxus (option B) and ECG findings of low QRS voltage and electrical alternans (option C). Bacterial and mycobacterial cultures should be

performed if bacterial infection or tuberculosis is suspected, respectively. However, TB is a slow-growing organism, and cultures can take weeks to become positive. Acid-fast bacilli staining (option D), adenosine deaminase, pericardial lysozyme, and interferon-γ levels, as well polymerase chain reaction testing, should be added in the evaluation of tuberculous pericarditis. Nonspecific blood markers of inflammation, such as the erythrocyte sedimentation rate, C-reactive protein (option E), and white blood cell count, usually increase in cases of pericarditis and can support the diagnosis.

66-6. **The answer is B.** *(Hurst's The Heart, 14th Edition, Chap. 66)* Cardiac tamponade corresponds to a corollary of hemodynamic derangements that are secondary to increased intrapericardial pressure. As intrapericardial pressure rises in patients with cardiac tamponade, elevated pericardial pressure is transmitted to all four chambers, affecting diastolic filling. Inspection of the jugular veins will show elevation in central venous pressure (option D); venous distention may or may not be present. Analysis of the venous wave contour will reveal absence or blunting of the *y* descent, representing impaired ventricular diastolic filling (option B).

Cardiac auscultation might reveal distant heart sounds. Because early diastolic filling is profoundly impaired, a third heart sound should not be present (option C); its occurrence suggests an alternative diagnosis. For unclear reasons, tamponade does not usually lead to pulmonary edema (option A); the lungs are often clear on auscultation in patients with isolated cardiac tamponade. Rather, hemodynamic compromise is the more striking finding.

66-7. **The answer is A.** *(Hurst's The Heart, 14th Edition, Chap. 66)* Cardiac tamponade is a cardiac emergency and should be treated with prompt needle pericardiocentesis (option B) unless it is caused by aortic dissection. The goal should be aspiration of all pericardial fluid. The procedure should be done with transthoracic echocardiographic guidance by an experienced operator (option C). During echo-guided pericardiocentesis, the largest collection of fluid in closest proximity to the chest wall should be identified, defining the optimal site for needle entry. Echocardiography also confirms the absence of interposed lung or liver tissue. Complications include cardiac or coronary perforation, hemothorax or liver injury, pneumothorax, and pneumopericardium. The daily output of pericardial fluid is recorded. The pigtail catheter should not be removed until the output is < 30 mL over a 24-hour period (option A). Before the intrapericardial catheter is removed, a limited echocardiogram is often repeated to reassess the effusion size and areas of loculation (option D).

66-8. **The answer is B.** *(Hurst's The Heart, 14th Edition, Chap. 66)* Constrictive pericarditis results from inflammation and/or scarring of the pericardium, leading to impairment of cardiac filling. The disease also appears to favor men over women (2:1 ratio) (option A). Given the abnormal pericardial compliance, diastolic filling is significantly impaired in patients with constrictive pericarditis (steeper increase in pressure per change in volume in the pressure–volume curve). As a consequence, cardiac filling pressures increase, and cardiac output falls as stroke volume decreases. The thickened pericardium has limited expansion, and cardiac chambers "compete" for pericardial space during diastolic filling. With respiration, an increase in preload in one ventricle occurs at the expense of filling in the other (ventricular interdependence) (option B). Patients with constrictive pericarditis typically present with features of right-sided heart failure (option D), manifested by elevated venous pressure, ascites, and leg edema. Orthopnea and paroxysmal nocturnal dyspnea are not usually observed and suggest another etiology (option C).

66-9. **The answer is C.** *(Hurst's The Heart, 14th Edition, Chap. 66)* Although patients presenting with constrictive pericarditis and evidence of active pericardial inflammation (either by CMR or elevated inflammatory markers) might respond to anti-inflammatory therapy (Class IIb recommendation; level of evidence: C) (option A), therapeutic pericardiectomy is the recommended treatment for symptomatic patients with constrictive pericarditis (Class I recommendation; level of evidence: C) (option C). Pericardiectomy is the surgical removal of the pericardium, and the procedure is applicable to all variants of pericardial disease. Some patients presenting with cardiac tamponade demonstrate features of constrictive pericarditis immediately after pericardiocentesis is performed and tamponade relieved, such as in the case of those with effusive constrictive pericarditis. In such cases, therapy should be focused on treating active inflammation; a subset of patients might develop chronic constrictive pericarditis and require pericardiectomy following the pericardiocentesis (option B). Therefore, close follow-up of patients with effusive-constrictive pericarditis is recommended (option D).

66-10. **The answer is B.** *(Hurst's The Heart, 14th Edition, Chap. 66)* Pericardial cysts are smooth, thin-walled structures filled with clear fluid (hence the term spring water cysts) (option A). Patients with pericardial cysts are usually asymptomatic, and the cysts tend not to increase in size (option C). Some patients with pericardial cysts complain of atypical chest pain or dyspnea, most likely as a result of compression of contiguous structures (option D). For patients with symptoms related to the pericardial cyst, percutaneous drainage or surgical removal can be performed (option E).[5] However, given the risks associated with both procedures and the benign, well-tolerated course of the disease, observation is likely most appropriate for the majority of patients with pericardial cysts (option B).

Learning Objectives

1. Distinguish between the treatment strategies for acute coronary syndrome: ST-segment elevation myocardial infarction and non–ST-segment elevation acute coronary syndrome.
2. Formulate evidence-based treatment strategies for patients with acute decompensated heart failure.
3. Devise a treatment plan for patients presenting with ventricular or life-threatening arrhythmias.
4. Differentiate between goals and treatment for hypertensive emergencies and hypertension without progressive organ damage.
5. Provide evidence-based treatment for a patient given a diagnosis of idiopathic pulmonary arterial hypertension.

Abbreviations in This Chapter

AAD	Antiarrhythmic drug
ACE	Angiotensin-converting enzyme
ACS	Acute coronary syndrome
ACT	Activated clotting time
ADHF	Acute decompensated heart failure
ADR	Adverse drug reaction
AF	Atrial fibrillation
aPTT	Activated partial thromboplastin time
BNP	B-type natriuretic peptide
CABG	Coronary artery bypass grafting
CAD	Coronary artery disease
CI	Cardiac index
CO	Cardiac output
CPR	Cardiopulmonary resuscitation
CV	Cardiovascular
DAPT	Dual antiplatelet therapy
ECG	Electrocardiogram
EF	Ejection fraction
GI	Gastrointestinal
GP	Glycoprotein
GRACE	Global Registry of Acute Coronary Events
HF	Heart failure
HIT	Heparin-induced thrombocytopenia
ICD	Implantable cardioverter-defibrillator
IPAH	Idiopathic pulmonary arterial hypertension
LOE	Level of evidence
LV	Left ventricle
LVEF	Left ventricular ejection fraction
MAP	Mean arterial pressure
MI	Myocardial infarction
mPAP	Mean pulmonary arterial pressure
NSTE-ACS	Non–ST-segment elevation acute coronary syndrome
NSTEMI	Non–ST-segment elevation myocardial infarctions
PAH	Pulmonary arterial hypertension
PCI	Percutaneous coronary intervention
PCWP	Pulmonary capillary wedge pressure
PH	Pulmonary hypertension
SCD	Sudden cardiac death
SHD	Structural heart disease
STEMI	ST-segment elevation myocardial infarction
SVR	Systemic vascular resistance
SVT	Supraventricular tachycardia
UA	Unstable angina
UFH	Unfractionated heparin
VT	Ventricular tachycardia

Self-Assessment Questions

Answers and explanations to these questions can be found at the end of this chapter.

1. A 62-year-old man presents to the emergency department with the chief concern of chest pain that woke him from sleep and radiates to his jaw. An electrocardiogram (ECG) reveals ST-segment depression in leads II, III, and aVF. His blood pressure is 112/62 mm Hg, and heart rate is 60 beats/minute. Cardiac enzymes have been obtained, and the first troponin result was slightly positive. Preparations are under way to take the patient to the cardiac catheterization laboratory for evaluation. Which medication regimen is most appropriate for this patient at this time?
   A. Aspirin 325 mg, clopidogrel 600-mg loading dose, and unfractionated heparin (UFH) infusion 80-unit/kg bolus, followed by 18 units/kg/hour and metoprolol 5 mg intravenously three times.
   B. Aspirin 81 mg; prasugrel 60-mg loading dose; UFH infusion 60-unit/kg bolus, followed by 12 units/kg/hour; and intravenous enalaprilat.

C. Aspirin 325 mg, ticagrelor 180-mg loading dose, and UFH infusion 60-unit/kg bolus, followed by 12 units/kg/hour.

D. Aspirin 81 mg, prasugrel 60-mg loading dose, nitroglycerin infusion at a rate of 10 mcg/minute, and bivalirudin 0.75 mg/kg bolus and 1.75 mg/kg/hour infusion.

2. An 81-year-old African American man (weight 90 kg) presents to the emergency department with chest pressure (10/10 on a pain scale). His ECG reveals ST-segment depression in the inferior leads. His medical history is significant for hypertension and chronic kidney disease. Pertinent laboratory results are troponin 5.8 ng/L, serum creatinine (SCr) 3.7 mg/dL, and estimated creatinine clearance (CrCl) 20 mL/minute. The patient has been given aspirin 325 mg single dose; a nitroglycerin drip, initiated at 5 mcg/minute, will be titrated to chest pain relief and blood pressure. The patient consents for cardiac catheterization after adequate hydration. Which anticoagulation strategy is most appropriate to initiate in this patient?

   A. Intravenous heparin 4000-unit intravenous bolus, followed by a 1000-unit/hour continuous infusion.

   B. Enoxaparin 90 mg subcutaneously every 12 hours.

   C. Fondaparinux 2.5 mg subcutaneously daily.

   D. Bivalirudin 67.5-mg bolus, followed by a 157-mg/hour infusion.

3. A 56-year-old man presents to the hospital with the chief concern of chest pain that was unrelieved at home with nitroglycerin. His ECG reveals ST-segment depression and T-wave inversion. Cardiac markers show an elevated troponin I. The cardiologist has requested that the patient go to the cardiac catheterization laboratory for further evaluation. The patient has a history of coronary artery disease (CAD) and had a myocardial infarction (MI) about 6 months ago. During his previous hospitalization, the patient was thought to have developed heparin-induced thrombocytopenia (HIT) because his platelet count dropped to 40,000/mm^3 after his previous catheterization. Given this patient's diagnosis and history, which treatment regimen would be most appropriate during his cardiac catheterization?

   A. Abciximab.

   B. Bivalirudin.

   C. Eptifibatide.

   D. Tenecteplase.

4. A 62-year-old man presents to the emergency department after several hours of chest discomfort. His ECG reveals 1- to 2-mm ST-segment elevation in leads V_1–V_4, with positive troponins. He has also had increasing shortness of breath and swelling over the past 2–3 weeks. His medical history is significant for tobacco use for 40 years, chronic obstructive pulmonary disease, diabetes, and hypertension. His blood pressure is 102/76 mm Hg and heart rate is 111 beats/minute. He has rales in both lungs and 2–3+ pitting edema in his extremities. His ECG reveals an ejection fraction (EF) of 25%. After primary percutaneous coronary intervention (PCI), he is transferred to the cardiac intensive care unit. Which best describes the acute use of β-blocker therapy in this patient?

   A. Give 12.5 mg of oral carvedilol within the first 24 hours.

   B. Give 5 mg of intravenous metoprolol at bedside.

   C. Give 50 mg of oral metoprolol at discharge.

   D. Give no β-blocker at this time.

5. A 60-year-old woman with New York Heart Association (NYHA) class IV heart failure (HF) (heart failure with reduced ejection fraction [HFrEF]) is admitted for increased shortness of breath and dyspnea at rest. Her extremities appear well perfused, but she has 3+ pitting edema in her lower extremities. Her vital signs include blood pressure 125/70 mm Hg, heart rate 92 beats/minute, and oxygen saturation (Sao_2) 89% on 100% facemask. After initiating an intravenous diuretic, which is the best intravenous drug to treat this patient?

   A. Dobutamine.

   B. Milrinone.

   C. Nitroglycerin.

   D. Metoprolol.

6. A 75-year-old woman has a history of NYHA class III HFrEF (left ventricular ejection fraction [LVEF] 25%) and several non–ST-segment elevation myocardial infarctions (NSTEMIs). She had an episode of sustained ventricular tachycardia (VT) during this hospitalization for pneumonia. Her corrected QT (QTc) interval was 380 milliseconds on the telemetry monitor, and her serum potassium and magnesium were 4.6 mEq/L and 2.2 mg/dL, respectively. Which intravenous agent is most appropriate for this patient?
   A. Procainamide.
   B. Metoprolol.
   C. Magnesium.
   D. Amiodarone.

7. A 53-year-old woman is admitted to the hospital after the worst headache she has ever had. Her medical history includes exertional asthma, poorly controlled hypertension, and hyperlipidemia. She is nonadherent to her medications, and she has not taken her prescribed blood pressure medications for 4 days. Vital signs include blood pressure 220/100 mm Hg and heart rate 65 beats/minute. She has a cerebrovascular accident. Which agent is most appropriate for this patient's hypertensive emergency?
   A. Fenoldopam 0.1 mcg/kg/minute.
   B. Nicardipine 5 mg/hour.
   C. Labetalol 0.5 mg/minute.
   D. Enalaprilat 0.625 mg intravenously every 6 hours.

8. A 56-year-old African American man has a long history of poorly controlled hypertension secondary to medication nonadherence and subsequent dilated cardiomyopathy (LVEF 35%). He is assessed in a community health clinic today and reports not having taken his medications for the past week. The patient is asymptomatic, and his examination is unremarkable except for blood pressure 180/120 mm Hg and heart rate 92 beats/minute. All laboratory values are within normal limits except for an SCr of 1.4 mg/dL and a urinalysis with 2+ proteinuria. Which regimen would be best to treat this patient in the clinic?
   A. Nifedipine 10 mg sublingually.
   B. Clonidine 0.2 mg orally.
   C. Captopril 12.5 mg orally.
   D. Labetalol 200 mg orally.

9. A 52-year-old woman experiences a witnessed cardiac arrest in a shopping mall; she is resuscitated with an automatic external defibrillator device. On electrophysiological study, she has inducible VT. Which agent is most appropriate for reducing the secondary incidence of sudden cardiac death (SCD)?
   A. Propafenone.
   B. Amiodarone.
   C. Implantable cardioverter-defibrillator (ICD).
   D. Metoprolol.

10. The Sudden Cardiac Death in Heart Failure trial evaluated the efficacy of amiodarone or an ICD versus placebo in preventing all-cause mortality in ischemic and nonischemic patients with NYHA class II and III HF. There was a 7.2% absolute risk reduction and a 23% relative risk reduction in all-cause mortality at 60 months with an ICD versus placebo. Which option best shows the number of patients needed to treat with an ICD to prevent one death versus placebo?
   A. 1.
   B. 4.
   C. 14.
   D. 43.

11. You are working on a review article about newer treatment strategies for hypertensive crises. You want to ensure that you retrieve all relevant clinical trials and related articles on your subject. Which comprehensive database is most appropriate to search to ensure that you have not missed key articles?
   A. International Pharmaceutical Abstracts.
   B. Iowa Drug Information Service.
   C. Clin-Alert.
   D. Excerpta Medica.

12. A physician on your team asks that you report an adverse drug reaction (ADR) experienced by a patient taking nesiritide. The patient had severe hypotension after the initial bolus dose of nesiritide, although his blood pressure was in the normal range before therapy initiation. The hypotension led to reduced renal perfusion, resulting in oliguric acute kidney injury and subsequent hemodialysis. The patient had no known renal insufficiency before developing this complication. Which statement best describes The Joint Commission requirements for institutional ADR reporting?
    A. A MedWatch form must be completed that explains the situation in which the ADR occurred.
    B. Institutions must create their own definition of ADR with which practitioners will be familiar.
    C. Hospital staff members must use the Naranjo algorithm to assess the severity of the ADR.
    D. Only severe or life-threatening ADRs need to be reported.

13. Your pharmacy and therapeutics committee wants you to perform a pharmacoeconomic analysis of a new drug available to treat decompensated HF. This drug works through a unique mechanism of action. Unlike other available inotropic therapies that can increase mortality, this drug appears to reduce long-term mortality. However, the cost is 10-fold greater than that of other available drugs. Which pharmacoeconomic analysis would be best to determine whether this new drug is a better formulary choice than currently available agents?
    A. Cost minimization analysis.
    B. Cost-effectiveness analysis.
    C. Cost-benefit analysis.
    D. Cost-utility analysis.

BPS Pharmacotherapy Specialty Examination Content Outline

This chapter covers the following sections of the Pharmacotherapy Specialty Examination Content Outline:

1. Domain 1: Patient–centered pharmacotherapy
    a. Tasks 1:1–17, 2:1–5, 7, 3:1–5, 4:1–7, 5:1–5
    b. Systems and patient-care problems:
        i. Acute coronary syndrome
        ii. Acute decompensated heart failure
        iii. Adult cardiac arrest
        iv. Advanced cardiac life support
        v. Basic life support and cardiopulmonary resuscitation (CPR)
        vi. Life-threatening arrhythmias
        vii. Hypertensive crises (urgency and emergency)
        viii. Pulmonary hypertension
2. Domain 2: Drug Information and Evidence-Based Medicine, Tasks 1:2, 3, 2:1, 5, 6, and 3:1, 2
3. Domain 3: System-Based Standards and Population-Based Pharmacotherapy, Tasks 1:4

I. ACUTE CORONARY SYNDROME

A. Definitions
1. Acute coronary syndrome (ACS) is a spectrum of conditions compatible with acute myocardial ischemia or infarction because of an abrupt reduction in coronary blood flow.
2. Atherogenic plaque rupture is the underlying pathophysiology for ACS, causing several prothrombotic substances to be released, which results in platelet activation and aggregation and eventual thrombus formation leading to partial or total occlusion of the coronary artery.
3. ACS can be divided into ST-segment elevation myocardial infarction (STEMI) and non–ST-segment elevation acute coronary syndrome (NSTE-ACS)
    a. STEMI
        i. Defined by characteristic symptoms of myocardial ischemia in association with persistent ST-segment elevation on ECG with positive troponins
        ii. STEMI is an indication for immediate coronary angiography to determine whether reperfusion can be performed.
    b. NSTE-ACS
        i. Suggested by the absence of persistent ST-segment elevation
        ii. NSTE-ACS can be divided into unstable angina (UA) and non-STEMI (NSTEMI) according to whether cardiac biomarkers of necrosis are present. UA and NSTEMI are closely related conditions whose pathogenesis and clinical presentation are similar but vary in severity.
        iii. Abnormalities on the ECG and elevated troponins in isolation are insufficient to make the diagnosis and must be interpreted in the appropriate clinical context (Table 1).
        iv. Optimal inhibition of thrombosis is paramount in the management of ACS.

B. Clinical Assessment and Initial Evaluation
1. A 12-lead ECG should be performed and interpreted within 10 minutes of presentation.
    a. Persistent ST-segment elevation should be treated according to the STEMI guidelines.
    b. Serial ECGs can be performed if initial is nondiagnostic.
2. Serial cardiac troponins (I or T) should be obtained at presentation and 3–6 hours after symptom onset.
3. At initial presentation, the clinical history, angina symptoms and equivalents, physical estimation, ECG, renal function, and cardiac troponin measurements can be integrated into an estimation of the risk of death and nonfatal cardiac ischemic events, which is useful for selecting the site of care, antithrombotic therapies, and invasive management. Risk calculators include the following:
    a. Thrombolysis in myocardial infarction (TIMI) risk score (available at www.timi.org [accessed December 13, 2017]) is useful in predicting 30-day and 1-year mortality in patients with NSTE-ACS.
        i. Composed of seven 1-point indicators rated on presentation; 1 point is given for each of the following: 65 years or older, three or more risk factors for CAD, prior coronary stenosis 50% or greater, ST deviation on ECG, two or more anginal events in previous 24 hours, use of aspirin in previous 7 days, and elevated cardiac biomarkers
        ii. Risk of mortality, new or recurrent MI, or severe recurrent ischemia through 14 days; 0–2 is low risk, 3 is intermediate risk, and 4 or more is high risk
        iii. Among patients with higher risk scores (e.g., TIMI of 3 or more), there is a greater benefit from therapies such as low-molecular-weight heparin, glycoprotein (GP) IIb/IIIa inhibitors, and invasive strategies.
    b. The Global Registry of Acute Coronary Events (GRACE) risk model (www.outcomes-umassmed.org/grace/acs_risk/acs_risk_content.html [accessed December 10, 2015]) predicts in-hospital and postdischarge mortality or MI. Patients with high GRACE risk model scores (i.e., GRACE score greater than 140) can be identified for early invasive strategies.

Table 1. ACS Definition

	Subjective Findings	Objective Findings	Extent of Injury
NSTE-ACS UA	Most commonly presents as a pressure-type chest pain that typically occurs at rest or with minimal exertion Pain most often starts in the retrosternal area and can radiate to either or both arms, neck, or jaw Pain may also present with diaphoresis, dyspnea, nausea, abdominal pain, or syncope Unexplained new-onset or increased exertional dyspnea is the most common angina equivalent Less common atypical symptoms[a] (without chest pain) include epigastric pain, indigestion, nausea, vomiting, diaphoresis, unexplained fatigue, and syncope	ST-segment depression, T-wave inversion, or transient or nonspecific ECG changes can occur No positive biomarkers for cardiac necrosis	No myocardial injury; partial occlusion of coronary artery
NSTEMI		ST-segment depression, T-wave inversion, or transient or nonspecific ECG changes can occur Positive biomarkers (troponin I or T elevation)	Myocardial injury; partial occlusion of coronary artery
STEMI	Classic symptoms include worsening of pain or pressure in chest, characterized as viselike, suffocating, squeezing, aching, gripping, and excruciating, that may be accompanied by radiation	ST-segment elevation > 1 mm above baseline on ECG in two or more contiguous leads Positive biomarkers (troponin I or T elevation)	Myocardial necrosis; total occlusion of coronary artery

[a]Up to half of all MIs are silent or unrecognized, and one-third present with symptoms other than chest discomfort.

NSTE-ACS = non–ST-segment elevation acute coronary syndrome; NSTEMI=non-ST segment elevation myocardial infarction; MI=myocardial infarction; STEMI= ST segment elevation myocardial infarction; UA = unstable angina.

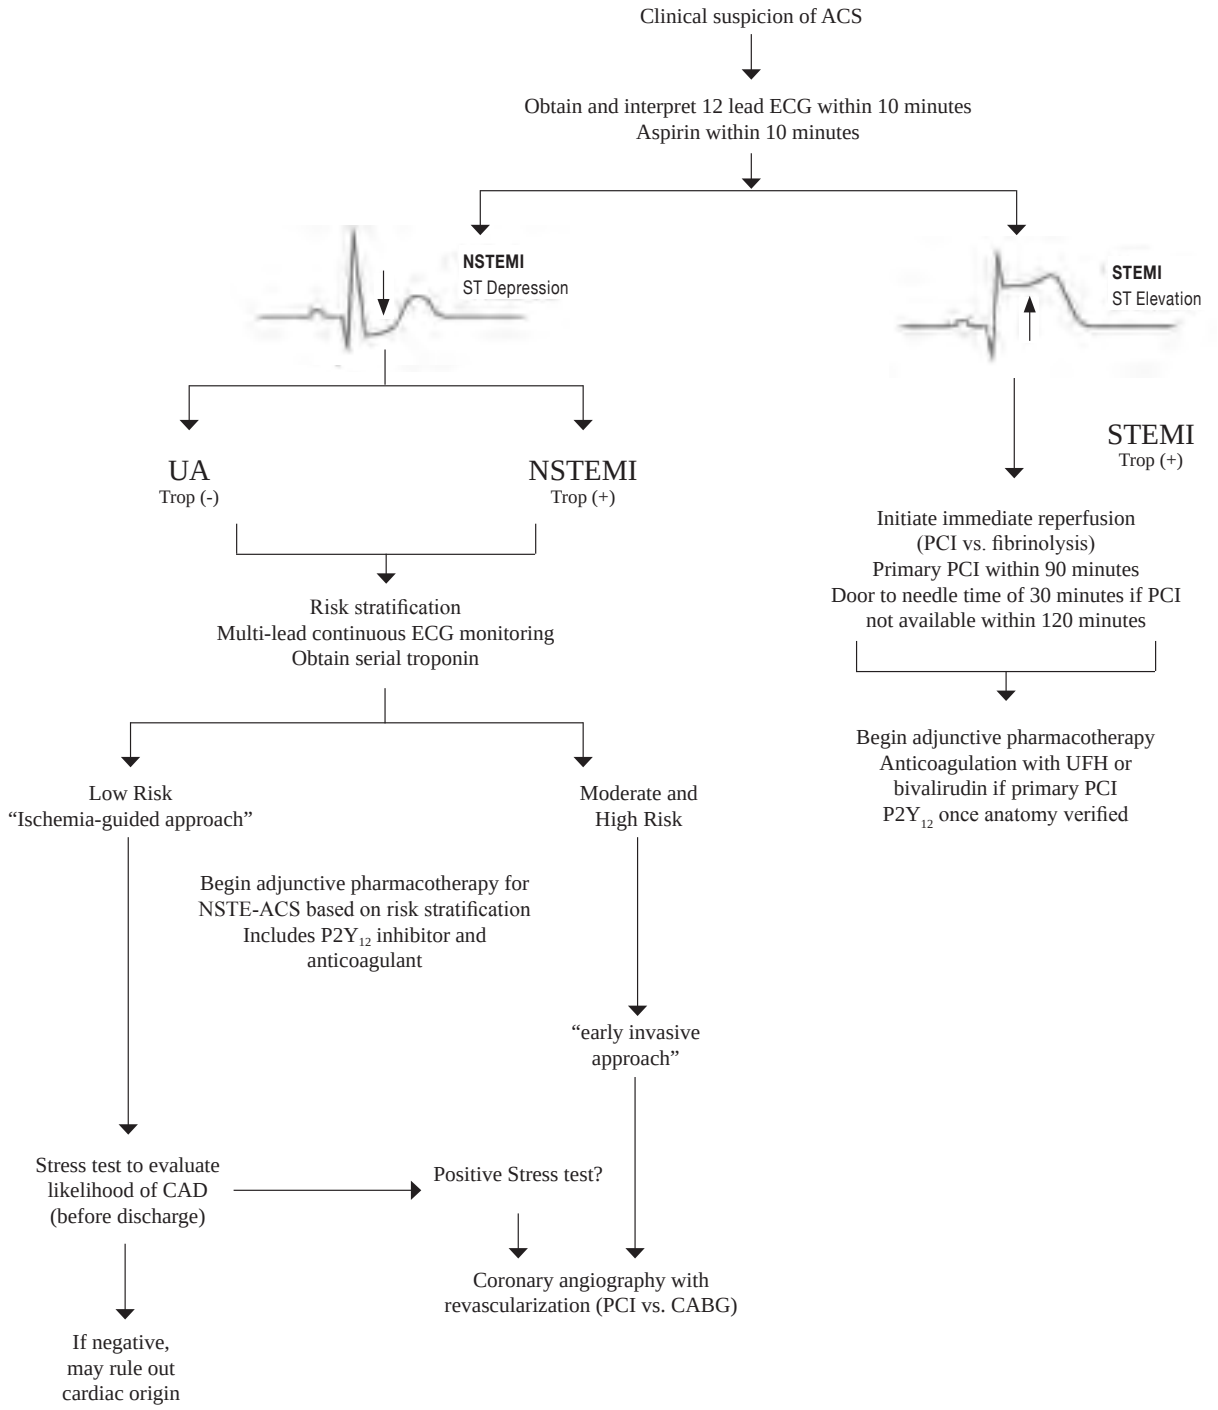

Figure 1. ACS diagnosis and risk stratification.

CABG = coronary artery bypass grafting.

C. Decision for Invasive Management
   1. STEMI
      a. The goal of therapy is to restore patency of the infarct-related artery and minimize infarct size. Secondary goals include prevention of complications such as arrhythmias or death as well as to control chest pain and associated symptoms.
      b. Requires urgent revascularization either interventionally or with drug therapy
      c. Primary PCI is preferred to lytic therapy. Performance measure includes goal of primary PCI within 90 minutes of first medical contact.
      d. Fibrinolytic therapy is indicated for patients with STEMI in whom PCI cannot be performed (discussed later in chapter). If PCI cannot be performed within 120 minutes, performance measure for lytic administration includes a door to needle time of 30 minutes.
   2. NSTE-ACS
      a. The goal of therapy is to prevent total occlusion of the related artery and to control chest pain and associated symptoms. Patients with NSTE-ACS are treated on the basis of risk (TIMI, GRACE) with either an early invasive strategy (interventional approach) or an ischemia-guided strategy (a conservative management strategy using medications rather than an interventional approach).
      b. Early invasive strategy is a diagnostic angiography with intent to perform revascularization if appropriate based on coronary anatomy.
         i. Indicated in those with NSTE-ACS who have refractory angina or hemodynamic or electrical instability or those with high risk based on clinical findings
         ii. Routine invasive therapy is generally superior to an ischemia-guided strategy (results in lower rates of recurrent UA, recurrent hospitalization, MI, and death) in patients with one or more of the following risk features: advanced age (older than 70 years), previous MI or revascularization, ST deviation, HF, depressed resting left ventricle (LV) function (i.e., LVEF less than 40%), noninvasive stress findings, high TIMI or GRACE scores, markedly elevated troponins, and diabetes.
         iii. Not for those with serious comorbidities or contraindications to such procedures (hepatic, renal, pulmonary failure, cancer), for whom the risks for the procedure may outweigh the benefits of revascularization
         iv. Ischemia-guided therapy seeks to avoid the routine early use of invasive procedures unless patients experience refractory or recurrent ischemic symptoms or develop hemodynamic instability.
            (a) Recommended for patients with a low risk score (TIMI 0 or 1, GRACE less than 109)
            (b) Indicated for those with acute chest pain with a low likelihood of ACS who are troponin negative (preferred for low-risk women)
            (c) Can be chosen according to clinician and patient preference
   3. All patients should receive anti-ischemic and analgesic medications early in care: morphine, oxygen, nitroglycerin, and aspirin plus β-blocker (Table 2).

Table 2. Initial Anti-ischemic and Analgesic Therapies in the Management of Acute Coronary Syndrome

Therapy	Comments
M = Morphine or other narcotic analgesic	Provides analgesia and decreased pain-induced sympathetic/adrenergic tone Commonly used because it can also induce vasodilation and mediate some degree of afterload reduction Morphine 1–5 mg IV every 5–30 min is reasonable if symptoms are not relieved despite maximally tolerated anti-ischemic medications[a] Carries a class IIb recommendation and may not be favored more than other narcotic analgesics, given that at least two large trials have identified an association between morphine administration and risk of death[b] Slows the absorption of antiplatelet therapy, reduces time to peak antiplatelet activity, and may decrease area under the curve
O = Oxygen	Can help attenuate anginal pain secondary to tissue hypoxia Consider supplemental oxygen if Sa_{O_2} < 90%, respiratory distress, or high-risk features of hypoxemia[c]
N = Nitroglycerin	Facilitates coronary vasodilation and may also be helpful in scenarios of severe cardiogenic pulmonary edema caused by venous capacitance NTG spray or sublingual tablet (0.3–0.4 mg) every 5 min for up to three doses to relieve acute chest pain (if pain is unrelieved after one dose, call 9-1-1); afterward, assess need for IV administration IV administration used in first 48 hr for treatment of persistent ischemic chest pain, HF, and HTN IV NTG 5–10 mcg/min; titrate to chest pain relief or max 200 mcg/min Use should not preclude other mortality-reducing therapies (β-blocker, ACE inhibitor) Contraindications: sildenafil or vardenafil (use within 24 hr) or tadalafil (use within 48 hr); SBP < 90 mm Hg or ≥ 30 mm Hg below baseline, HR < 50 beats/min, HR > 100 beats/min in absence of symptomatic HF or right ventricular infarction
A = Aspirin	Inhibits platelet activation Mortality reducing therapy Chew and swallow non–enteric coated 162–325 mg × 1 dose[c] Clopidogrel if aspirin allergy Performance measure
β-Blocker	Decrease myocardial ischemia, reinfarction, and frequency of dysrhythmias and increase long-term survival Oral β-blocker[c] should be initiated within 24 hr in patients who do not have signs of HF, evidence of low-output state, increased risk of cardiogenic shock, or other contraindications to β-blockade (e.g., PR interval > 0.24 s, second- or third-degree heart block, active asthma, or reactive airway disease) Reasonable to continue in patients with NSTE-ACS with normal LV function[a] Use metoprolol succinate, carvedilol, or bisoprolol in concomitant stabilized HFrEF[c]; add cautiously in decompensated HF Avoid agents with intrinsic sympathomimetic activity (acebutolol, pindolol, penbutolol) IV β-blocker[d] is potentially harmful in patients who have risk factors for shock (age > 70 yr, HR > 110 beats/min, SBP < 120 mm Hg, and late presentation)

[a]Class IIb may be considered.

[b]From: Montalescot G, van't Hof AW, Lapostolle F, et al. Prehospital ticagrelor in ST-segment elevation myocardial infarction. N Engl J Med 2014;371:1016-27; and Meine TJ, Roe MT, Chen AY, et al. Association of intravenous morphine use and outcomes in acute coronary syndromes: results from the CRUSADE Quality Improvement Initiative. Am Heart J 2005;149:1043-9.

[c]Class I, should be performed or administered; class IIa, reasonable to be performed or administered.

[d]Class III, not to be administered or harmful.

ACE = angiotensin-converting enzyme; HF = heart failure; HFrEF = heart failure with reduced ejection fraction; HTN = hypertension; LV = left ventricle; NTG = nitroglycerin; SBP = systolic blood pressure.

4. Patients with STEMI and NSTE-ACS should be treated with antiplatelet and anticoagulant therapy (Tables 3–9).
   a. Platelets are activated by several different mechanisms, only some of which can be inhibited by medications.
   b. Combination therapy with multiple antiplatelet agents plus a concomitant anticoagulant are the mainstay of acute ACS management, which targets the underlying pathophysiology of thrombus formation in ACS.
   c. The roles and combinations of antiplatelet therapies continue to be refined through clinical trials in varying subsets of ACS presentation (Table 3).
   d. In general, all patients receive aspirin and $P2Y_{12}$ receptor antagonists, and some patients benefit from the addition of GP IIb/IIIa inhibition in the acute management of ACS.

Table 3. Antiplatelet Management Strategies According to ACS Presentation

Antiplatelet	NSTE-ACS Ischemia Guided	NSTE-ACS Invasive	STEMI Primary PCI	STEMI + Fibrinolytic
Aspirin	Aspirin	Aspirin	Aspirin	Aspirin
$P2Y_{12}$ receptor antagonist	Clopidogrel Ticagrelor	Clopidogrel Prasugrel[a] Ticagrelor[a]	Clopidogrel Prasugrel Ticagrelor	Clopidogrel[b]
GP IIb/IIIa inhibitor	Greatest benefit when given to patients and high-risk features (e.g., elevated troponin) not adequately pretreated with clopidogrel or ticagrelor[c]			

[a]It may be reasonable to choose ticagrelor or prasugrel (in those who are not at high bleeding risk) over clopidogrel in patients treated with early invasive strategy for NSTE-ACS (class IIa, 2014 NSTE-ACS guideline).

[b]Pre-PCI after fibrinolytic therapy: 300-mg loading dose if within 24 hr of event; clopidogrel 600-mg loading dose if > 24 hr after event.

[c]Benefit from adding GP IIb/IIIa inhibitors to aspirin therapy is greatest among those with highest-risk features (those with elevated biomarkers, those with diabetes, those undergoing revascularization) and in those not receiving adequate pretreatment with $P2Y_{12}$. It is reasonable (class IIa, 2014 NSTE-ACS guideline) to give GP IIb/IIIa inhibitors to high-risk patients with NSTE-ACS treated with UFH and adequately pretreated with clopidogrel.

GP = glycoprotein; PCI = percutaneous coronary intervention.

   e. Antiplatelet recommendations
      i. Aspirin
         (a) An irreversible cyclooxygenase-1 inhibitor blocking the formation of thromboxane A_2– and thromboxane A_2–mediated platelet activation
         (b) Given to all patients (class I)
         (c) Established first-line therapy in ACS; reduces the incidence of recurrent MI and death
         (d) Loading dose is necessary for aspirin-naive patients; avoid enteric coated initially because of delayed and reduced absorption.
            (1) Dosing is 162–325 mg for patients at initial presentation of ACS (Table 4).
            (2) Dosing is 81–325 mg for those who are undergoing PCI, depending on chronic aspirin therapy regimen.
         (e) Aspirin is given indefinitely at a preferred dose of 81 mg after ACS with or without PCI (class I).
            (1) High dose (greater than 160 mg) is associated with more bleeding than lower dose (less than 160 mg).

(2) High dose (greater than 160 mg) has not been shown to improve outcomes after ACS more effectively than lower dose (less than 160 mg).

(f) Dual antiplatelet therapy (DAPT) with aspirin plus a $P2Y_{12}$ receptor inhibitor is indicated for all patients after ACS for at least 12 months (discussed later). The optimal dose of aspirin in patients treated with DAPT appears to be 75–100 mg daily.

Table 4. Guideline Recommendations for Aspirin Therapy in ACS with or without PCI

Guideline Recommendation	Class/Grade
Initiate 162–325 mg of ASA before PCI; after PCI, give ASA indefinitely • 2013 ACCF/AHA guideline for STEMI	I
Initiate 81–325 mg of nonenteric-coated ASA before PCI in patients already taking ASA; in patients not taking ASA, give 325 before PCI; after PCI, continue ASA indefinitely • 2014 NSTE-ACS guideline • 2011 ACCF/AHA/SCAI guideline for PCI	I
81 mg of ASA preferred to higher maintenance doses • 2014 NSTE-ACS guideline • 2013 ACCF/AHA guideline for STEMI • 2011 ACCF/AHA/SCAI guideline for PCI	IIa IIa IIa

Class I, should be performed or administered; Class IIa, reasonable to be performed or administered; Class IIb, may be considered; Class III, not to be administered or harmful.

ACCF = American College of Cardiology Foundation; AHA = American Heart Association; ASA = acetylsalicylic acid; SCAI = Society for Cardiovascular Angiography and Interventions.

ii. $P2Y_{12}$ inhibitors

(a) Inhibit the effect of adenosine diphosphate on the platelet, a key mediator resulting in amplification of platelet activation

(b) $P2Y_{12}$ inhibitor therapy is given to all patients (class I).

(c) Choice of oral $P2Y_{12}$ inhibitor depends on an ischemia-guided therapy or early invasive approach and pharmacokinetic differences (Tables 5–7).

(1) Prasugrel should not be administered to patients with a history of stroke or transient ischemic attack (class III).

(2) The efficacy or ticagrelor is decreased in patients treated with higher doses of aspirin (greater than 300 mg daily) compared with lower doses (less than 100 mg daily).

(d) Clopidogrel and ticagrelor are preferred for a medical (i.e., ischemia-guided) strategy (Table 5).

(e) Clopidogrel, ticagrelor, and prasugrel are options for an early invasive strategy (Table 5).

(1) It is reasonable to choose ticagrelor over clopidogrel for $P2Y_{12}$ inhibition treatment in patients with NSTE-ACS or STEMI treated with an early invasive strategy or coronary stenting (class IIa).

(2) It is reasonable to choose prasugrel over clopidogrel for $P2Y_{12}$ inhibition treatment in patients with NSTE-ACS or STEMI who undergo PCI who are not at high risk of bleeding complications and have no history of transient ischemic attack or stroke (class IIa).

(f) No randomized data are available on the long-term safety or efficacy of "switching" patients treated for weeks or months with a $P2Y_{12}$ inhibitor to a different $P2Y_{12}$ inhibitor.

Table 5. Guideline Recommendations for $P2Y_{12}$ Inhibitor Therapy in ACS with or without PCI

Guideline Recommendation	Class/Grade[a]
A loading dose of $P2Y_{12}$ receptor inhibitor should be given before PCI. Options include: a. Clopidogrel[b] 600 mg followed by 75 mg daily b. Prasugrel 60 mg followed by 10 mg daily; or c. Ticagrelor 180 mg followed by 90 mg twice daily • 2013 ACCF/AHA guideline for STEMI • 2014 NSTE-ACS guideline	I LOE B LOE B LOE B
For NSTE-ACS patients treated with an early invasive or ischemia-guided strategy: a. Clopidogrel 600 mg followed by 75 mg daily b. Ticagrelor 180 mg followed by 90 mg twice daily • 2014 NSTE-ACS guideline	I LOE B LOE B
For NSTE-ACS patients treated with an early invasive or ischemia-guided strategy: It is reasonable to use ticagrelor in preference to clopidogrel • 2014 NSTE-ACS guideline	IIa LOE B
For NSTE-ACS patients treated with PCI who are not at risk of bleeding complications • It is reasonable to choose prasugrel over clopidogrel • 2014 NSTE-ACS guideline	IIa LOE B
Prasugrel should not be administered to patients with a prior history of TIA or stroke • 2014 NSTE-ACS guideline • 2013 ACCF/AHA guideline for STEMI	Class III

[a]Class I, should be performed or administered; class IIa, reasonable to be performed or administered; class IIb, may be considered; class III, not to be administered or harmful.

[b]Before PCI after fibrinolytic therapy: 300-mg loading dose if within 24 hr of event; clopidogrel 600-mg loading dose if > 24 hr after event.

TIA = transient ischemic attack.

Table 6. Comparison of Oral $P2Y_{12}$ Receptor Inhibitors

Parameter	Clopidogrel (Plavix)[a]	Prasugrel (Effient)[b]	Ticagrelor (Brilinta)[c]
Mechanism of action	Thienopyridine; inhibits ADP-mediated platelet activation at the $P2Y_{12}$ receptor	Thienopyridine; inhibits ADP-mediated platelet activation at the $P2Y_{12}$ receptor	Inhibits ADP-mediated platelet activation at the $P2Y_{12}$ receptor
Peak platelet inhibition	300 mg load ~6 hr 600 mg load ~2 hr	60-mg load ~30 min[d]	180 mg load ~30 min[d]
% platelet inhibition	30%–40%	60%–70%	60%–70%
Loading dose	300–600 mg[e]	60 mg	180 mg
Maintenance dose	75 mg daily	10 mg daily; (5 mg if < 60 kg, BW ≥ 75 years)[f]	90 mg BID[g]
Metabolism	Prodrug; converted by two-step process to active metabolite involving 2C19 in addition to other CYP enzymes	Prodrug; converted by one step to active metabolite by several CYP pathways	Not prodrug; reversible, noncompetitive binding; 3A4 (primary), 3A5, P-gp inhibitor
Reversible platelet binding	No	No	Yes
Half-life	8 hr (metabolite)	3.7 hr (metabolite, range 2–15 hr)	7 hr (parent), 9 hr (active metabolite)
Nonresponders	Exposure to active drug affected by *CYP2C19* genetic polymorphisms	No known issues	No known issues

Table 6. Comparison of Oral $P2Y_{12}$ Receptor Inhibitors

Parameter	Clopidogrel (Plavix)[a]	Prasugrel (Effient)[b]	Ticagrelor (Brilinta)[c]
Drug-disease interactions and common nonbleeding-related adverse events	PPIs inhibit *CYP2C19* (concomitant use with esomeprazole/omeprazole is discouraged on package labeling); increased bleeding with NSAIDs, OACs, O3FAs	No clinically significant drug interactions; more bleeding with NSAIDs, OACs	Careful with asthma, bradycardia: More bleeding with NSAIDs, OACs Strong 3A4 inhibitors increase ticagrelor concentrations; strong 3A4 inducers decrease ticagrelor concentrations; do not exceed 40 mg of simvastatin or lovastatin Limit aspirin to < 100 mg; monitor digoxin concentrations
Surgery hold time[h]	5 days	7 days	5 days
Bleeding risk	Less than PRA and TIC with standard dosing	Risk of non-CABG, spontaneous, and fatal bleeds higher than standard-dose clopidogrel	Risk of non-CABG bleeds higher than standard-dose clopidogrel
Box warning	*CYP2C19* polymorphisms	Age-related bleeding CVA	Aspirin dosing > 100 mg
Contraindications		TIA, CVA	ICH, severe hepatic disease
Supporting trials	CREDO, CURE, PCI-CURE, CLARITY, COMMIT	TRITON-TIMI 38, TRILOGY	PLATO, PEGASUS
FDA indication	ACS managed medically or with PCI	ACS with PCI	ACS managed medically or with PCI

[a]Administer clopidogrel indefinitely if aspirin allergy. Avoid loading dose if patient is ≥ 75 yr in STEMI when fibrinolysis is given.

[b]Avoid PRA in patients with active pathological bleeding or a history of TIA or CVA and in patients > 75 yr unless patient has diabetes mellitus or history of myocardial infarction.

[c]Avoid TIC in patients with active pathologic bleeding or a history of ICH. Avoid doses of aspirin > 100 mg daily (exception: first dose of 325 mg).

[d]A significant antiplatelet effect has been observed at 30 min. Onset of effect is quicker, and extent of platelet inhibition is greater than with clopidogrel.

[e]A 600-mg loading dose results in greater, more rapid, and more reliable platelet inhibition than a 300 mg loading dose.

[f]Although using 5 mg in patients weighing < 60 kg should be considered, this dose has not been studied in patients undergoing PCI.

[g]Maintenance dosing of 60 mg BID is FDA approved for reduction of thrombotic events after an initial 12 months of therapy.

[h]In emergency CABG, clopidogrel and ticagrelor should be held for at least 24 hr to minimize the risk of CABG-related bleeding.

ADP = adenosine diphosphate; BID = twice daily; BW = boxed warning; CABG = coronary artery bypass grafting; CVA = cerebrovascular accident; CYP = cytochrome P450; FDA = U.S. Food and Drug Administration; ICH = intracranial hemorrhage; NSAID = nonsteroidal anti-inflammatory drug; O3FA = omega-3 fatty acid; OAC = oral anticoagulant; P-gp = P-glycoprotein; PRA = prasugrel; TIC=ticagrelor.

iii. Intravenous $P2Y_{12}$ inhibitor
   (a) Cangrelor, a direct-acting, rapidly reversible, intravenous $P2Y_{12}$ inhibitor, achieves a high level of platelet inhibition (greater than 90% with a 30 mcg/kg intravenous bolus followed by a 4 mcg/kg/minute infusion) within 5 minutes and reaches steady state within 15–30 minutes of administration.
   (b) Rapid onset and offset (half-life less than 5 minutes) allows quick, high degree of platelet inhibition with resolution of normal platelet function within 1 hour of ending treatment.
   (c) Primarily studied in the setting of PCI only and may be considered in those who are not candidates for oral agents

(d) Pivotal trials comparing cangrelor with clopidogrel in ACS have not shown superiority of cangrelor; however, both the CHAMPION PHOENIX PCI and PLATFORM trials were discontinued prematurely.
(e) Cangrelor has had better efficacy than post-PCI clopidogrel with increases in minor bleeding (not major) (CHAMPION PHOENIX).
(f) Cangrelor treatment is associated with risk for dyspnea.
(g) Cangrelor has not been studied in settings with preloaded clopidogrel or compared with prasugrel or ticagrelor.
(h) Cangrelor has a potential use as a bridge therapy after discontinuation of oral $P2Y_{12}$ inhibitor in high-risk patients undergoing coronary artery bypass grafting (CABG) (Angiolillo 2012).
(i) The onset of action of both clopidogrel and prasugrel is delayed when coadministered with cangrelor, suggesting that cangrelor preferentially binds to the $P2Y_{12}$ and prevents irreversible inhibition with prasugrel and clopidogrel's active metabolite. Therefore, clopidogrel and prasugrel should not be initiated until termination of the cangrelor infusion. No such drug interaction exists with ticagrelor.
(j) Expense and lack of evidence demonstrating superiority to other $P2Y_{12}$ agents limits its use.
(k) Cangrelor has not been included in the ACS guidelines to date because FDA approval occurred after guideline release.

iv. Intravenous GP IIb/IIIa inhibitors
(a) Intravenous GP IIb/IIa receptor inhibitors can be added to aspirin with or without an oral $P2Y_{12}$ inhibitor for cardiovascular (CV) benefit in select high-risk patients in the acute management of ACS.
(b) Block the final common pathway of platelet aggregation; achieves 80% inhibition of ex vivo platelet aggregation
(c) GP IIb/IIIa inhibition may be beneficial in patients with high-risk features, particularly in those not adequately pretreated with $P2Y_{12}$ inhibition.
(d) Abciximab, double-bolus eptifibatide, and high-dose bolus tirofiban are class I options for invasive strategy (Table 7). Preferred options are eptifibatide and tirofiban (class IIb).

v. GP IIb/IIIa inhibitors reduce the incidence of composite ischemic events, primarily through a decrease in documented MI, but they can increase the risk of bleeding.
vi. Most, but not all, data were gathered in the era before routine $P2Y_{12}$ use.
vii. Benefit from adding GP IIb/IIIa inhibitors to aspirin therapy is greatest among those with highest-risk features (elevated biomarkers, diabetes, undergoing revascularization) and in those not receiving adequate pretreatment with clopidogrel or ticagrelor
viii. It is reasonable (class IIa, 2014 NSTE-ACS guideline) to give GP IIb/IIIa inhibitors to high-risk patients with NSTE-ACS treated with UFH and adequately pretreated with clopidogrel or ticagrelor.
ix. Most studies combined GP IIb/IIIa inhibitors with UFH as the anticoagulant.
x. Upstream administration (given before PCI) has not been shown to be superior to delayed administration (given at time of PCI).
(a) Upstream administration is noninferior to delayed timing for reducing ischemic events.
(b) Significantly higher rates of bleeding occur in those receiving upstream GP IIb/IIIa inhibitors than in those receiving delayed administration.
(c) Bolus-only GP IIb/IIIa inhibitor administration has been adopted in clinical practice but not into practice guidelines.

xi. Common adverse events of GP IIb/IIIa inhibitors:
  (a) Most common adverse effect is bleeding, with rates as low as 1.4% and as high as 10.6%, depending on length of therapy and how bleeding rates were accrued in the individual studies.
  (b) Note that the smaller-molecule agents eptifibatide and tirofiban depend on renal clearance; adjustment of the infusion is recommended to decrease risk of bleeding; monitor SCr (CrCl)
  (c) All GP IIb/IIIa inhibitors can cause thrombocytopenia; monitor hemoglobin (Hgb), hematocrit (Hct), and platelets.
    (1) Rates of thrombocytopenia (platelet count less than 50,000 cells/mm^3) with abciximab in clinical trials indicate 0.4%–1.4% incidence
    (2) When administered with UFH, rates of thrombocytopenia with either tirofiban or eptifibatide are no greater than UFH alone
  (d) The antiplatelet effects of abciximab can be reversed by platelet transfusion, whereas those of eptifibatide and tirofiban cannot.
  (e) Secondary to their short half-life, eptifibatide and tirofiban can be reversed within a few hours by discontinuing the infusion and are preferred options (Class IIb) in NSTE-ACS guideline .

Table 7. GP IIb/IIIa Inhibitor Dosing in ACS with or without PCI[a]

Agent	Pretreated with $P2Y_{12}$	Not Pretreated with $P2Y_{12}$	Renal Adjustments
Abciximab (ReoPro)[b]	Of uncertain benefit	PCI: 0.25 mg/kg IVB, then 0.125 mcg/kg/min (max 10 mcg/kg) for 12 hr; ACS without PCI: not recommended	Not necessary
Eptifibatide (Integrilin)	Of uncertain benefit	PCI: 180 mcg/kg IVB × 2 (10 min apart); 2 mcg/kg/min initiated after first bolus for 18–24 hr[c]; ACS without PCI: of uncertain benefit in patients adequately pretreated with a $P2Y_{12}$ receptor inhibitor; single bolus used as above	If CrCl < 50 mL/min/1.73 m^2, reduce infusion 50%; avoid in patients on hemodialysis; not studied in patients with SCr > 4 mg/dL
Tirofiban (Aggrastat)	Of uncertain benefit	PCI: 25 mcg/kg IVB over 3 min; then 0.15 mcg/kg/min for 18 hr ACS without PCI[d]: 0.4 mcg/kg/min for 30 min (LD infusion), then 0.1 mcg/kg/min for 18–72 hr	If CrCl ≤ 60 mL/min/1.73 m^2, reduce infusion 50%

[a]GP IIb/IIIa inhibitors should be used in combination with heparin (either unfractionated heparin or low-molecular-weight heparin) or used provisionally with bivalirudin and aspirin.

[b]Not recommended in those not undergoing PCI because of clinical trial results.

[c]Double bolus is recommended to support PCI in STEMI and NSTE-ACS.

[d]Lower dose used to treat medically managed NSTE-ACS or when there is substantial delay to PCI (i.e., 48 hr).

CrCl = creatinine clearance; IVB = intravenous bolus; LD = loading dose.

xii. Platelet function testing
   (a) Although platelet function can be evaluated by platelet function testing or genotyping, neither is routinely performed in the clinical setting.
   (b) Clinical outcomes with use of platelet function testing to modify antiplatelet therapy (i.e., high-dose vs. standard-dose clopidogrel) in PCI patients with high on-treatment platelet reactivity have been negative to date). Outcomes with prospective genotype-guided antiplatelet therapy (CYP2C19) from large cohorts of PCI patients are forthcoming.
   (c) Routine use of platelet function and genetic testing is not currently recommended (class III: no benefit).

f. Anticoagulant recommendations
   i. Use of anticoagulants is mainly concentrated in the procedural setting, though use may continue for a finite period after the procedure.
   ii. Selection and use among agents may depend on ACS presentation, timing or dose of preprocedural antiplatelet medication, clot burden during procedure, and estimated risk of bleeding during procedure.
   iii. Anticoagulants increase the risk of bleeding and will require some type of monitoring for agent-specific risks.

Table 8. Anticoagulant Management Strategies in ACS

Management Strategy	Class I Recommendations[a]
STEMI (PPCI)	UFH, bivalirudin
STEMI, with fibrinolytic[b] therapy	UFH, enoxaparin, fondaparinux
NSTE-ACS, early invasive strategy	Enoxaparin, bivalirudin,[c] UFH
NSTE-ACS, ischemia-guided strategy	Enoxaparin, fondaparinux[d], UFH

[a]Class I, should be performed or administered; class IIa, reasonable to be performed or administered; class IIb, may be considered; class III, not to be administered or harmful.

[b]Fibrinolytics preferred when PCI cannot be performed within 120 min of first medical contact (class I). Door-to-needle time was < 30 min. Those who receive fibrinolytic therapy should receive anticoagulation after fibrinolysis for at least 48 hr with IV UFH or IV/SC enoxaparin during hospitalization, up to 8 days (preferred, selected patients), or IV/SC fondaparinux during hospitalization, up to 8 days.

[c]If bleeding risk is high, it is reasonable to use bivalirudin monotherapy in preference to UFH plus GP IIb/IIIa inhibitor (class IIa).

[d]Fondaparinux should not be used as the sole anticoagulant to support PCI. Give additional anticoagulant during revascularization if fondaparinux was initially chosen as the anticoagulant strategy. Fondaparinux is given a class I recommendation in the 2014 NSTE-ACS guidelines (for an ischemia-guided strategy) and a class III or harmful recommendation in the 2011 PCI and 2013 STEMI guidelines when PCI is indicated.

PPCI = primary percutaneous coronary intervention; UFH = unfractionated heparin.

g. Anticoagulant agents (see Table 9 for dosing and contraindications)
   i. UFH
      (a) Exerts its effects as an indirect thrombin inhibitor on fibrin-bound clots
      (b) Given as intravenous bolus with or without infusion and adjusted according to activated partial thromboplastin time (aPTT) or activated clotting time (ACT) to maintain therapeutic anticoagulation according to specific hospital protocol, usually continued for 48 hours or until PCI is performed
      (c) Risks include bleeding, thrombocytopenia, and HIT with or without thrombosis.
      (d) Monitoring includes aPTT or ACT, Hgb/Hct, and platelets.
      (e) Unlike other anticoagulants, UFH is not renally cleared and can be used safely in those with renal impairment.
   ii. Enoxaparin
      (a) Molecular weight is one-third of UFH with balanced anti-factor Xa (anti-Xa) and anti-IIa activity.

(b) Given as subcutaneous injection at least 2 inches on either side of the navel at a 90-degree angle into 1 inch of pinched skin (avoid injection into muscle); alternate dosing sites
(c) Does not require routine anti-Xa monitoring; SCr to calculate CrCl for dosing; monitor Hgb, Hct, platelets
(d) Risks include bleeding, injection site hematomas, spinal or epidural hematomas, retroperitoneal hematoma/bleeding, thrombocytopenia including HIT with or without thrombosis, mechanical prosthetic valve thrombosis (in pregnancy)

iii. Fondaparinux
(a) Selective inhibitor of activated factor X
(b) Longest half-life of anticoagulants (17 hours)
(c) Given as subcutaneous injection into fatty tissue, at a 90-degree angle into a pinched skinfold; alternate dosing sites between the left and right anterolateral and posterolateral abdominal wall
(d) Does not require routine anti-Xa monitoring; requires SCr to calculate CrCl to assess for contraindication; monitor Hgb, Hct, platelets
(e) Risks include bleeding, thrombocytopenia, and spinal or epidural hematomas.
(f) No increased risk of HIT

iv. Bivalirudin
(a) A direct thrombin inhibitor; directly inhibits thrombin in both circulating and bound clots and inhibits thrombin-mediated platelet aggregation
(b) Given as an intravenous bolus with or without infusion fixed rate and usually continued until the end of PCI (with or without delay after infusion in some high-risk patients)
(c) Does not require monitoring for adjustment; monitor SCr (adjustment required for infusion in those impaired CrCl), Hgb, Hct, platelets
(d) Can be given in patient with history of or suspected HIT undergoing PCI

v. An anticoagulant should be administered to all patients with ACS in addition to antiplatelet therapy to reduce the risk of intracoronary and catheter thrombus formation (Tables 8 and 9) irrespective of initial treatment strategy.
(a) Enoxaparin: 30-mg intravenous bolus, then 1 mg/kg subcutaneously every 12 hours (or 1 mg/kg subcutaneously once daily for CrCl less than 30 mL/minute), continued for the duration of hospitalization or until PCI is performed
(b) Bivalirudin: 0.1 mg/kg loading dose followed by 0.25 mg/kg per hour (only in patients with early invasive strategy), continued until diagnostic angiography or PCI, with only provisional use of GP IIb/IIIa inhibitor
(c) Fondaparinux: 2.5 mg subcutaneously daily, continued for the duration of hospitalization or until PCI is performed
(d) Intravenous UFH: initial bolus of 60 units/kg (maximum 4000 units) with initial infusion of 12 units/kg/hour (maximum 1000 units/hour) adjusted on the basis of aPTT to maintain therapeutic anticoagulation according to specific hospital protocol, continued for 48 hours or until PCI is performed

vi. In an ischemia-guided strategy, UFH, enoxaparin, and fondaparinux are class I recommended options.

vii. For an invasive strategy, UFH, enoxaparin, and bivalirudin are class I recommended options.
(a) Fondaparinux should not be used as the sole anticoagulant to support PCI (class III). Give additional 85 units/kg of intravenous UFH immediately before PCI revascularization to reduce risk of catheter thrombosis if fondaparinux was initially chosen as the anticoagulant strategy if no GP IIb/IIIa inhibitor is used and 60 units/kg intravenously if a GP IIb/IIIa inhibitor is used with UFH dosing according to target-activated clotting time.

(b) Use of enoxaparin during PCI may be reasonable in patients treated with upstream subcutaneous enoxaparin with an ischemia-guided strategy.
  (1) An additional dose of 0.3 mg/kg intravenous enoxaparin should be administered at time of PCI to patients who have received fewer than two therapeutic subcutaneous doses or received the last subcutaneous dose 8–12 hours before PCI.
  (2) Patients who have received enoxaparin within 8 hours of the last subcutaneous dose generally have adequate anticoagulation to undergo PCI without supplemental bolus.
  (3) Patients who undergo PCI more than 12 hours after the last subcutaneous dose are usually treated with full-dose de novo anticoagulation with an established regimen (e.g., full-dose UFH or bivalirudin).
  (4) In patients who have not received anticoagulant therapy, a 0.5- to 0.75-mg/kg intravenous loading dose is needed.

(c) In those at high risk of bleeding, it is reasonable to use bivalirudin monotherapy in preference to the combination of UFH and GP IIb/IIIa receptor antagonist (class IIa).
  (1) For patients who have received UFH, wait 30 minutes and then give a 0.75-mg/kg intravenous loading dose, followed by a 1.75-mg/kg/hour intravenous infusion.
  (2) For patients already receiving bivalirudin infusion, give additional 0.5 mg/kg loading dose and increase infusion to 1.75 mg/kg/hour during PCI.

(d) Anticoagulant therapy is generally discontinued after PCI unless there is a compelling reason to continue.

viii. In patients undergoing primary PCI, either UFH or bivalirudin is preferred.

ix. When a fibrinolytic agent is given as a reperfusion strategy, UFH, enoxaparin, and fondaparinux are recommended.
  (a) Those given fibrinolytic therapy should receive anticoagulation after fibrinolysis for at least 48 hours with intravenous UFH or intravenous/subcutaneous enoxaparin during hospitalization, up to 8 days (preferred, selected patients), or intravenous/subcutaneous fondaparinux during hospitalization, up to 8 days.
  (b) Bivalirudin is not recommended in this population.

Table 9. Antithrombotic Dosing in ACS with or without PCI

	UFH	Enoxaparin (Lovenox)	Fondaparinux (Arixtra)	Bivalirudin (Angiomax)
Classification	—	LMWH	Factor Xa inhibitor	Direct thrombin inhibitor
NSTE-ACS	60 units/kg IVB (maximum 4000 units), 12 units/kg/hr IV (maximum 1000 units/hr) for 48 hr or until PCI performed; goal aPTT/anti-Xa according to hospital-specific protocol	1 mg/kg SC every 12 hr for 24–48 hr or until PCI performed or throughout hospitalization (up to 8 days); 30 mg IVB	2.5 mg SC daily	0.1 mg/kg IVB; then 0.25 mg/kg/hr IV (only for planned invasive strategy)

Table 9. Antithrombotic Dosing in ACS with or without PCI *(Cont'd)*

	UFH	Enoxaparin (Lovenox)	Fondaparinux (Arixtra)	Bivalirudin (Angiomax)
PCI	Supplemental doses to target ACT[a]; if GP IIb/IIIa inhibitors, UFH 50–70 units/kg IVB; if no GP IIb/IIIa inhibitors, UFH 70–100 units/kg IVB	If last dose < 8 hr, nothing additional needed; if last dose > 8 hr, 0.3 mg/kg IVB if last dose 8–12 hr before or < 2 therapeutic doses received before PCI	Fondaparinux should not be used as a sole anticoagulant for PCI	0.75 mg/kg IVB, 1.75 mg/kg/hr IV d/c at end of PCI, or continue for up to 4 hr after procedure if needed; hold UFH 30 min before administration
STEMI ± primary PCI	Supplemental doses to target ACT[a]; if GP IIb/IIIa, UFH 50–70 units/kg IVB; if no GP IIb/IIIa, UFH 70–100 units/kg IVB	30 mg IVB, followed immediately by 1 mg/kg SC every 12 hr; do not exceed 100 mg on first two doses; if > 75 yr, omit bolus; 0.75 mg/kg SC every 12 hr; do not exceed 75 mg on first two doses	2.5 mg IVB; then 2.5 mg SC daily	0.75 mg/kg IVB, 1.75 mg/kg/hr IV
Dose adjustments and contraindications	Avoid if history of HIT	If CrCl < 30 mL/min/1.73 m^2, 1 mg/kg SC daily; avoid if history of HIT	Contraindicated if CrCl < 30 mL/min/1.73 m^2	Adjust infusion dose in severe renal dysfunction If CrCl < 30 mL/min/1.73 m^2, reduce infusion to 1 mg/kg/hr; if on hemodialysis, reduce infusion to 0.25 mg/kg/hr

[a]Target ACT is 250–300 s for HemoTec and 300–350 s for Hemochron without GP IIb/IIIa inhibitors and is 200–250 s in patients given concomitant GP IIb/IIIa inhibitors.

ACT = activated clotting time; aPTT = activated partial thromboplastin time; HIT = heparin-induced thrombocytopenia; LMWH = low-molecular-weight heparin; SC = subcutaneous(ly).

5. Fibrinolytic therapy is indicated for patients with STEMI in whom PCI cannot be performed (Table 10).
   a. In the absence of contraindications (Table 11), fibrinolytic therapy should be given to patients with STEMI (class I when onset of ischemic symptoms is within the previous 12 hours) when it is anticipated that primary PCI cannot be performed within 120 minutes of first medical contact, with an ideal door-to-needle time of less than 30 minutes.
   b. Patients undergoing reperfusion with fibrinolytics should receive anticoagulant therapy for at least 48 hours and preferably for the duration of the index hospitalization, for up to 8 days, or until revascularization is performed.
   c. Recommended regimens include the following:
      i. UFH administration of a 60-unit/kg bolus (maximum 4000 units) and 12 units/kg/hour (maximum 1000 units/hour), to obtain an aPTT of 1.5–2.0 times control (about 50–70 seconds)
      ii. Enoxaparin 30 mg intravenously (if 75 years or older, omit bolus), followed in 15 minutes by a 1 mg/kg subcutaneous injection (if 75 years or older, 0.75 mg/kg) every 12 hours for the duration of index hospitalization, for up to 8 days, or until revascularization. Maximum 100 mg for the first two doses. If 75 years or older, maximum 75 mg for the first two doses. If CrCl is less than 30 mL/minute/1.73 m^2, extend dosing interval to daily administration.
      iii. Fondaparinux administered with initial 2.5 mg intravenous dose, followed in 24 hours by 2.5 mg/day subcutaneous injections (contraindicated if CrCl is less than 30 mL/minute/1.73 m^2) for the duration of the index hospitalization, for up to 8 days, or until revascularization

Table 10. Fibrinolytic Therapy

	Dosing
Alteplase (t-PA, Activase)	≤ 67 kg: 15 mg IVP over 1–2 min, then 0.75 mg/kg IV over 30 min (maximum 50 mg), then 0.5 mg/kg (maximum 35 mg) over 60 min > 67 kg: 15 mg IVP over 1–2 min, then 50 mg over 30 min, then 35 mg over 1 hr (maximum total dose 100 mg)
Reteplase (r-PA, Retavase)	10 units IVP; repeat 10 units IV in 30 min
Tenecteplase (TNK-t-PA, TNKase)	< 60 kg: 30 mg IVP; 60–69 kg: 35 mg IVP; 70–79 kg: 40 mg IVP; 80–89 kg: 45 mg IVP; > 90 kg: 50 mg IVP (~0.5 mg/kg)

IVP = intravenous push; r-PA = recombinant plasminogen activator; t-PA = tissue plasminogen activator.

Table 11. Contraindications to Fibrinolytic Therapy

Relative Contraindications	Absolute Contraindications
BP > 180/110 mm Hg on presentation or history of chronic poorly controlled HTN History of ischemic stroke > 3 mo before Recent major surgery (< 3 wk before) Traumatic or prolonged CPR (> 10 min) Recent internal bleeding (within 2–4 wk) Active peptic ulcer Noncompressible vascular punctures Pregnancy Known intracranial pathology (dementia) Oral anticoagulant therapy	Any prior hemorrhagic stroke Ischemic stroke within 3 mo (except in past 4½ hr) Intracranial neoplasm or arteriovenous malformation Active internal bleeding Aortic dissection Considerable facial trauma or closed-head trauma in past 3 mo Intracranial or intraspinal surgery within 2 mo Severe uncontrolled HTN (unresponsive to emergency therapy) For streptokinase,[a] treatment within previous 6 mo (if considering streptokinase again)

[a]Streptokinase is no longer marketed in the United States but is available in other countries.

BP = blood pressure; CPR = cardiopulmonary resuscitation.

D. Long-term Management After ACS
   1. DAPT: 12 months
      i. Aspirin should be continued indefinitely at a maintenance dose of 81 mg daily in all patients after ACS (class I).
      ii. In patients who were treated with an ischemia-guided therapy, aspirin plus either clopidogrel 75 mg daily or ticagrelor 90 mg twice daily should be continued for up to 12 months.
      iii. After PCI (bare metal stent or drug-eluting stent), aspirin plus clopidogrel 75 mg daily, prasugrel 10 mg daily, or ticagrelor 90 mg twice daily should be continued for at least 12 months.
   2. Early discontinuation of DAPT
      a. Early discontinuation is reasonable when the risk of morbidity exceeds the anticipated benefit (class IIa).
         i. DAPT should be continued after ACS (with or without stent) for at least 12 months (class I)
         ii. Shorter-duration DAPT can be considered for patients with stable ischemic heart disease who have undergone PCI with elective stent placement (class I, 6 months duration for elective PCI).
      b. In general, shorter durations of DAPT are appropriate for those with a lower ischemic risk and a high bleeding risk, whereas longer-duration DAPT may be reasonable for patients at higher ischemic risk with a lower bleeding risk.
         i. No trials have compared duration of DAPT specifically in ACS.
         ii. Prior recommendations for DAPT duration for patients treated with drug-eluting stents were based on data from first-generation stents.

iii. Trials comparing shorter durations of DAPT have evaluated newer-generation stents in all patients undergoing PCI (including elective cases).
iv. Compared with first-generation stents, newer-generation stents have an improved safety profile and lower risk of stent thrombosis.

3. Long-term DAPT
   a. In general, longer-duration DAPT may be reasonable for patients at higher ischemic risk with a lower bleeding risk.
   b. Trials evaluating the need for an extended duration in patients with and without ACS undergoing PCI (greater than 12 months) of DAPT therapy after PCI show a reduction in stent thrombosis and ischemia end points with increased bleeding for patients continued on DAPT beyond 12 months.
   c. The risk of stent thrombosis is greater on cessation of DAPT; however, continued DAPT beyond 1 year is unassociated with a reduction in CV or total mortality.
   d. A longer duration of $P2Y_{12}$ inhibitor therapy is an individualized approach according to the patient's risk of ischemia and bleeding.
      i. It is reasonable to consider DAPT beyond 12 months if the patient is tolerating therapy and not at high risk of bleeding (class IIb).
      ii. Durations of DAPT may be reasonable beyond 12 months if patient is at high risk and no significant history of bleeding on DAPT (class IIb).
      iii. A DAPT score derived from the dual antiplatelet study may be useful in making decisions about whether to prolong or extend DAPT in patients treated with coronary stent implantation (Table 12).
         (a) For those with a high DAPT score (2 or greater), prolonged DAPT reduces net (ischemic plus bleeding) events.
         (b) For those with a low DAPT score (less than 2), the benefit-risk ratio for prolonged DAPT is not favorable (increased bleeding without a reduction in ischemic events
         (c) Derived from the DAPT study, which included 11,648 patients with mainly clopidogrel as $P2Y_{12}$ inhibitor
         (d) Duration of DAPT more or less than 12 months should jointly be made by the clinician and the patient, balancing the risks of stent thrombosis and ischemic complications with risks of bleeding.
   e. Ticagrelor has been shown to reduce CV end points of death, MI, and revascularization better than placebo at a reduced dose of 60 mg twice daily (after at least 12 months of 90 mg twice daily) with less bleeding than extended use of 90 mg twice daily. (Bonaca 2015)

4. β-Blockers
   a. Indicated for all patients unless contraindicated
   b. If not started orally within the first 24 hours, reevaluate for possible initiation before discharge.
   c. Continue for at least 3 years (when EF is greater than 40%).
   d. If moderate or severe LV failure, initiate carvedilol, bisoprolol, or metoprolol succinate with gradual titration. Continue indefinitely in patients with EF less than 40%.
5. Angiotensin-converting enzyme (ACE) inhibitors
   a. ACE inhibitors should be started and continued indefinitely for all patients with LVEF of 40% or less and in those with hypertension, diabetes mellitus, or stable chronic kidney disease unless contraindicated.
   b. ACE inhibitors may be acceptable in all other patients with cardiac or other vascular disease.
   c. Angiotensin receptor blocker is indicated if the patient has contraindications to or is intolerant of ACE inhibitors.
   d. Contraindications include hypotension, pregnancy, and bilateral renal artery stenosis.

Table 12. DAPT Score to Determine Favorability of Prolonged DAPT

Factors Used to Calculate DAPT Score	Add Points for Total Score[a]
Age ≥ 75 yr	-2
Age 65–74 yr	-1
Current tobacco user	1
Diabetes mellitus	
NSTEMI or STEMI at presentation	
Prior MI or PCI	
Stent diameter < 3 mm	
Paclitaxel-eluting stent	
CHF or LVEF < 30%	2
Saphenous vein graft PCI	2

[a]A score ≥ 2 favors prolonged DAPT; a score < 2 is of unfavorable risk-benefit.

CHF = congestive heart failure; DAPT = dual antiplatelet therapy; LVEF = left ventricular ejection fraction; MI = myocardial infarction; NSTEMI = non–ST-segment elevation myocardial infarction; STEMI = ST-segment elevation myocardial infarction.

From: Levine GN, Bates ER, Bittl JA, et al. 2016 ACC/AHA guideline focused update on duration of dual antiplatelet therapy in patients with coronary artery disease: a report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines. J Am Coll Cardiol 2016;68:1082-115; and Yeh RW, Secemsky EA, Kereiakes DJ, et al. Development and validation of a prediction rule for benefit and harm of dual antiplatelet therapy beyond 1 year after percutaneous coronary intervention. JAMA 2016;315:1735-49.

6. Aldosterone receptor blockers
   a. Indicated in patients who are already receiving an ACE inhibitor and β-blocker after MI and who have an LVEF of 40% or less and either symptomatic HF or diabetes, unless contraindicated
   b. Contraindications include hyperkalemia (potassium [K^+] 5.0 or greater), CrCl less than 30 mL/minute/1.73 m^2, and SCr greater than 2.5 mg/dL in men and greater than 2.0 mg/dL in women.
7. Lipid management: High-intensity statins are indicated in all patients after ACS without contraindication. In high-risk patients achieving a less-than-anticipated response to statins (less than a 50% reduction in LDL), or in those who are completely statin intolerant, non-statin therapy may be considered for CV benefit.
   a. Depending on additional desired LDL percentage reduction, consideration can be given to either ezetimibe or a PCSK9 inhibitor in combination with statin therapy in very high-risk patients.
   b. Both ezetimibe and evolocumab (given in combination with statins) have been shown to reduce CV end points.
8. Pain control
   a. NSAIDs and select cyclooxygenase-2 inhibitors (class III) should be discontinued at time of presentation because they have been associated with increased risk of major adverse cardiac events.
   b. Before discharge, the patient's musculoskeletal discomfort should be addressed, and a stepped-care approach should be used for selection of therapy.
   c. Pain should be treated with acetaminophen, nonacetylated salicylates, tramadol, or narcotics at the lowest dose to control symptoms.
   d. It is reasonable to use nonselective NSAIDs, such as naproxen, if initial therapy is insufficient.
      i. Monitor regularly for sustained hypertension, edema, worsening renal function, or gastrointestinal (GI) bleeding.
      ii. If these occur, consider dose reduction or discontinuation.
9. Vaccination
   a. Pneumococcal vaccination is recommended for patients 65 years and older and in high-risk patients (including smokers with asthma) with CV disease.
   b. An annual influenza vaccination is recommended for patients with CV disease.

10. Patient education
    a. All patients should be counseled on the duration of DAPT and the avoidance of premature discontinuation.
    b. Patients should be educated about appropriate cholesterol management, blood pressure control, smoking cessation, and lifestyle management.
    c. Risk factor modification should be addressed in all patients after ACS.
11. Cardiac rehabilitation: All eligible patients should be referred to a comprehensive CV rehabilitation program.

E. Special Populations
1. Antiplatelet recommendations in patients going on to CABG
    a. Aspirin should be continued preoperatively to patients undergoing CABG (81–325 mg).
    b. In patients referred for elective CABG, clopidogrel and ticagrelor should be discontinued for at least 5 days before surgery and prasugrel for at least 7 days before surgery.
    c. In patients referred for urgent CABG, clopidogrel and ticagrelor should be discontinued for at least 24 hours to reduce major bleeding.
    d. In patients referred for CABG, short-acting GP IIb/IIIa (eptifibatide or tirofiban) should be discontinued for at least 2 hours before surgery and abciximab for at least 12 hours to limit blood loss and transfusion.
2. Combined oral anticoagulant therapy and antiplatelet therapy in NSTE-ACS
    a. The duration of triple antithrombotic therapy with an oral anticoagulant, low-dose aspirin, and a $P2Y_{12}$ inhibitor (clopidogrel preferred) should be minimized to the extent possible to limit the risk of bleeding.
    b. Proton pump inhibitors should be prescribed to those with a history of GI bleeding (and is reasonable in those without a known history of GI bleeding) who need triple antithrombotic therapy.
    c. Targeting a lower international normalized ratio (INR) of 2.0–2.5 may be reasonable (class IIb in NSTE-ACS guideline; class IIa in STEMI guideline) in patients needing triple therapy.
3. Older patients (i.e., 75 years or older)
    a. Doses should be individualized by weight or CrCl to reduce adverse events caused by age-related changes in pharmacokinetics and dynamics, volume of distribution, comorbidities, drug interactions, and increased drug sensitivity.
    b. Bivalirudin, rather than GP IIb/IIIa inhibitors plus UFH, is reasonable in older patients given similar efficacy but less bleeding (class IIa).
    c. CABG may be preferred to PCI in older patients, particularly those with diabetes mellitus or complex three-vessel disease (e.g., SYNTAX score greater than 22), with or without involvement of the proximal left anterior descending artery.
4. Chronic kidney disease
    a. CrCl should be estimated in patients with ACS, and doses of renally cleared medications should be adjusted accordingly.
    b. Patients with chronic kidney disease undergoing coronary and LV angiography should receive adequate hydration and reduced contrast volume.
    c. In patients with CrCl less than 60 mL/minute/1.73 m^2, ticagrelor was associated with a 4% absolute risk reduction in all-cause mortality compared with clopidogrel in a prespecified analysis from PLATO without increased risk of bleeding.
    d. No clinical trials to date have shown the utility of prasugrel in renal insufficiency.

5. Women
    a. Women of all ages have higher rates of in-hospital and long-term complications from ACS than men.
    b. Women derive the same benefit from aspirin, $P2Y_{12}$ inhibitors, anticoagulants, β-blockers, ACE inhibitors, and statins as men, but women may be at higher risk of adverse events.
        i. Women incur a higher rate of bleeding complications, renal failure, and vascular complications.
        ii. A risk score has been developed to attempt to reduce bleeding risk.
    c. Women with NSTE-ACS and high-risk features (e.g., troponin positive) should undergo an early invasive strategy.
    d. Women with NSTE-ACS and low-risk features should not undergo early invasive treatment because of the lack of benefit and potential for harm (class III).
    e. Hormone therapy with estrogen plus progestin, or estrogen alone, should not be given as new drugs for secondary prevention and should not be continued in previous users unless the benefits outweigh the estimated risks.
        i. Hormone therapy increases the risk of thrombotic events, especially in the first year of therapy, and does not provide CV protection.
        ii. Women who are more than 1 year past the initiation of hormone therapy who want to continue such therapy for another compelling indication should weigh the risks and benefits, recognizing the greater risk of CV events and breast cancer (combination therapy) or stroke (estrogen).

Patient Cases

1. A 66-year-old woman (weight 70 kg) with a history of MI, hypertension, hyperlipidemia, and diabetes mellitus presents with sudden-onset diaphoresis, nausea, vomiting, and dyspnea, followed by a bandlike upper chest pain (8/10) radiating to her left arm. She had felt well until 1 month ago, when she noticed her typical angina was occurring with less exertion. Electrocardiography revealed ST-segment depression in leads II, III, and aVF and hyperdynamic T waves and positive cardiac enzymes. Blood pressure is 150/90 mm Hg, and all laboratory results are normal; SCr is 1.2 mg/dL. Home medications are aspirin 81 mg/day, simvastatin 40 mg every night, metoprolol 50 mg twice daily, and metformin 1 g twice daily. Which regimen is the best treatment strategy for this patient?

    A. Aspirin 325 mg, ticagrelor 180 mg × 1 dose, and UFH 60-unit/kg bolus; then 12 units/kg/hour titrated to 50–70 seconds with an early invasive approach.

    B. Aspirin 325 mg and enoxaparin 70 mg subcutaneously twice daily with an early invasive approach.

    C. An ischemia-guided strategy with abciximab 0.25 mg/kg bolus; then 0.125 mg/kg/minute for 12 hours plus enoxaparin 80 mg subcutaneously twice daily, aspirin 325 mg/day, and clopidogrel 300 mg 1 dose; then 75 mg once daily.

    D. An ischemia-guided strategy with aspirin 325 mg and ticagrelor 180 mg × 1 dose; plus UFH 70-unit/kg bolus; then 15 units/kg/hour.

2. A 45-year-old patient underwent an elective percutaneous transluminal coronary angioplasty and drug-eluting stent placement in her right coronary artery. Which duration best represents the minimum time DAPT should be continued?

    A. At least 1 month.

    B. At least 3 months.

    C. At least 6 months.

    D. At least 12 months.

Patient Cases *(Cont'd)*

3. A 52-year-old man (weight 100 kg) with a history of hypertension and hypertriglyceridemia presents at a major university teaching hospital with a cardiac catheterization laboratory. He has had 3 hours of crushing 10/10 substernal chest pain radiating to both arms that began while he was eating his lunch (seated), which is accompanied by nausea, diaphoresis, and shortness of breath. He has never before experienced chest pain of this character or intensity. He usually can walk several miles without difficulty and smokes 1.5 packs of cigarettes per day. Home medications are lisinopril 2.5 mg/day and aspirin 81 mg daily. Current vital signs include heart rate 68 beats/minute and blood pressure 178/94 mm Hg. Electrocardiography reveals a 3-mm ST-segment elevation in leads V_2–V_4, I, and aVL. Serum chemistry values are within normal limits. The first set of cardiac markers shows positive troponins, 0.8 mcg/L (normal defined as less than 0.1 mcg/L). Which regimen is best to treat this patient's STEMI?

   A. Reperfusion with primary PCI and stenting of occluded artery, together with abciximab 0.25 mcg/kg intravenous push, then 0.125 mg/kg/minute, clopidogrel 300 mg 1 dose, and aspirin 325 mg 1 dose.

   B. Reperfusion with a reteplase 10-unit bolus twice, 30 minutes apart, plus a UFH 60-unit/kg bolus and a 12-unit/kg/hour infusion, clopidogrel, and aspirian.

   C. Reperfusion with tenecteplase 25-mg intravenous push 1 dose, enoxaparin 30-mg intravenous bolus plus 100 mg subcutaneously twice daily, aspirin 325 mg x 1 dose, ticagrelor 180 mg x 1 dose, and bivalirudin 0.75 mg/kg followed by 1.75 mg/kg/hour.

   D. Reperfusion with primary PCI with stenting, prasugrel 60 mg 1 dose, aspirin 325 mg 1 dose, and bivalirudin 0.75 mg/kg followed by 1.75 mg/kg/hour.

4. A 76-year-old male smoker (weight 61 kg) has a history of hypertension, benign prostatic hypertrophy, and lower back pain. Three weeks ago, he began to experience substernal chest pain with exertion (together with dyspnea), which radiated to both arms and was associated with nausea and diaphoresis. Episodes have increased in frequency to four or five times daily; they are relieved with rest. He has never had an ECG. Today, he awoke with 7/10 chest pain and went to the emergency department of a rural community hospital 2 hours later. He was acutely dyspneic and had ongoing pain. Home medications are aspirin 81 mg/day for 2 months, doxazosin 2 mg/day, and ibuprofen 800 mg three times daily. Vital signs include heart rate 42 beats/minute (sinus bradycardia) and blood pressure 104/48 mm Hg. Laboratory results include blood urea nitrogen (BUN) 45 mg/dL, SCr 2.5 mg/dL, and troponin 1.5 mcg/L (normal value less than 0.1 mcg/L). His ECG reveals a 3-mm ST-segment elevation. Aspirin, ticagrelor, and sublingual nitroglycerin were given in the emergency department. The nearest hospital with a catheterization laboratory facility is 2.5 hours away. Which regimen is best?

   A. Give alteplase 15 units intravenously plus enoxaparin 30 mg intravenous bolus.

   B. Use an ischemia-guided treatment strategy with UFH 4000-unit intravenous bolus, followed by 800 units intravenously per hour.

   C. Give tenecteplase 35 mg intravenously plus UFH 4000-unit intravenous bolus followed by 800 units intravenously per hour.

   D. Transfer the patient to a facility for primary PCI.

II. ACUTE DECOMPENSATED HEART FAILURE

A. Precipitating Factors
   1. Medication related (nonadherence to medications, recent addition of negative inotropic drugs, initiation of medications that enhance salt retention, excessive alcohol or illicit drug use)
   2. Disease related (nonadherence to sodium or fluid restriction, acute myocardial ischemia, uncorrected high blood pressure, pulmonary embolus, atrial fibrillation or other arrhythmias, concurrent infections, other acute CV disorders)

B. Diagnosis
   1. Must include a detailed history and physical examination
   2. B-type natriuretic peptide (BNP) or NT-proBNP useful to support diagnosis and establish prognosis for acute decompensated heart failure (ADHF)
   3. Hemodynamic monitoring (Table 13)
      a. Routine use of hemodynamic monitoring with invasive intravenous lines (e.g., Swan-Ganz pulmonary artery catheters) is not recommended; however, signs and symptoms of congestion and perfusion (Table 14) or noninvasive means to determine hemodynamic values are commonly used to determine status of decompensation.
      b. Hemodynamic monitoring with pulmonary artery catheters is helpful for evaluating patients refractory to initial therapy, for those with unknown or unclear volume status, or for those with clinical significant hypotension or worsening renal function.

Table 13. Hemodynamic Values in Patients with ADHF and Sepsis

Parameter	Normal Value	Typical ADHF Value	Typical Sepsis Value
Mean arterial pressure[a] (MAP; mm Hg)	80–100	60–80	60–80
Heart rate (HR; beats/min)	60–80	70–90	90–100
Cardiac output (CO; L/min)[b]	4–7	2–4	5–8
Cardiac index (CI; L/min/m^2)[c]	2.8–3.6	1.3–2	3.5–4
Pulmonary capillary wedge pressure (mm Hg)[d]	8–12[b]	18–30	5–8
Systemic vascular resistance (SVR; dynes/s/cm^5)[e]	900–1400	1500–3000	300–800
Central venous pressure (CVP; mm Hg)[f]	2–6	6–15	2–6

[a]MAP = diastolic blood pressure + [⅓(SBP − diastolic blood pressure)].

[b]CO = stroke volume × HR.

[c]CI = CO/body surface area.

[d]A range of 15–18 mm Hg is often desired or optimal in patients with HF to ensure optimal filling pressures.

[e]VR = [(MAP − CVP) / CO] × 80.

[f]BP = CO × SVR.

C. Clinical Presentation
   1. Patients with ADHF can be categorized into four subsets on the basis of fluid status and cardiac function (Figure 2).
   2. "Wet or dry" is commonly used to describe volume status.
   3. "Warm or cold" is used to describe cardiac function or ability to perfuse tissues.

Table 14. Signs and Symptoms of ADHF

Congestion (elevated PCWP)	Hypoperfusion (low CO)
Dyspnea on exertion or at rest Orthopnea, paroxysmal nocturnal dyspnea Peripheral edema Rales Early satiety, nausea, or vomiting Ascites Hepatomegaly, splenomegaly Jugular venous distension Hepatojugular reflux	Fatigue Altered mental status or sleepiness Cold extremities Worsening renal function Narrow pulse pressure Hypotension Hyponatremia

CO = cardiac output; PCWP = pulmonary capillary wedge pressure.

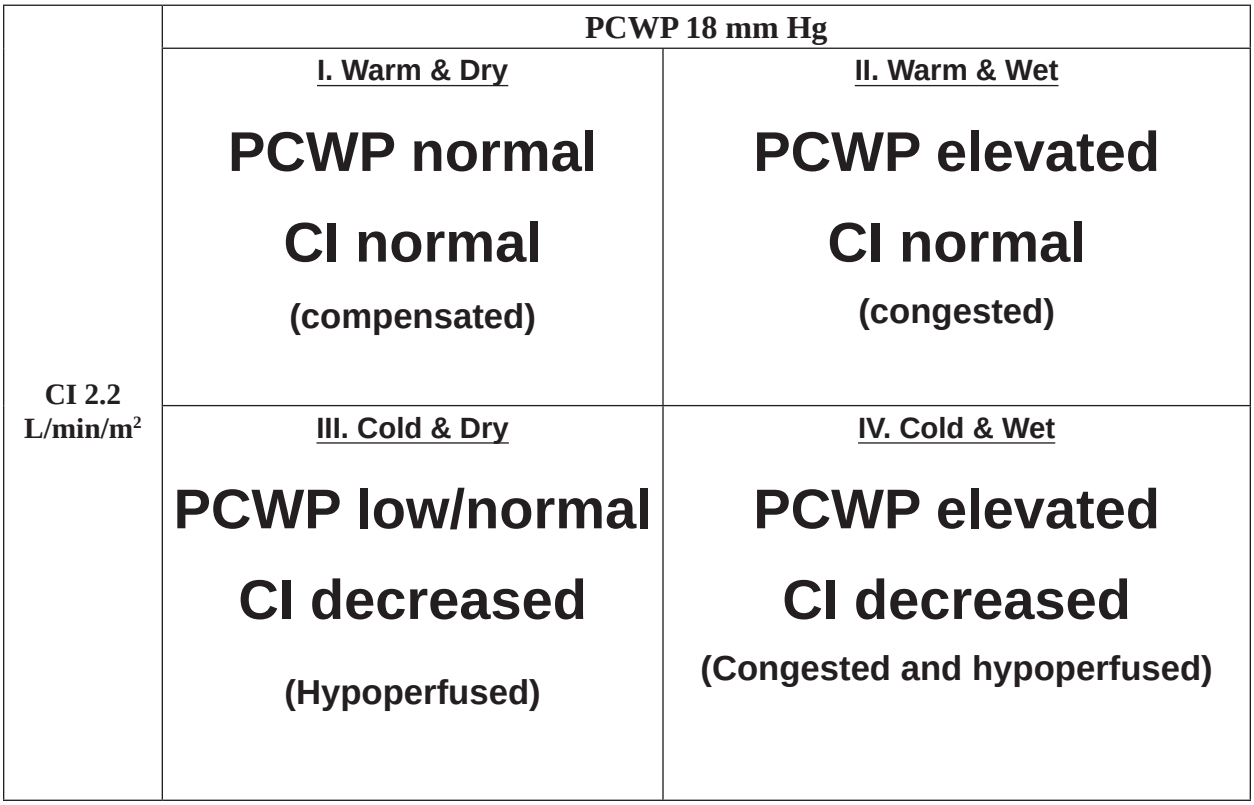

Figure 2. Forrester hemodynamic subsets based on signs and symptoms or hemodynamic parameters in ADHF

Table 15. ADHF Therapy Based on Hemodynamic Subset

Subset and description	Treatment
Subset I: Warm and Dry (normal parameters) (PCWP 15–18 mm Hg[a] and CI > 2.2 L/min/m^2)	Optimize oral medications
Subset II: Warm and Wet (pulmonary or peripheral congestion) (PCWP > 18 mm Hg and CI >2.2 L/min/m^2)	IV diuretics ± IV vasodilators (venous[b]) If symptoms persist, adjunct strategies to overcome diuretic resistance may be necessary.
Subset III: Cold and Dry (hypoperfusion ± orthostasis) (PCWP 15–18 mm Hg[a] and CI < 2.2 L/min/m^2)	If PCWP < 15 mm Hg, IVF until PCWP = 15–18 mm Hg If PCWP ≥ 15 mm Hg, SBP <90 mm Hg, IV inotrope[c] If PCWP ≥ 15 mm Hg, SBP ≥90 mm Hg, IV vasodilator (arterial[d]) ±IV vasopressor[e] if needed
Subset IV: Cold and Wet (pulmonary/peripheral congestion + hypoperfusion) (PCWP >18 mm Hg and CI < 2.2 L/min/m^2)	IV diuretics + If SBP ≥90 mm Hg, IV vasodilator (arterial[d]) If SBP <90 mm Hg, IV inotrope[c] ±IV vasopressor[e] if needed

[a]Goal PCWP is 8–12 mm Hg in a normal patient and 15–18 mm Hg in a patient with HF. If PCWP < 15 mm Hg in a patient with HF, either remove fluid restriction or cautiously administer fluids until PCWP is 15–18 mm Hg and then reassess CI.

[b]Venous vasodilator: Reduces PCWP.

[c]Compelling reason for inotrope = SBP < 90 mm Hg, symptomatic hypotension, or worsening renal function.

[d]Arterial vasodilator: reduce systemic vascular resistance with compensatory increase in CI.

[e]IV vasopressors may be required when marked hypotension precludes the use of traditional IV inotropes (e.g., septic or cardiogenic shock) but are generally avoided in ADHF

CI = cardiac index; IV = intravenous(ly); IVF = intravenous fluids; MAP = mean arterial pressure; PCWP = pulmonary capillary wedge pressure; SBP = systolic blood pressure.

D. Chronic HF Therapy in the Setting of Acute Decompensation
   1. It is recommended to continue guideline-directed medical therapies during decompensation unless hemodynamic instability or contraindications exist (e.g., hypotension, cardiogenic shock).
   2. ACE inhibitors
      a. Caution with initiation or titration during aggressive diuresis
      b. Increases in SCr (decrease in glomerular filtration rate of 20% or more) from ACE inhibitor use are not associated with worse outcomes.
   3. β-Blockers
      a. Do not discontinue in patients who are stable on dose before admission (i.e., recent initiation or titration was not responsible for decompensation).
      b. Initiation is recommended after optimization of volume status and successful discontinuation of intravenous diuretics, vasodilators, and inotropic agents.
      c. Should be initiated at a low dose only in stable, euvolemic patients
      d. Caution should be used when initiating in patients who have received inotropes during their hospital course.
   4. Digoxin
      a. Continue at dose to achieve serum digoxin concentration of 0.5–0.8 ng/mL.
      b. Avoid discontinuation unless there is a compelling reason to do so, because digoxin withdrawal has been associated with worsening HF symptoms.
      c. Caution if renal function begins to deteriorate or often fluctuates

E. ADHF Therapy Overview (Table 15; Box 1)
   1. The main drug classes used to treat ADHF include diuretics, inotropes, and vasodilators.
   2. No therapy studied to date has been shown conclusively to decrease mortality.
   3. Treatments are directed toward relieving symptoms, restoring perfusion, and minimizing further cardiac damage and adverse events.

Box 1. Overview of Acute Decompensated Heart Failure Guideline Recommendations

Diuretic therapy Recommended as intravenous loop diuretics for patients with fluid overload. Change to oral route on day before discharge, if possible. When response to diuretics is minimal, the following options should be considered: • Fluid and sodium restriction • Initiation of increased doses or continuous infusion of loop diuretic • Addition of a second diuretic with a different mechanism of action (metolazone, hydrochlorothiazide, chlorothiazide) • Ultrafiltration
Inotropic therapy May be considered to relieve symptoms and improve end-organ function in patients with reduced left ventricular ejection fraction and diminished peripheral perfusion or end-organ dysfunction (low output syndrome), particularly if • Marginal SBP (< 90 mm Hg) • Symptomatic hypotension despite adequate filling pressure • No response to or intolerance of intravenous vasodilators May be considered in similar patients with evidence of fluid overload if they respond poorly to intravenous diuretics or manifest diminished or worsening renal function
Vasodilator therapy May be considered in addition to intravenous loop diuretics to rapidly improve symptoms in patients with acute pulmonary edema or severe hypertension (if symptomatic hypotension absent) May be considered in patients with persistent symptoms despite aggressive diuretics and oral drug therapy When adjunctive therapy is necessary in addition to loop diuretics, intravenous vasodilators should be considered over inotropic drugs

F. Diuretics (Box 2): Used primarily to treat patients with pulmonary and peripheral congestion or wet (subset II or IV) HF
   1. Considered first-line therapy for management of ADHF associated with fluid overload
   2. No difference between bolus and continuous administration of intravenous diuretics
   3. Administering high-dose intravenous diuretic (2.5 times the previous oral dose) is associated with greater fluid removal.

Box 2. Diuretic Therapy for Acute Decompensated Heart Failure

Loop diuretics (ascending limb of loop of Henle)
Most widely used and most potent, effective at low CrCl (< 30 mL/min/1.73 m^2)
Furosemide most commonly used; furosemide 40 mg PO = furosemide 20 mg IV = bumetanide 1 mg IV or PO = torsemide 20 mg IV or PO
Thiazides (distal tubule)
Weak diuretics when used alone, not effective at low glomerular filtration rate (CrCl < 30 mL/min/1.73 m^2)
Reserved for add-on therapy in patients refractory to loops
Diuretic resistance
Increase dose before increasing frequency of loop diuretic (note ceiling effect at ~160–200 mg of IV furosemide)
Add a second diuretic with a different mechanism of action • Hydrochlorothiazide 12.5–25 mg PO daily, metolazone 2.5–5 mg PO daily (30 min before loop diuretic administration) • Chlorothiazide 250–500 mg IV daily; consider if GI edema; generic is very expensive; reserve for NPO or refractory to other alternatives
Continuous infusion of loop diuretic: Furosemide 0.1 mg/kg/hr IV doubled every 4–8 hr, maximum 0.4 mg/kg/hr
Adverse effects: Electrolyte depletion (sodium, K^+, magnesium), worsening renal function

GI = gastrointestinal; NPO = nothing by mouth; PO = oral(ly).

G. Vasodilator Therapy (Table 16)
   1. Used primarily to manage pulmonary congestion or wet (subset II or IV) HF
      a. No data to suggest intravenous vasodilators improve outcomes
      b. Use is limited to relief of dyspnea in those with intact blood pressure.
   2. When adequate blood pressure is maintained, use in preference to inotropic therapy.
   3. Venous vasodilation results in a reduction in PCWP and acute relief of shortness of breath while awaiting the onset of diuretic effects.
   4. Vasodilators with arterial vasodilating properties (nitroprusside and nesiritide) can also be used as an alternative to inotropes in patients with elevated systemic vascular resistance (SVR) and low cardiac output (CO).
   5. Vasodilators should be avoided in patients with symptomatic hypotension.
   6. Frequent blood pressure monitoring is necessary.

Table 16. Vasodilator Therapy for ADHF

	Sodium Nitroprusside (Nipride)	Nesiritide (Natrecor)	IV Nitroglycerin
Mechanism of action	Nitric oxide–induced stimulation of GC to convert GTP to cGMP	Recombinant B-type natriuretic peptide binds to natriuretic peptide receptor A to stimulate GC and production of cGMP; natriuretic mechanism unknown	Combines with sulfhydryl groups in vascular endothelium to create *S*-nitrosothiol compounds that mimic nitric oxide's stimulation of GC and production of cGMP
Clinical effects	Balanced arterial and venous vasodilator	**Hemodynamic effects:** ↓ PCWP and SVR, ↑ CI, minimal changes in HR **Neurohormonal effects:** ↓ NE, ET-1, and aldosterone Natriuretic effects at supratherapeutic doses	Preferential venous vasodilator > arterial vasodilator, arterial vasodilation at high doses (e.g., >100 mcg/min)
Indication	Warm and wet ADHF, alternative to inotropes in cold and wet ADHF, hypertensive crises	Warm and wet ADHF, alternative to inotropes in cold and wet ADHF	Warm and wet ADHF, ACS, or hypertensive crises
Dosing	0.1–0.2 mcg/kg/min IV, increase by 0.2–3 mcg/kg/min every 10-20 min	2 mcg/kg IVB, 0.01 mcg/kg/min IV	5 mcg/min IV, increase by 5 mcg/min every 5-10 minutes up to 200 mcg/min
Typical dose	0.5–1 mcg/kg/min IV	0.01 mcg/kg/min IV; can omit bolus if low SBP	25–100 mcg/min IV, titrated to response
Half-life	< 10 min	18 min	1–3 min
Elimination	Cyanide hepatically metabolized, thiocyanate renally excreted	Natriuretic peptide receptor C (no renal or hepatic adjustment)	Inactive metabolites in urine
AEs	Hypotension or cyanide or thiocyanate toxicity	Primarily hypotension (up to 1 hr), tachycardia (less than inotropes)	Hypotension, reflex tachycardia, headache, tachyphylaxis

AE = adverse effect; cGMP = cyclic guanine monophosphate; CI = cardiac index; ET-1 = endothelin; GC = guanylate cyclase; GTP = guanosine triphosphate; IVB = intravenous bolus; NE = norepinephrine.

H. Inotropic Therapy (Table 17)
   1. Used primarily to manage hypoperfusion or cold (subset III or IV) HF
   2. It is important to confirm that patients in subset III have adequate filling pressures (i.e., pulmonary capillary wedge pressure [PCWP] 15–18 mm Hg) before administering inotropic therapy.
   3. Useful for symptom relief in patients with low systolic blood pressure (less than 90 mm Hg) or symptomatic hypotension
   4. Given risk of sequelae, it is reasonable to consider vasodilators before inotropes.
   5. Monitor continuously for arrhythmias.
   6. Differences in the pharmacologic effects of dobutamine and milrinone may confer advantages and disadvantages.

Table 17. Inotropic Therapy for ADHF

	Dobutamine (Dobutrex)	Milrinone (Primacor)
Mechanism of action	β_1-Agonist: Stimulates AC to convert ATP to cAMP to ↑ CO; slight peripheral vasodilation	PDE inhibitor: Inhibits cAMP breakdown in heart to ↑ CO and in vascular smooth muscle to ↓ SVR
Clinical effects	Positive inotropic, chronotropic, lusitropic effects	Positive inotropic and lusitropic effects, no direct chronotropic effects
Indication	**ADHF: Cold and wet (Forester subset IV) or cold and dry exacerbations (Forester III) (if PCWP > 15 mm Hg)**	
Dosing	Start 2.5–5 mcg/kg/min IV; may titrate to maximum of 20 mcg/kg/min	50 mcg/kg IVB (rarely administered), then 0.1–0.2 mcg/kg/min IV; may titrate to maximum of 0.75 mcg/kg/min
Typical dose	5 mcg/kg/min IV	No bolus, 0.1–0.375 mcg/kg/min IV
Half-life	2 min	1 hr, prolonged to 2–3 hr if HF or CrCl < 50 mL/min/1.73 m^2
Elimination	Hepatically metabolized (inactive), renally eliminated	90% renal
AEs	Proarrhythmia, tachycardia, hypokalemia, myocardial ischemia, tachyphylaxis (> 72 hr); possible increased mortality with long-term use	Proarrhythmia, hypotension (avoid bolus), tachycardia, < 1% thrombocytopenia, possible increased mortality with long-term use
Other comments	Consider if hypotensive	Consider if receiving a β-blocker

AC = adenylate cyclase; ATP = adenosine triphosphate; cAMP = cyclic adenosine monophosphate; CO = cardiac output; PDE = phosphodiesterase.

I. Vasopressin Antagonists
   1. Therapeutic option for managing euvolemic or hypervolemic hyponatremia in those at risk of or having active cognitive symptoms despite water restriction (i.e., serum sodium less than 125 mEq/L or less marked hyponatremia that is symptomatic and resisted correction with fluid restriction, including patients with HF and syndrome of inappropriate secretion of antidiuretic hormone)
   2. Trials show effectiveness in correcting sodium with maintained therapy but no improvement in global clinical status, mortality, or reductions in rehospitalization.
      a. Hyponatremia redevelops after therapy cessation.
      b. Role in long-term management of HF remains unclear.
   3. Tolvaptan is the only vasopressin antagonist indicated for clinically significant hyponatremia associated with HF.
      a. Oral dosing: 15 mg daily, then titrated to 30–60 mg as needed
      b. Pharmacology: Binds to and inhibits the V_2 receptor, located in the renal tubule where water reabsorption is regulated
      c. Initiate only in hospital setting to allow monitoring of volume status and serum sodium concentrations.
      d. Contraindicated with cytochrome P450 3A4 inhibitors (tolvaptan is a substrate of 3A4)
      e. An overly rapid rise in serum sodium (maximum correction in any 24-hour period of chronic hyponatremia should be less than 9 mEq/L) can result in hypotension, hypovolemia, and neurological sequelae.

Patient Case

Questions 5–7 pertain to the following case.

A 72-year-old man is admitted to the hospital for HF decompensation. The patient has progressively increased dyspnea when walking (now 10 ft [3 m], previously 30 ft [6 m]) and orthopnea (now four pillows, previously two pillows), increased bilateral lower extremity swelling (3+), 13 kg of weight gain in the past 3 weeks, and dietary nonadherence. He has a history of idiopathic dilated cardiomyopathy (LVEF 25%, NYHA class III), paroxysmal atrial fibrillation (AF), and hyperlipidemia. Pertinent laboratory values are as follows: BNP 2300 pg/mL (0–50 pg/mL), K^+ 4.9 mEq/L, BUN 32 mg/dL, SCr 2.0 mg/dL (baseline 1.9 mg/dL), aspartate aminotransferase (AST) 40 IU/L, alanine aminotransferase 42 IU/L, INR 1.3, aPTT 42 seconds, blood pressure 108/62 mm Hg, heart rate 82 beats/minute, and Sa_{O_2} 95%. Home medications include carvedilol 12.5 mg twice daily, lisinopril 40 mg/day, furosemide 80 mg twice daily, spironolactone 25 mg/day, and digoxin 0.125 mg/day.

5. Which regimen is best for treating his ADHF?
   A. Carvedilol 25 mg twice daily.
   B. Nesiritide 2 mcg/kg bolus, then 0.01 mcg/kg/minute.
   C. Furosemide 120 mg intravenously twice daily.
   D. Milrinone 0.5 mcg/kg/minute.

6. After being initiated on intravenous loop diuretics with only minimal urine output, the patient is transferred to the coronary care unit for further management of diuretic-refractory decompensated HF. His Sa_{O_2} is now 87% on a 4-L nasal cannula, and an arterial blood gas is being obtained. His blood pressure is 110/75 mm Hg, and his heart rate is 75 beats/minute. The patient's SCr and K^+ concentrations have begun to rise; they are now 2.7 mg/dL and 5.4 mmol/L, respectively. In addition to a one-time dose of intravenous chlorothiazide, which regimen is most appropriate for this patient?
   A. Nitroglycerin 20 mcg/minute.
   B. Sodium nitroprusside 0.3 mg/kg/minute.
   C. Dobutamine 5 mcg/kg/minute.
   D. Milrinone 0.5 mcg/kg/minute.

7. The patient initially responds with 2 L of urine output overnight, and his weight decreases by 1 kg the next day. However, by day 5, his urine output has diminished again, and his SCr has risen to 4.3 mg/dL. He was drowsy and confused this morning during rounds. His extremities are cool and cyanotic, blood pressure is 89/58 mm Hg, and heart rate is 98 beats/minute. It is believed that he is no longer responding to his current regimen. A Swan-Ganz catheter is placed to determine further management. Hemodynamic values are cardiac index (CI) 1.5 L/minute/m^2, SVR 2650 dynes/second/cm^5, and PCWP 30 mm Hg. Which regimen is most appropriate for his current symptoms?
   A. Milrinone 0.2 mcg/kg/minute.
   B. Dobutamine 5 mcg/kg/minute.
   C. Nesiritide 2 mcg/kg bolus, then 0.01 mcg/kg/minute.
   D. Phenylephrine 20 mcg/minute.

III. ACUTE LIFE-THREATENING ARRHYTHMIAS

A. Adult Cardiac Arrest (Box 3)

Box 3. Select Advanced Cardiovascular Life Support Algorithms[a]

1. Start CPR (give oxygen; attach monitor/defibrillator)
2. Rhythm shockable? (If yes, go to Pulseless VT/VF No. 3; if no, go to asystole/PEA No. 11)
Algorithm for Pulseless Ventricular Tachycardia or Fibrillation
3. Defibrillation (shock 1)
4. CPR 2 min Establish IV/IO access
5. Reassess rhythm; shock if appropriate and proceed If no sign of ROSC, go to Asystole/PEA algorithm If ROSC, initiate post–cardiac arrest care
6. Defibrillation (shock 2)
7. CPR 2 min Epinephrine 1 mg IV/IO every 3–5 min Consider advanced airway, capnography
8. Reassess rhythm; shock if appropriate and proceed If no sign of ROSC, go to asystole/PEA algorithm If ROSC, initiate post–cardiac arrest care
9. Defibrillation (shock 3)
10. CPR 2 min Amiodarone[b] 300 mg IV/IO × 1; may repeat at 150 mg bolus × 1 Reversible causes of the event should be identified and corrected[c]
Algorithm for Asystole or PEA
11. CPR 2 min IV/IO access Epinephrine 1 mg IV/IO every 3–5 min Consider advanced airway, capnography
12. Reassess rhythm; shock if appropriate and proceed to No. 6 or 7 for pulseless VT/VF If no sign of ROSC, proceed
13. CPR 2 min Treat reversible causes[c]
14. Reassess rhythm; shock if appropriate and proceed to No. 6 or 7 for pulseless VT/VF If no sign of ROSC, continue steps 11–14 If ROSC, initiate post–cardiac arrest care

[a]If no IV/IO access, endotracheal administration of epinephrine, lidocaine, and atropine is allowed at 2–2.5 times the recommended IV/IO dose. Dilute this dose with 5–10 mL of sterile water or normal saline.

[b]If amiodarone is unavailable, lidocaine may be considered. Lidocaine 1–1.5 mg/kg IV, repeat 0.5–0.75 mg/kg IV/IO every 5–10 min (maximum 3 mg/kg). Lidocaine has not been shown to improve ROSC and hospital admission compared with amiodarone.

[c]Hypovolemia, hypoxia, hydrogen ion (acidosis), hypokalemia or hyperkalemia, hypothermia, tension pneumothorax, tamponade (cardiac), toxins, thrombosis (pulmonary), thrombosis (coronary).

CPR = cardiopulmonary resuscitation; IO = intraosseous(ly); PEA = pulseless electrical activity; ROSC = return of spontaneous circulation; VF = ventricular fibrillation; VT = ventricular tachycardia.

B. Symptomatic Bradycardia
   1. If unstable, atropine 0.5 mg every 3–5 minutes (maximum dose 3 mg). (Note: Unstable = hypotension, acutely altered mental status, signs of shock, ischemic chest discomfort, acute HF)
   2. If atropine fails, transcutaneous pacing, dopamine 2–10 mcg/kg/minute, or epinephrine 2–10 mcg/minute

C. Symptomatic Tachycardia
   1. If unstable, synchronized cardioversion
   2. If stable, determine whether QRS complex is narrow or wide.
      a. Narrow-complex tachycardia (QRS less than 120 milliseconds); usually atrial arrhythmias
         i. Regular ventricular rhythm: Supraventricular tachycardia (SVT) or sinus tachycardia likely
            (a) Vagal maneuvers or adenosine 6 mg intravenous push, followed by a 20 mL saline flush, then a 12 mg intravenous push (may repeat once)
               (1) Rapid push followed by elevation of arm to increase circulation
               (2) Larger doses may be needed in patients taking theophylline or caffeine.
               (3) Initial dose should be reduced to 3 mg in patients taking dipyridamole or carbamazepine and in patients after heart transplantation, and when the drug is being given by central access.
               (4) Use adenosine cautiously in severe CAD.
               (5) Adenosine should not be given to patients with asthma.
               (6) Do not give adenosine for unstable or for irregular or polymorphic wide complex tachycardias, because it can cause degeneration to ventricular fibrillation (VF).
            (b) If vagal maneuvers or adenosine fails to convert paroxysmal SVT, calcium channel blockers (CCBs) or β-blockers can be used. If Wolff-Parkinson-White syndrome, avoid verapamil, diltiazem, and digoxin
         ii. Irregular (narrow complex) ventricular rhythm: AF (or possibly atrial flutter)
            (a) General management should focus on control of the rapid ventricular rate.
               (1) Usually non-dihydropyridine CCBs (diltiazem, verapamil) or β-blockers; digoxin sometimes useful
               (2) Rate is acceptable if it is less than 110 beats/minute at rest in asymptomatic persistent AF.
            (b) If patient is hemodynamically unstable, synchronized cardioversion is recommended.
            (c) Patients with AF for more than 48 hours are at high risk of cardioembolic events and should not be immediately cardioverted if stable.
            (d) Transesophageal echocardiography before cardioversion is an alternative strategy to ensure the absence of left atrial clot.
            (e) Risk of thromboembolic event surrounding cardioversion (both pharmacologic and electrical) is greatest within the first 10 days.
            (f) Cardioversion
               (1) If AF for up to 7 days, either elective direct current conversion or chemical cardioversion
                  (A) Flecainide, dofetilide, propafenone, ibutilide, or amiodarone (proven efficacy)
                  (B) Digoxin and sotalol are not recommended and may be harmful.
                  (C) Disopyramide, quinidine, and procainamide are less effective or incompletely studied.
               (2) If AF greater than 7 days, administer either elective direct current conversion or chemical cardioversion with dofetilide, amiodarone, or ibutilide (proven efficacy).

b. Wide complex tachycardia (QRS greater than 120 milliseconds): Usually ventricular arrhythmias
   i. Ventricular tachycardia (VT) or unknown mechanism
      (a) Consider adenosine only if regular and monomorphic.
      (b) Intravenous procainamide, amiodarone (or sotalol); lidocaine second line
      (c) Avoid procainamide and sotalol if prolonged QTc.
   ii. Definite SVT with aberrancy: Probably transiently slowed or converted by adenosine
   iii. Polymorphic (irregular) VT
      (a) Induced primarily when the QTc interval is greater than 500 milliseconds (torsades de pointes)
      (b) If unstable, polymorphic (irregular) VT requires immediate defibrillation with the same strategy as VF.
      (c) If stable, intravenous magnesium (Mg^{2+}) 1–2 g intravenous bolus (maximum 16 g every 24 hours) may be given; however, this is supported only by observational studies in the setting of wide QRS.
      (d) Withdrawal of QT-prolonging medications, correction of low Mg^{2+} or K^{+} levels
         (1) Class I and III antiarrhythmic drugs
         (2) Assess for drug interactions by cytochrome P450 3A4 (e.g., azole antifungals, erythromycin).
         (3) Assess for other QTc-prolonging drugs such as haloperidol, ziprasidone, droperidol, promethazine, macrolide and quinolone antibiotics, tricyclic antidepressants, or drugs contraindicated with dofetilide such as sulfamethoxazole/trimethoprim or thiazides.

D. Antiarrhythmic Overview (Tables 18 and 19)

Table 18. Vaughn-Williams Antiarrhythmic Drug Classes

Class/Ion Affected	Agents	Physiological Effect	Result on Electrophysiological Parameters	Clinical Utility
Class I/Na^{+} channel blockers				
Ia (intermediate)	Disopyramide quinidine, procainamide	↓ Conduction velocity; ↑ refractory period	↑ QRS complex and ↑ QT interval	Atrial and ventricular arrhythmias
Ib (fast)	Lidocaine, mexiletine, phenytoin	↓ Conduction velocity; ↓↑ refractory period	↓ QT interval	Ventricular arrhythmias
Ic (slow)	Flecainide, propafenone	↓↓↓ Conduction velocity; Ø refractory period	↑ QRS complex	Supraventricular arrhythmias and ventricular arrhythmias
Class II β-blockers	Metoprolol, esmolol, atenolol	↓ Conduction velocity; ↑ refractory period	↓ HR and ↑ PR interval	Atrial and ventricular arrhythmias
Class III K^{+} channel blockers	Amiodarone,[a] dronedarone,[a] sotalol,[b] dofetilide, ibutilide	Ø Conduction velocity; ↑↑↑ refractory period	↑ QT interval	Atrial and ventricular arrhythmias
Class IV Ca^{2+} channel blockers	Diltiazem, verapamil	↓ Conduction velocity; ↑ refractory period	↓ HR and ↑ PR interval	Atrial and ventricular arrhythmias

[a]Amiodarone and dronedarone have Ib, II, and IV class activity in addition to class III actions.

[b]Sotalol has 50%/50% β-blocking properties/K^{+}-blocking properties.

Ca^{2+} = calcium; Na^{+} = sodium. ↑= increases; ↓decreases; Ø= no effect

Table 19. Antiarrhythmic Drug Properties and Dosing (class I and III agents only)

Drug	AEs, Contraindications, Pharmacokinetics, and Drug Interactions	Dosing by Indication
Class Ia: Na^+ channel blockers		
Quinidine (Quinidex, Quinaglute)	AEs: Nausea, vomiting, and diarrhea (30%), "cinchonism" (CNS and GI symptoms, tinnitus), strong vagolytic and anticholinergic properties, TdP (first 72 hr), hypotension, GI upset PK: Half-life 5–9 hr Potent inhibitor of CYP2D6; substrate and inhibitor of CYP3A4 DIs: Warfarin, digoxin	AF conversion: Avoid use because of GI AEs AF and VT maintenance: Sulfate: 200–400 mg PO every 6 hr Gluconate (CR): 324 mg PO every 8–12 hr Decrease dose 25% if CrCl < 10 mL/min/1.73 m^2
Procainamide (Pronestyl)	AEs: hypotension (IV use, 5%), TdP CI: LVEF < 40% PK: Active metabolite NAPA (class III effects) may accumulate in renal dysfunction	AF conversion: 1 g IV for 30 min; then 2 mg/min (1-hr efficacy 51%) AF maintenance: No oral agent available VT conversion: 20 mg/min IV until 17 mg/kg, arrhythmia ceases, hypotension, or QRS widens > 50% VT maintenance: 1–4 mg/min Reduce dose in renal and liver dysfunction
Disopyramide (Norpace, Norpace CR)	AEs: Anticholinergic effects, TdP, ADHF (potent negative inotropic effect) CIs: Cardiogenic shock, congenital long QT syndrome, second- or third-degree AVB, glaucoma PK: Half-life 4–8 hr Substrate of CYP2D6 DI: May enhance the effect of β-blockers	AF conversion: IR 200 mg (if < 50 kg) or 300 mg (if > 50 kg) PO every 6 hr AF maintenance: 400–800 mg/day in divided doses (recommended adult dose 600 mg/day given as IR 150 mg PO every 6 hr or as CR 300 mg PO every 12 hr) If < 50 kg, moderate renal dysfunction (CrCl > 40 mL/min/1.73 m^2) or hepatic dysfunction, maximum 400 mg/day If severe renal dysfunction (IR only; avoid CR) CrCl 30–40 mL/min/1.73 m^2, 100 mg every 8 hr CrCl 15–30 mL/min/1.73 m^2, 100 mg every 12 hr CrCl < 15 mL/min/1.73 m^2, 100 mg every 24 hr Ventricular tachycardias: Use has fallen out of favor because of the availability of newer agents with less toxicity
Class Ib: Na^+ channel blockers		
Lidocaine (Xylocaine)	AEs: CNS (perioral numbness, seizures, confusion, blurry vision, tinnitus) CI: Third-degree AV heart block PK: Reduce dose in those with HF, liver disease, low body weight, and renal dysfunction and in older adults DI: Amiodarone (increased lidocaine levels)	Pulseless VT/VF conversion or VT with a pulse: 1–1.5 mg/kg IVP; repeat 0.5–0.75 mg/kg every 3–5 min (maximum 3 mg/kg) (If LVEF < 40%, 0.5–0.75 mg/kg IVP) (Amiodarone DOC in pulseless VT/VF; lidocaine acceptable if amiodarone not available) VT maintenance: 1–4 mg/min Reduce maintenance infusion in liver disease
Mexiletine (Mexitil)	AEs: CNS (tremor, dizziness, ataxia, nystagmus) CI: Third-degree AV heart block PK: Half-life 12–20 hr Substrate CYP2D6, CYP1A2 Inhibitor CYP1A2	VT maintenance: 200–300 mg PO every 8 hr; maximum 1200 mg/day Reduce dose by 25%–25% in hepatic impairment

Table 19. Antiarrhythmic Drug Properties and Dosing (class I and III agents only) *(Cont'd)*

Drug	AEs, Contraindications, Pharmacokinetics, and Drug Interactions	Dosing by Indication
Class Ic: Na^+ channel blockers (Note: Avoid in patients with HF or after MI; increased risk of sudden death)		
Propafenone[a] (Rythmol, Rythmol SR)	AEs: Metallic taste, dizziness, ADHF, bronchospasm, bradycardia, heart block (negative inotropy and β-blocking properties) CIs: HF (NYHA III–IV), liver disease, valvular disease (TdP), CAD, MI PK: Half-life 10–25 hr Substrate CYP2D6, CYP1A2, CYP3A4 Inhibitor CYP1A2, CYP2D6 DIs: Digoxin ↑ by 70%; warfarin ↑ by 50% as well as drugs that inhibit CYP 2D6, 1A2, 3A4 (increased propafenone)	AF conversion: 600 mg PO × 1 (efficacy 45% at 3 hr) 450 mg PO × 1 (weight < 70 kg) AF maintenance: HCl: 150–300 mg PO every 8–12 hr HCl (SR): 225–425 mg PO every 12 hr Reduce dose 70%–80% in hepatic impairment
Flecainide[a] (Tambocor)	AEs: Dizziness, tremor, ADHF (negative inotropy), vagolytic, anticholinergic, hypotension CIs: HF, CAD, valvular disease, LVH (TdP) PK: Half-life 10–20 hr Substrate CYP2D6, CYP1A2 Inhibitor CYP2D6 DI: Digoxin ↑ by 25%	AF conversion: 300 mg PO × 1 (efficacy 50% at 3 hr) AF maintenance: 50–150 mg PO BID Reduce dose by 50% when CrCl < 50 mL/min/1.73 m^2
Class III: K^+ channel blockers		
Amiodarone (Cordarone)	AEs: Pulmonary fibrosis 3%–17%, hyperthyroidism 3%, hypothyroidism 30%, neurological toxicity 20%–40%, GI upset, photosensitivity, corneal deposits, hepatitis, blue-gray skin 15%, TdP < 1%, heart block 14%, hypotension (IV), phlebitis (IV; Ca^{2+}- and β-blocking properties), bradycardia CIs: Iodine hypersensitivity, hyperthyroidism, third-degree AV heart block PK: Half-life 58 days (average) Inhibits CYP3A4/2D6/2C9/1A2/2C19 and intestinal P-gp Substrate CYP3A4/1A2/2C19/2D6 DIs: Warfarin, digoxin, statins (maximum simvastatin dose 20 mg/day), phenytoin ↑ ≥ 50%, lidocaine, and others Does not increase mortality in patients with HF	AF conversion: IV: 5–7 mg/kg IV over 30–60 min, then 1.2–1.8 g/day continuous IV or divided oral doses until 10 g PO: 1.2–1.8 g/day in divided doses until 10 g AF maintenance: 200–400 mg/day PO Pulseless VT/VF conversion: 300 mg or 5 mg/kg IVB in 20 mL of D_5W or NS; repeat 150 mg IVB every 3–5 min Stable VT: 150 mg IVB in 100 mL of D_5W for 10 min VT/VF maintenance: 1 mg/min × 6 hr, then 0.5 mg/min (maximum 2.2 g/day)
Sotalol (Betapace, Betapace AF)	AEs: ADHF, bradycardia, AVB, wheezing, 3%–8% TdP within 3 days of initiation, bronchospasm (β-blocking effects) CIs: Baseline QTc > 440 ms or CrCl < 40 mL/min/1.73 m^2 (AF only), LVEF < 40% PK: Renally eliminated, half-life 30–40 hr Hospitalization ideal for initiation of therapy because of BW: Do not initiate if baseline QTc interval > 450 ms; if QTc > 500 ms during therapy, reduce the dose, prolong the infusion duration, or d/c use Not effective for AF conversion	AF maintenance (based on CrCl): 80 mg PO BID (> 60 mL/min/1.73 m^2) 80 mg PO daily (40–60 mL/min/1.73 m^2) CI < 40 mL/min/1.73 m^2 VT maintenance (based on CrCl): 80 mg PO BID (> 60 mL/min/1.73 m^2) 80 mg PO daily (30–60 mL/min/1.73 m^2) 80 mg PO every 36–48 hr (10–30 mL/min) 80 mg PO: individualize; every 48 hr minimum (< 10 mL/min/1.73 m^2)

Table 19. Antiarrhythmic Drug Properties and Dosing (class I and III agents only) *(Cont'd)*

Drug	AEs, Contraindications, Pharmacokinetics, and Drug Interactions	Dosing by Indication
Class III: K^+ channel blockers		
Dofetilide (Tikosyn)	AEs: TdP (0.8%; 4% if no renal adjustment), diarrhea CIs: Baseline QTc > 440 ms or CrCl < 20 mL/min/1.73 m^2 PK: Renal and hepatic elimination Half-life 6–10 hr Substrate CYP3A4 DIs: CYP3A4 inhibitors and drugs secreted by kidney (cimetidine, ketoconazole, verapamil, trimethoprim, prochlorperazine, megestrol), HCTZ BW: Hospitalization mandatory for initiation, obtain QTc 2–3 hr after each of the first 5 doses, reduce 50% if QTc ↑ > 15%; NTE QTc > 500 ms Does not increase mortality in patients with HF	AF conversion (based on CrCl; efficacy 12% at 1 mo): 500 mcg PO BID (> 60 mL/min/1.73 m^2) 250 mcg PO BID (40–60 mL/min/1.73 m^2) 125 mcg PO BID (20–40 mL/min/1.73 m^2) CI < 20 mL/min/1.73 m^2 AF maintenance: Dose as above according to renal function; adjust for QTc NTE 500 ms or > 15% ↑ in QTc
Ibutilide (Corvert)	AEs: TdP 8%, AV heart block (β-blocking properties) CIs: Baseline QTc > 440 ms, LVEF < 30%, concomitant antiarrhythmic drugs PK: Half-life 2–12 hr (average 6) DIs: CYP3A4 inhibitors or QT-prolonging drugs ECG monitoring during and 4 hr after CV	AF conversion: 1 mg IV (≥ 60 kg) or 0.01 mg/kg IV (< 60 kg); repeat in 10 min if ineffective (efficacy 47% at 90 min) BW: Potentially fatal arrhythmias (e.g., polymorphic VT) can occur with ibutilide, usually in association with TdP; patients with chronic AF may not be the best candidates for ibutilide conversion
Dronedarone (Multaq)	AEs: Worsening HF, QT prolongation, hypokalemia or hypomagnesemia with K^+-sparing diuretics, hepatic failure CIs: QTc ≥ 500 ms or PR ≥ 280 ms, NYHA class IV HF or NYHA class II–III HF with recent ADHF, severe hepatic impairment, second- or third-degree AVB, or HR < 50 beats/min PK: Half-life 13–19 hr Substrate 3A4 Inhibitor intestinal P-gp DIs: CYP3A4 inhibitors, QT-prolonging drugs, simvastatin, tacrolimus/sirolimus, warfarin, and other CYP3A4 substrates with narrow therapeutic range, digoxin and other P-gp substrates (dabigatran, rivaroxaban)	AF maintenance: 400 mg orally BID D/C if QTc is ≥ 500 ms BW: The risk of death is doubled when used in patients with symptomatic HF with recent decompensation necessitating hospitalization or NYHA class IV symptoms; use is contraindicated in these patients Use in patients with permanent AF doubles the risk of death, stroke, and hospitalization for HF; use is contraindicated in patients with AF who will not or cannot be converted to normal sinus rhythm

[a]Indicates that pill-in-pocket approach can be used for selected patients.

AF = atrial fibrillation; AV = atrioventricular; AVB = atrioventricular block; BW = Boxed Warning CAD = coronary artery disease; CI = contraindication; CNS = central nervous system; CR = controlled release; CV = cardioversion; D_5W = dextrose 5%; DI = drug interaction; DOC = drug of choice; GI = gastrointestinal; HCl = hydrochloride; HCTZ = hydrochlorothiazide; IR = immediate release; LVH = left ventricular hypertrophy; ms = millisecond(s); NAPA = *N*-acetylprocainamide; NS = normal saline; NTE = not to exceed; NYHA = New York Heart Association; PK = pharmacokinetics; QTc = corrected QT interval; SR = sustained release; TdP = torsades de pointes; VF = ventricular fibrillation; VT = ventricular tachycardia.

E. Long-term Management of Ventricular Arrhythmias
   1. Nonsustained VT
      a. Asymptomatic
         i. Infrequent ventricular ectopic beats, couplets, and triplets without other signs of underlying structural heart disease (SHD) or inherited arrhythmia syndrome should be considered a normal variant in asymptomatic patients.

ii. No treatment other than reassurance is needed for patients without SHD or inherited arrhythmia disorder.
iii. Treat survivors of MI and HF with reduced EF with β-blockers (class I) unless contraindicated.

b. Symptomatic
i. β-Blockers may be considered for a therapeutic trial in symptomatic patients (class IIb, level of evidence [LOE] C).
ii. Non-dihydropyridine CCBs may be considered as an alternative to β-blocker therapy in suitable patients without SHD.
iii. Antiarrhythmic drug (AAD) therapy (amiodarone, flecainide, mexiletine, propafenone, sotalol) may be considered to improve symptoms associated with arrhythmias in patients on adequate doses of β-blocker or CCB (class IIb; LOE C).
(a) Flecainide and propafenone are not recommended to suppress premature ventricular contractions in patients with reduced LV function (class III).
(b) Sotalol should be used with caution in patients with chronic kidney disease and should be avoided in patients with prolonged QT interval at baseline or excessive prolongation of QT interval (500 milliseconds) on therapy initiation (class I; LOE B).
(c) Amiodarone appears to have less overall proarrhythmic risk than other AADs in patients with HF and may be preferred to other membrane-active AADs unless functioning defibrillator has been implanted (class IIb; LOE C).
iv. Amiodarone, sotalol, and other β-blockers are useful after defibrillator implantation to reduce shocks and to suppress nonsustained VT in patients who are unsuitable for ICD therapy, in addition to optimal medical therapy for patients with HF.

2. Sustained VT
a. Immediate defibrillation (advanced CV life support management)
b. Evaluate cardiac structure and function.
c. ICDs indicated for most patients with SHD

F. Implantable Cardioverter-Defibrillators
1. For primary prevention of SCD
a. Previous MI, at least 40 days earlier and EF of 35% or less
b. Nonischemic dilated cardiomyopathy, LVEF of 35% or less receiving optimal chronic medications for at least 3 months
c. Syncope with SHD and inducible VT/VF during electrophysiological study
d. High risk of life-threatening VT/VF; congenital long QT syndrome with recurrent symptoms or torsades de pointes while receiving β-blocker
e. Must have reasonable survival expectation for more than 1 year
2. For secondary prevention of SCD
a. Previous episode of resuscitated VT/VF, hemodynamically unstable VT with no completely reversible cause, or sustained VT in presence of heart disease
b. Must be receiving optimal chronic medications (β-blockers, ACE inhibitors)
c. Must have reasonable survival expectation for more than 1 year
3. General medication considerations with ICD (Table 19)
a. β-Blockers
i. Considered mainstay therapy
ii. Effective in suppressing ventricular ectopic beats and in reducing SCD in a spectrum of cardiac disorders in patients with and without HF (nonsustained VT)

b. Amiodarone
   i. No better than ICD in reducing SCD as a lone agent; no mortality benefit
   ii. Can be used to treat symptomatic nonsustained VT if β-blockers not effective when ICD not indicated
   iii. Can be used in combination with β-blockers to decrease firing of ICD (defibrillator storm)
c. Sotalol
   i. No mortality advantage
   ii. Can suppress VT and be used to decrease frequency of ICD firing
   iii. Greater proarrhythmic potential; avoid in patients with severely depressed LVEF or significant HF; renal dosing necessary

Table 20. Alteration of Defibrillation Threshold

Threshold Alteration	Medications	Comments
Increase threshold	Amiodarone, lidocaine, and mexiletine	Reprogram ICD, increased energy (joules) needed
Decrease threshold	Sotalol	May decrease energy needed for DCC

DCC = direct current conversion; ICD = implantable cardioverter-defibrillator.

G. Treatment of Arrhythmias in Special Patient Populations
   1. HF
      a. Avoid class Ia and class Ic agents.
      b. Amiodarone and dofetilide (used for atrial arrhythmias only) have a neutral effect on mortality in patients with LV dysfunction after MI.
      c. Dronedarone (used in atrial arrhythmias only) is contraindicated in patients with symptomatic HF with recent decompensation necessitating hospitalization or NYHA class IV symptoms; risk of death was doubled in these patients.
   2. Acute MI
      a. Avoid class Ia and class Ic agents.
      b. CAST trial with class Ic agents (encainide, flecainide) showed greater mortality when used to treat post-MI non–life-threatening ventricular arrhythmias; avoid class Ic agents in patients with SHD.
      c. Class Ia medications: Increased mortality in MI survivors
      d. Amiodarone and dofetilide (used for atrial arrhythmias only) have a neutral effect on mortality in patients with LV dysfunction after MI.

H. Drug-Induced Arrhythmias: Review all potential drug etiologies and treat appropriately.
   1. Drug-induced QT prolongation
      a. Discontinue offending agent if QT prolongation significant (i.e. > 450 msec)
      b. Ensure proper renal and hepatic dosing adjustments.
      c. Review electrolyte abnormalities and thyroid function tests.
      d. Ensure that all electrolytes are maintained at critical levels: K^+ greater than 4 mmol/L and less than 5 mmol/L and Mg^{++} greater than 2 mg/dL.
      e. Ensure that all ECG parameters are within normal limits (e.g., QT interval less than 500 milliseconds).
   2. Drug-induced bradycardia or atrioventricular block
      a. β-Blocker, CCB, digoxin
      b. Administer antidote if appropriate (e.g., calcium for CCB toxicity).
   3. Review for drug interactions. Antiarrhythmic agents have drug interactions that may cause significant outcomes.

Patient Cases

Questions 8 and 9 pertain to the following case.

A 68-year-old man is admitted after an episode of syncope, with a presyncopal syndrome of seeing black spots and experiencing dizziness before passing out. Telemetry monitor showed sustained VT for 45 seconds. His medical history includes HF NYHA class III, LVEF 30%, two MIs, hypertension for 20 years, LV hypertrophy, DM, and diabetic nephropathy. His medications include lisinopril 5 mg/day, furosemide 20 mg twice daily, metoprolol 25 mg twice daily, digoxin 0.125 mg/day, glyburide 5 mg/day, and aspirin 81 mg/day. His blood pressure is 120/75 mm Hg, heart rate 80 beats/minute, BUN 30 mg/dL, and SCr 2.2 mg/dL.

8. Which is the best therapy to initiate for conversion of his sustained VT?
   A. Amiodarone 150 mg intravenously for 10 minutes, then 1 mg/minute for 6 hours, then 0.5 mg/minute.
   B. Sotalol 80 mg twice daily titrated to QTc of about 450 milliseconds.
   C. Dofetilide 500 mcg twice daily titrated to QTc of about 450 milliseconds.
   D. Procainamide 20 mg/minute, with a maximum of 17 mg/kg.

9. The patient presents to the emergency department 3 months after amiodarone maintenance initiation (he refused ICD placement) after a syncopal episode, during which he lost consciousness for 30 seconds, according to witnesses. He also has rapid heart rate episodes during which he feels dizzy and light-headed. He feels very warm all the time (he wears shorts, even though it is winter), is unable to sleep, and has experienced a 3-kg weight loss. He received a diagnosis of hyperthyroidism caused by amiodarone therapy. On telemetry, he shows runs of nonsustained VT. Which would best predict the duration of amiodarone-associated hyperthyroidism in this patient?
   A. Never.
   B. 1 month.
   C. 6 months.
   D. 1 year.

10. A 64-year-old woman presents to the emergency department with the chief concern of palpitations. Her medical history includes hypertension controlled with a diuretic and an inferior-wall MI 6 months ago. She is pale and diaphoretic, but she can respond to commands. The patient's laboratory values are within normal limits. Her vital signs include blood pressure 95/70 mm Hg and heart rate 145 beats/minute; telemetry shows sustained VT. Although initially unresponsive to β-blockers, the patient is successfully treated with lidocaine. Subsequent electrophysiological testing reveals inducible VT, and sotalol 80 mg orally twice daily is prescribed. Two hours after the second dose, the patient's QTc is 520 milliseconds. Which regimen change would be most appropriate for this patient?
   A. Continue sotalol at 80 mg orally twice daily.
   B. Increase sotalol to 120 mg orally twice daily.
   C. Discontinue sotalol and initiate dofetilide 125 mcg orally twice daily.
   D. Discontinue sotalol and initiate amiodarone 400 mg orally three times daily.

IV. HYPERTENSIVE CRISES

A. Definitions
   1. Hypertensive emergency
      a. Severe elevations in blood pressure (usually greater than 180/120 mm Hg) with evidence of new or worsening target-organ damage
      b. Acute target-organ damage can include hypertensive encephalopathy, intracranial hemorrhage, acute ischemic stroke or other acute neurological deficit; unstable angina or acute MI; acute LV failure with pulmonary edema; dissecting aortic aneurysm; retinopathy or papilledema; decreased urinary output or acute renal failure; eclampsia.
      c. Actual blood pressure may not be as important at the rate of blood pressure rise.
      d. Requires immediate blood pressure lowering (not necessarily to normal ranges) to prevent or limit further target-organ damage
      e. In general, oral therapy is discouraged for hypertensive emergencies.
   2. Hypertensive urgency
      a. Situations associated with severe blood pressure elevation in otherwise stable patients without acute or impending change in target-organ damage or dysfunction
      b. Short-term risk is not as high; therefore, blood pressure reduction occurs over several days, not immediately.

B. Goals and Treatment
   1. Hypertensive emergency
      a. Goal is to minimize target-organ damage safely by rapid recognition of the problem and early initiation of appropriate antihypertensive treatment.
      b. Patients are usually admitted for intensive care unit care and close follow-up.
      c. Lower mean arterial pressure (MAP) by no more than 25% or diastolic blood pressure to 100–110 mm Hg within first hour, then/100 mm Hg over next 2–6 hours, then to normal over next 24–48 hours.
      d. Compelling conditions requiring rapid lowering of SBP, usually to less than 140 mm Hg, in the first hour of treatment include aortic dissection, severe preeclampsia or eclampsia, and pheochromocytoma with hypertensive crisis.
      e. Intravenous medications used commonly (Table 21)
      f. No randomized evidence to suggest one drug of choice because of small trial size, lack of long-term follow-up, and failure to report outcomes
      g. Two trials have shown that nicardipine is better than labetalol in achieving the short-term blood pressure target.
      h. Agents are chosen on the basis of drug pharmacology, pathophysiological factors underlying the patient's hypertension, degree of progression of target-organ damage, desirable rate of blood pressure decline, and presence of patient characteristics (Table 21-22).
      i. No randomized evidence exists comparing different strategies to reduce blood pressure, except in patients with intracranial hemorrhage.
      j. No randomized evidence suggests how rapidly to reduce blood pressure.
      k. Clinical experience indicates that excessive reductions in blood pressure can cause renal, cerebral, or coronary ischemia and should be avoided.
   l. Oral loading doses of antihypertensive agents can bring about cumulative effects, causing hypotension after discharge.

2. Hypertensive urgency
   a. Treated by reinstitution or intensification of antihypertensive drug therapy
   b. No indication for referral to the emergency department, immediate reduction in blood pressure in the emergency department, or hospitalization
   c. No proven benefit exists from rapid reduction in blood pressure.
   d. The choice of agent used in this setting varies, and in many cases, adjusting chronic oral therapy (increasing doses), reinitiating therapy in the nonadherent, or adding a new agent (i.e., diuretic) to long-term therapy is appropriate.
   e. All patients with hypertensive urgency should be reevaluated within 7 days (preferably after 1–3 days).

C. Treatment Options (Table 21)

Table 21. Commonly Used IV Drugs for Hypertensive Emergencies

Drug (onset, duration)	IV Dose	Comments/AEs
Vasodilators		
Sodium nitroprusside (Nipride) (immediate, 2–3 min)	0.3–0.5 mcg/kg/min, increase in increments of 0.5 mcg/kg/min to achieve BP target; maximum 10 mcg/kg/min; for infusion rates ≥ 4–10 mcg/kg/min or duration > 30 min, thiosulfate can be coadministered to prevent cyanide toxicity	Intra-arterial BP monitoring recommended to prevent "overshoot"; lower doses required in older adult patients; tachyphylaxis common with extended use AEs: Cyanide or thiocyanate toxicity with prolonged use can result in irreversible neurological changes and cardiac arrest, nausea, vomiting, methemoglobinemia CIs: Renal, hepatic failure Caution: Elevated ICP
Nitroglycerin (2–5 min, 5–10 min)	5–10 mcg/min, increase in increments of 5 mcg/min every 3–5 min to a maximum 20 mcg/min	Use only in patients with ACS and/or acute pulmonary edema; do not use in volume-depleted patients AEs: Headache, nausea, vomiting, tachyphylaxis
Hydralazine (Apresoline) (10 min, 1–4 hr)	5–10 mg via slow IV infusion every 4–6 hr (NTE initial 20 mg/dose)	BP begins to decrease within 10–30 min, and lasts 2–4 hr; unpredictability of response and prolonged duration of action make hydralazine less desirable first agent AEs: Reflex tachycardia, headache, flushing Caution: Angina or MI, elevated ICP, aortic dissection
Enalaprilat (Vasotec) (within 30 min, 12–24 hr)	0.625–1.25 mg over 5 min; doses can be increased up to maximum 5 mg every 6 hr	Should not be used in acute MI; mainly useful in hypertensive emergencies associated with hypertensive emergencies associated with high plasma renin activity; dose not easily adjusted; relatively slow onset (15 min) and unpredictability of BP response AEs: Renal insufficiency or failure, hyperkalemia CIs: Pregnancy, bilateral renal artery stenosis, angioedema (Note: Long half-life)

Table 21. Commonly Used IV Drugs for Hypertensive Emergencies *(Cont'd)*

Drug (onset, duration)	IV Dose	Comments/AEs
Vasodilators		
Fenoldopam (Corlopam) (< 5 min, 30 min)	0.1–0.3 mcg/kg/min, increased by 0.05–0.1 mcg/kg/min every 15 min to a maximum of 1.6 mcg/kg/min	Contraindicated in patients at risk of increased intraocular pressure (glaucoma) or intracranial pressure and those with sulfite allergy AEs: Headache, flushing, tachycardia, cerebral ischemia
Nicardipine (Cardene) (1–5 min, 15–30 min; up to 4 hr if prolonged infusion)	5 mg/hr, increased by 2.5 mg/hr every 5 min to a maximum 15 mg/hr	Contraindicated in advanced aortic stenosis; no dose adjustment needed for older patients AEs: Reflex tachycardia, nausea, vomiting, headache, flushing Caution: Angina or MI, acute HF
Clevidipine (Cleviprex) (2–4 min, 5–15 min)	1–2 mg/hr, doubling every 90 s until BP approaches target, then increasing by less than double every 5–10 min; maximum 32 mg/hr; maximum duration 72 hr	Patients with renal failure and hepatic failure and older adults not specifically studied—use low end range for older adults; contraindicated in soy or egg product allergy, severe aortic stenosis, defective lipid metabolism (e.g. pathological hyperlipidemia, lipoid nephrosis or acute pancreatitis) Caution: HF, concomitant β-blocker use, reflex tachycardia, rebound HTN
Adrenergic Inhibitors		
Esmolol (Brevibloc) (1–2 min, 10–30 min)	LD 500–1000 mcg/kg IVB over 1 min, then a 50 mcg/kg/min infusion; for additional BP lowering, the bolus dose is repeated and the infusion is increased in 50 mcg/kg/min increments as needed to a maximum 200 mcg/kg/min	Contraindicated in patients with concurrent β-blocker therapy, bradycardia, or decompensated HF AEs: Bronchospasm, HF exacerbation, bradycardia or heart block Caution: May worsen acute HF, asthma (higher doses may block β_2 receptors and impact lung function in reactive airway disease), heart block
Labetalol (Normodyne, Trandate) (5–10 min, 3–6 hr)	20–80 mg every 15 min or initial 0.3–1 mg/kg dose (max 20 mg) slow IV injection every 10 min or 0.4–1.0 mg/kg/hr infusion up to maximum 3 mg/kg/hr	Contraindicated in reactive airway disease or chronic obstructive pulmonary disease; especially useful in hyperadrenergic syndromes; may worsen HF and should not be given in patients with second- or third-degree heart block or bradycardia
Phentolamine (2 min, 15–30 min)	IVB dose 5 mg; additional bolus doses every 10 min as needed	Used in hypertensive emergencies induced by catecholamine excess (pheochromocytoma, monamine oxidase inhibitors interactions with food and/or drugs, cocaine toxicity, amphetamine overdose, or clonidine withdrawal)

CI = contraindication; ICP = intracranial pressure.

Table 22. Agents Preferred for Hypertensive Crises According to Comorbidities

Comorbidity	Preferred Agents	Comments
Acute aortic dissection	Labetalol, esmolol	Requires rapid lowering of SBP to ≤ 120 mm Hg; β-blocker should be given before vasodilator (nicardipine or nitroprusside) if needed for BP control or to prevent reflect tachycardia or inotropic effect; SBP ≤ 120 mm Hg should be achieved within 20 min
Acute coronary syndromes	Esmolol or nitroglycerin (preferred), labetalol, nicardipine	Nitrates given in the presence of PDE-5 inhibitors may induce profound hypotension; contraindications to β-blockers include moderate to severe LV failure with pulmonary edema, bradycardia (< 60 beats/min), hypotension (SBP < 100 mm Hg), poor peripheral perfusion, second- or third-degree heart block, and reactive airway disease
Acute pulmonary edema	Clevidipine, nitroglycerin, nitroprusside	β-Blockers contraindicated
Acute renal failure	Clevidipine, fenoldopam, nicardipine	
Eclampsia or preeclampsia	Hydralazine, labetalol, nicardipine	Requires rapid BP lowering; ACE inhibitor, ARBs, renin inhibitors, and nitroprusside contraindicated
Perioperative HTN (BP ≥ 160/90 mm Hg or SBP elevation > 20% of the preoperative value that persists > 15 min)	Clevidipine, esmolol, nicardipine, nitroglycerin	Intraoperative hypertension is most common during anesthesia induction and airway manipulation
Acute sympathetic discharge or catecholamine excess states (e.g., pheochromocytoma, post-carotid endarterectomy status)	Clevidipine, nicardipine, phentolamine (Note: Avoid unopposed β-blockade)	Requires rapid lowering of BP
Acute intracranial hemorrhage	IV continuous infusion	Lower BP in those who present with SBP > 220 mm Hg with continuous IV infusion and close BP monitoring; immediate lowering of SBP < 140 mm Hg is not of benefit and may be harmful
Acute ischemic stroke	No preference of agent	Early initiation or resumption of antihypertensive treatment indicated only in (1) patients treated with tissue-type plasminogen activator to a SBP < 185/110 mm Hg and (2) patients with SBP > 220 mm Hg or DBP > 120 mm Hg; cerebral autoregulation in the ischemic penumbra of the stroke is grossly abnormal and rapid reduction of BP can be detrimental; reinitiate antihypertensive therapies in those with preexisting hypertension after neurological stability

ARB = angiotensin receptor blocker.

Patient Cases

11. A 68-year-old man with a history of chronic kidney disease stage V on hemodialysis, hypertension, CAD post-MI, moderately depressed LVEF, and gastroesophageal reflux disease presents with acute-onset shortness of breath and chest pain. After his recent dialysis, he had a large barbecue meal with salt and smoked some marijuana laced with cocaine. He was nonadherent to medical therapy for 2 days and noticed he had gained 2 kg in 24 hours. His baseline orthopnea worsened to sleeping sitting up in a chair for the 2 nights before admission. He developed acute-onset chest tightness with diaphoresis and nausea, and his pain was 7/10. He went to the emergency department, where a blood pressure of 250/120 mm Hg was noted. He had crackles halfway up his lungs on examination, and chest radiography detected bilateral fluffy infiltrates with prominent vessel cephalization. Electrocardiography revealed sinus tachycardia, heart rate 122 beats/minute, and ST-segment depressions in leads 2, 3, and aVF. He was admitted for a hypertensive emergency. Laboratory results are as follows: BUN 48 mg/dL, SCr 11.4 mg/dL, BNP 2350 pg/mL, troponin T 1.5 mcg/L (less than 0.1 mcg/L), creatine kinase 227 units/L, and creatine kinase-MB 22 units/L. Which medication is best to manage this patient's hypertensive emergency?
    A. Intravenous nitroglycerin 5 mcg/minute titrated to a 25% reduction in MAP.
    B. Labetalol 2 mcg/minute titrated to a 50% reduction in MAP.
    C. Sodium nitroprusside 0.25 mcg/kg/minute titrated to a 25% reduction in MAP.
    D. Clonidine 0.1 mg orally every 2 hours as needed for a 50% reduction in MAP.

12. A 56-year-old white woman with a long history of hypertension because of nonadherence and recently diagnosed HF (EF 35%) presents to the local emergency department with a blood pressure of 210/120 mm Hg and heart rate of 105 beats/minute. She states that she felt a little light-headed but that she now feels okay. She ran out of her blood pressure medications (including hydrochlorothiazide, carvedilol, and lisinopril) 3 days ago. Current laboratory values are within normal limits. Which medication is best for this patient?
    A. Sodium nitroprusside 0.25 mcg/kg/minute titrated to a 25% reduction in MAP.
    B. Labetalol 80 mg intravenously; repeat until blood pressure is less than 120/80 mm Hg.
    C. Resumption of home medications; refer for follow-up within 2 days.
    D. Resumption of home medications; initiate amlodipine 10 mg daily; refer for follow-up in 1 week.

V. PULMONARY HYPERTENSION

A. Definition, Diagnosis, and Treatment Goals
    1. Pulmonary hypertension (PH)
        a. A hemodynamic and pathophysiological condition defined as an increase in mean pulmonary arterial pressure (mPAP) of 25 mm Hg or greater at rest as assessed by right heart catheterization
        b. PH can be found in many clinical conditions.
        c. Current clinical classification
            i. Individualizes different categories of PH sharing similar pathological and hemodynamic characteristics (Table 23)
            ii. Used by the FDA and European Agency for Drug Evaluation for new drugs approved for PH

Table 23. Clinical Classification of PH

Category of PH	Clinical Characteristics
Group 1	PAH; pathological lesions affect the distal pulmonary arteries in particular
Group 2	PH caused by left heart disease; pathologic changes are characterized by enlarged and thickened pulmonary veins, pulmonary capillary dilatation, interstitial edema, alveolar hemorrhage, and lymphatic vessel and lymph node enlargement
Group 3	PH caused by chronic lung disease or hypoxia; pathological changes include medial hypertrophy and intimal obstructive proliferation of the distal pulmonary arteries
Group 4	CTEPH; pathological lesions are characterized by organized thrombi tightly attached to the pulmonary arterial medial layer in the elastic pulmonary arteries, replacing the normal intima; nonoccluded areas may be indistinguishable from PAH; collateral vessels can grow to reperfuse at least partly the areas distal to complete obstructions
Group 5	PH caused by unclear multifactorial mechanisms

CTEPH = chronic thromboembolic pulmonary hypertension; PAH = pulmonary arterial hypertension; PH = pulmonary hypertension.

2. Symptoms
   a. Dyspnea with exertion (60% of patients), fatigue, chest pain, syncope, weakness (40%); caused by impaired oxygen delivery to tissues and diminished CO
   b. Orthopnea, peripheral edema, liver congestion, abdominal bloating, and other signs of right ventricular hypertrophy and failure occur when disease progresses to involve the heart.
3. Diagnosis and classification: Severity of disease should be evaluated in a systemic and consistent manner through a combination of clinical and functional classifications (Tables 23–25), exercise capacity, and echocardiographic, laboratory, and hemodynamic variables to inform therapeutic decisions.

Table 24. Diagnostic Findings of PAH

Type	Diagnostic Findings
Hemodynamic alterations	mPAP ≥ 25 mm Hg at rest, PAWP ≤ 15 mm Hg, and PVR > 3 Wood units on RHC
ECG	Signs of RV hypertrophy, right-axis deviation, and anterior ST- and T-wave abnormalities consistent with RV strain pattern
Echocardiography	Estimated RV systolic pressure elevation, enlarged RV, RV dysfunction
Chest radiography	Enlarged pulmonary arteries and diminished peripheral pulmonary vascular markings, RV enlargement
Physical examination	Cool or cyanotic extremities, jugular venous distension, pulsatile hepatomegaly, peripheral edema, ascites

mPAP = mean pulmonary arterial pressure; PAWP = pulmonary artery wedge pressure; PVR = pulmonary vascular resistance; RHC = right heart catheterization; RV = right ventricle.

Table 25. World Health Organization Classification of Functional Status for PAH

Class	Definition
I	No symptoms (dyspnea, fatigue, syncope, chest pain) with normal daily activities
II	Symptoms with strenuous normal daily activities that slightly limit functional status and activity level
III	Symptoms of dyspnea, fatigue, syncope, and chest pain with normal daily activities that severely limit functional status and activity level
IV	Symptoms at rest; cannot conduct normal daily activities without symptoms

4. Treatment goals
    a. Relieve acute dyspnea symptoms.
    b. Improve exercise capacity and quality of life and prevent death.
5. Acute vasodilator response testing
    a. Mandatory in patients with idiopathic pulmonary arterial hypertension (PAH) to identify those who will respond favorably to long-term treatment with high doses of CCBs
    b. Inhaled nitric oxide is the compound of choice.
    c. Intravenous epoprostenol and intravenous adenosine are alternatives but carry risk of systemic vasodilatory effects.
    d. Positive response: mPAP reduction of at least 10 mm Hg to an absolute mPAP of less than 40 mm Hg
    e. Positive response predicts mortality reduction with long-term CCB or vasodilator use.

B. Treatment of PAH (Boxes 4 and 5; Table 26-27)
1. All patients with PAH should be evaluated promptly at a center with expertise in the diagnosis of PAH before initiation of therapy.
2. Collaborative and closely coordinated care of patients with PAH should involve the expertise of the local physician and those with expertise in PAH care.
3. Treatment decisions are based on World Health Organization functional classification, prior treatment status, response to CCBs, and mode of administration desired.
4. Use of PAH drugs, particularly tested in clinical trials with PAH, might not be helpful in other forms of PH.
5. Use of PAH drugs in other forms of PH should not be generalized; treatment decisions must be made on an individual basis.

Box 4. Initial PAH Treatment Algorithm: Supportive Care

Supportive care: Treat corrective causes of hypoxemia and avoid dehydration, pain, fatigue, high altitude, smoking, pregnancy, and iron deficiency
Oxygen to maintain Sao_2 > 90%, diuretic if peripheral edema or ascites
Oral anticoagulation, warfarin (INR 1.5–2.5) if IPAH ± diuretics ± digoxin (Anticoagulation to prevent catheter thrombosis [IV prostaglandin use] and venous thromboembolism) (IPAH, heritable PAH, and PAH caused by anorexigens [class IIa; LOE C], APAH)
Immunizations for influenza and *Pneumococcus* spp.
Discuss effective methods of birth control with women of childbearing potential

Class I, should be performed or administered; class IIa, reasonable to be performed or administered; class IIb, may be considered; class III, not to be administered or harmful.

APAH= associated pulmonary arterial hypertension; IPAH = idiopathic pulmonary arterial hypertension; LOE = level of evidence; PAH = pulmonary arterial hypertension.

Box 5. PAH Treatment Algorithm: Vasoreactive Algorithm

Positive response to acute vasoreactivity testing
Initiate oral CCB (WHO FC I–II)
If sustained response, continue CCB
If no sustained response, initiate non-vasoreactive algorithm in Table 26

CCB = calcium channel blocker; WHO FC = World Health Organization functional classification.

Table 26. PAH Treatment Algorithm: Non-vasoreactive Algorithm

Negative response to acute vasoreactivity testing (or unresponsive to CCB therapy)				
Initiate therapy with approved medications				
Recommendation	**Evidence**	**WHO FC II**	**WHO FC III**	**WHO FC IV**
I	A or B	Ambrisentan Bosentan Macitentan[a,b,c] Riociguat[a] Sildenafil Tadalafil	Ambrisentan Bosentan Epoprostenol IV[c] Iloprost inhaled Macitentan[a,b,c] Riociguat[a] Sildenafil Tadalafil Treprostinil SC, inhaled[a]	Epoprostenol IV[c]
IIa	C		Iloprost IV + treprostinil IV	Ambrisentan Bosentan Iloprost inhaled and IV[a] Macitentan[a,b,c] Riociguat[a] Sildenafil Tadalafil Treprostinil SC, IV, inhaled
IIb	B		Beraprost[a]	
	C		Initial combination therapy	Initial combination therapy
If inadequate clinical response: Consider eligibility for lung transplantation Sequential combination therapy with ERAs, prostanoids, PDE-5 inhibitor, or soluble guanylate cyclase stimulator				
If inadequate response on maximal therapy: Referral for lung transplantation (class I) BAS (IIa; LOE C)				

Class I, should be performed or administered; class IIa, reasonable to be performed or administered; class IIb, may be considered; class III, not to be administered or harmful.

[a]Approved only by the U.S. Food and Drug Administration (macitentan, riociguat, treprostinil inhaled), in New Zealand (iloprost IV), and in Japan and South Korea (beraprost).

[b]Received positive opinion for approval by the European Medicines Agency.

[c]Morbidity and mortality as primary end point in randomized controlled study or reduction in all-cause mortality (prospectively defined).

BAS = balloon atrial septostomy; CCB = calcium channel blocker; ERA = endothelin receptor antagonist; PDE-5 = phosphodiesterase type 5; WHO FC = World Health Organization functional classification.

Table 27. Overview of Pulmonary Arterial Hemorrhage Treatment Options

Drug, Mechanism, and Indication	Dose	Adverse Effects	Considerations
CCBs Class II PAH	Varies by agent and patient tolerance	Hypotension, headache, dizziness, peripheral edema, cardiac conduction delay (diltiazem)	Should not be used empirically without positive response to acute vasodilatory response testing Diltiazem, amlodipine, nifedipine most commonly used Select agent on the basis of HR at baseline If tachycardic, choose diltiazem If bradycardic, choose amlodipine, nifedipine
Epoprostenol (Flolan, Veletri) Prostanoid Class III–IV PAH	2–40 ng/kg/min IV	Jaw pain, nausea, vomiting, flushing, headache, muscle aches and pain, catheter-related thrombosis, and IV line infections; rebound worsening of symptoms if abruptly discontinued	Continuous IV infusion by pump Flolan: Unstable at acidic pH and room temperature (refrigerate or use ice packs before and during infusion) Veletri: Stable at room temperature Drug must be reconstituted in sterile environment Medical emergency if infusion interrupted (half-life, 6 min); spare drug cassette and infusion pump should be kept available
Treprostinil (Remodulin, Tyvaso) Prostanoid Class II–IV PAH	1.25–40 ng/kg/min SC infusion, IV Inhaled	Severe erythema and induration (83%) and injection site pain (85%) limits use; also headache, nausea, diarrhea, rash	Longer half-life (3 hr); longer to seek medical attention Premixed, prefilled syringe easier to administer Local treatments (hot/cold packs or topical analgesics) can be used to minimize infusion site discomfort Moving infusion site every 3 days minimizes irritation
Inhaled iloprost (Ventavis) Prostanoid Class III–IV PAH	2.5 mcg × 1; then 5 mcg/inhalation by nebulizer 6–9 times daily while awake	Mild, transient cough, flushing, headache, syncope	6–9 inhalations daily (15 min each with jet nebulizer) Prodose AAD nebulization system required Inhaled form has fewer systemic adverse reactions Use no more than every 2 hr
Oral treprostinil (Orenitram) Prostanoid	0.25 mg every 12 hr or 0.125 mg every 8 hr; may increase dose in increments of 0.25 mg or 0.5 mg every 12 hr or 0.125 mg every 8 hr every 3–4 days as tolerated to achieve optimal clinical response	Limb pain (14%), hypokalemia (9%), abdominal distress (6%)	Administer with food Swallow tablets whole; do not crush, split, or chew; use only intact tablets Dose reduction in moderate hepatic impairment Contraindicated in severe hepatic impairment (Child-Pugh class C) Alcohol increases absorption of treprostinil

Table 27. Overview of Pulmonary Arterial Hemorrhage Treatment Options *(Cont'd)*

Drug, Mechanism, and Indication	Dose	Adverse Effects	Considerations
Bosentan (Tracleer) Nonselective endothelin receptor antagonist (ET_A and ET_B) Class III–IV PAH	62.5–125 mg PO BID	Peripheral edema 5%–14%, hypotension 7%, increased LFTs 11%, flushing 7%–14%, palpitations 5%	Available only through REMS Severe drug interactions with glyburide (increased LFTs) and cyclosporine (decreased efficacy of both cyclosporine and bosentan) Monitor LFTs monthly Monitor Hgb and Hct every 3 mo Potential teratogen; if childbearing age, use two contraceptive methods (reduced efficacy of hormonal contraceptives); monthly pregnancy test needed Efficacy decreased with inducers and toxicity increased with inhibitors of CYP 2C8/9 and 3A4
Ambrisentan (Letairis) Selective endothelin receptor antagonist (ET_A only) Class II–III PAH	5–10 mg PO once daily	Peripheral edema 17%, hypotension 0%, increased LFTs 0%–2.8%, flushing 4%, palpitations 5%, fluid retention	Available only through REMS Caution with cyclosporine; maximum dose is 5 mg daily Contraindicated in patients with idiopathic pulmonary fibrosis Potential teratogen (see above comments) Periodic Hgb and Hct monitoring No CYP drug interactions documented
Macitentan (Opsumit) Dual endothelin receptor antagonist Class II–III PAH	10 mg once daily	Anemia, nasopharyngitis, bronchitis, headache, influenza, urinary tract infection	Contraindicated in pregnancy; available only through REMS Metabolized by CYP3A4; avoid use with strong CYP3A4 inhibitors Monitor for elevations of aminotransferases, hepatotoxicity, liver failure, and anemia
Sildenafil (Revatio) PDE-5 inhibitor Class II–IV PAH	20–80 mg PO three times daily	Headache, epistaxis, facial flushing, bluish or blurry vision, light sensitivity, dyspepsia, insomnia	Half-life 4–5 hr May augment effects of other vasodilators when used in combination (especially prostacyclin) Contraindicated in patients receiving nitrates Avoid combined use with strong CYP3A4 inhibitors (e.g., ritonavir, cimetidine, erythromycin) and inducers (rifampin)
Tadalafil (Adcirca) PDE-5 inhibitor Class II–IV PAH	20–40 mg PO once daily	Headache, flushing, indigestion, nausea, backache, myalgia, nasopharyngitis, respiratory tract infection	Half-life 17.5 hr May augment effects of other vasodilators when used in combination (especially prostacyclin) Contraindicated in patients receiving nitrates If CrCl = 31–80 mL/min/1.73 m^2, initiate 20 mg PO once daily and titrate as tolerated If CrCl < 30 mL/min/1.73 m^2 or hemodialysis, avoid use If Child-Pugh class A or B, initiate 20 mg PO once daily and titrate as tolerated If Child-Pugh class C, avoid use Avoid use with potent CYP3A4 inhibitors or inducers

Table 27. Overview of Pulmonary Arterial Hemorrhage Treatment Options *(Cont'd)*

Drug, Mechanism, and Indication	Dose	Adverse Effects	Considerations
Riociguat (Adempas) Soluble guanylate cyclase stimulator Chronic thromboembolic PH and class II–IV PAH	1 mg PO three times daily; increase by 0.5 mg no sooner than 2-wk intervals; maximum dose 2.5 mg three times daily	Headache, dizziness, dyspepsia or gastritis, nausea, diarrhea, hypotension, vomiting, anemia, gastroesophageal reflux, and constipation Serious bleeding occurred in 2.4%, compared with 0% in placebo in clinical trials, including one fatal event	Contraindicated with nitrates; NO donors in any form or use with any PDE inhibitors (including nonspecific and specific PDE-5 inhibitors) Teratogenic, contraindicated in pregnancy Available only through restricted REMS program for women Not recommended for patients with pulmonary veno-occlusive disease Half-life: 7–12 hr Plasma concentrations reduced in smokers Drug interaction with strong CYP3A4 inhibitors and P-gp/breast cancer resistance protein; may use a lower starting dose of 0.5 mg three times daily; decrease dose by 0.5 mg if hypotension occurs Not recommended in severe renal or hepatic disease (CrCl < 15 mL/min/1.73 m^2 or Child-Pugh class C)
Ambrisentan/ tadalafil combination Class II–III PAH	Initiate ambrisentan 5 mg once daily, with or without tadalafil 20 mg once daily Increase to 20 mg ambrisentan or 40 mg tadalafil at 4-wk intervals	Most common: peripheral edema, headache, nasal congestion, cough, anemia, dyspepsia, and bronchitis	Same considerations for each individual agent as above REMS program Do not split, crush, or chew tablets
Selexipag (Uptravi) Oral non-prostanoid prostacyclin IP receptor agonist Class II–III PAH	Initiate at 200 mcg BID; increase by 200 mcg BID at weekly intervals up to 1600 mcg BID reached	Headache, diarrhea, jaw pain, nausea, myalgia, vomiting, pain in extremity and flushing	Take with food to improve tolerability. Can cause pulmonary edema with pulmonary veno-occlusive disease. D/C treatment if confirmed Strong CYP2C8 inhibitors should be avoided Decrease dosing to once daily in patients with moderate hepatic impairment and avoid in patients with severe hepatic impairment Not for use in breastfeeding

AAD = adaptive aerosol delivery; d/c = discontinue; ET = endothelin; Hct = hematocrit; Hgb = hemoglobin; LFT = liver function test; NO = nitric oxide; PAH = pulmonary artery hemorrhage; REMS = Risk Evaluation and Mitigation Strategies.

Patient Cases

13. A 38-year-old woman with obesity presents with increasingly severe symptoms of fatigue and shortness of breath. She could walk only 10–20 feet at baseline and is now short of breath at rest. Her arterial blood gas is pH 7.31, P_{CO_2} 65 mm Hg, P_{O_2} 53 mm Hg, and 85% Sa_{O_2}. She has three-pillow orthopnea and 3+ pitting edema in her lower extremities. Her medical history is significant only for AF. Computed tomographic angiography shows that her pulmonary artery trunk is substantially enlarged, with a mean pressure of 56 mm Hg. Echocardiography reveals right atrial and ventricular hypertrophy. Chest radiography detects prominent interstitial markings. Pertinent laboratory test values are BUN 21 mg/dL, SCr 1.2 mg/dL, AST 145 IU/L, alanine aminotransferase 90 IU/L, INR 2.1, and aPTT 52 seconds; vital signs include blood pressure 108/62 mm Hg and heart rate 62 beats/minute. Home medications are warfarin 2.5 mg/day, ipratropium 2 puffs every 6 hours, salmeterol 2 puffs twice daily, and diltiazem 480 mg/day. Her diagnosis is idiopathic pulmonary arterial hypertension (IPAH). Which regimen is the best evidence-based management strategy?

    A. Increase diltiazem to 600 mg/day.

    B. Start sildenafil 20 mg three times daily.

    C. Start epoprostenol 2 ng/kg/minute.

    D. Start bosentan 62.5 mg twice daily.

14. A 48-year-old man with IPAH is admitted to the medical intensive care unit for severe respiratory distress. Medications before admission included bosentan and sildenafil. His vital signs include blood pressure 97/45 mm Hg, heart rate 130 beats/minute, and respiratory rate 24 breaths/minute, and his oxygen requirements are increasing. Recently, during a previous hospital admission, pulmonary artery catheter placement revealed an mPAP of 40 mm Hg, right atrial pressure 16 mm Hg, CI 1.2 L/minute, and PCWP 15 mm Hg. Echocardiography reveals EF 60% with significant right ventricular dilation. Which regimen is most appropriate?

    A. Epoprostenol and add phenylephrine, if needed, for blood pressure support.

    B. Furosemide and add norepinephrine, if needed, for blood pressure support.

    C. Nitroprusside and add epinephrine, if needed, for blood pressure support.

    D. Dobutamine to increase CO.

Special Acknowledgment: ACCP gratefully acknowledges the contribution of previous authors Drs. Jo Ellen Rodgers, Robert Page, and Sheryl Chow to this chapter.

ANSWERS AND EXPLANATIONS TO PATIENT CASES

1. Answer: A

This patient's atypical symptoms, ST-segment depression on ECG, and positive biomarkers for myocardial necrosis suggest NSTE-ACS. She has at least three risk factors for CAD, a history of CAD (prior MI), and positive troponins, which places her at high risk of future events. In such high-risk patients, an early invasive strategy (as in Answers A and B) is used to determine whether occluded or partly occluded arteries exist, which ones can be intervened on, and whether to make an intervention. An ischemia-guided approach, also called *medical management*, as in Answers C and D, would not be preferred because of this patient's risk category (i.e., positive troponins). Dual antiplatelet therapy (aspirin plus a $P2Y_{12}$ inhibitor) is indicated for an early invasive strategy in the management of an NSTE-ACS. In patients undergoing PCI, clopidogrel, prasugrel, or ticagrelor is an appropriate option (Answer A is correct). After an initial bolus of 60 units/kg and an infusion of 12 units/kg/hour (Answer A is correct; Answer D is incorrect), UFH can be titrated to an aPTT of 50–70 seconds, making Answer A correct. Aspirin alone without a $P2Y_{12}$ agent, as in Answer B, would not provide adequate antiplatelet therapy. Furthermore, enoxaparin would need to be dosed with a 30-mg intravenous bolus before initiating twice-daily subcutaneous dosing because this patient has positive troponins. Glycoprotein inhibitors, as in Answer C, can be useful in high-risk patients, typically those with positive troponins; however, their benefit has been shown mainly when UFH, not low-molecular-weight heparin, is given as the anticoagulant.

2. Answer: D

It is important to understand that this patient case occurs in the context of elective stent placement, not after ACS. In the non-ACS setting, the duration of DAPT is determined by the type of stent placed (bare metal stent vs. drug-eluting stent). After elective drug-eluting stent placement, DAPT is recommended for at least 12 months because the risk of in-stent thrombosis is highest during this time. The recommendation is for at least 1 month—and ideally up to 1 year—after bare metal stent placement because endothelialization of the stent usually occurs early, typically within 1 month after stenting. Bleeding risk may be a reason to consider earlier termination (after a minimum of 1 month) of DAPT after bare metal stent placement.

3. Answer: D

Although this patient presented within 3 hours of chest pain onset and is a candidate for thrombolytic therapy (within 6 hours of onset is preferred), up to 95% of patients can achieve normal, brisk TIMI-3 flow rates with primary PCI, compared with only 50%–60% of patients achieving normal TIMI-3 coronary flow with thrombolytic therapy. Because the patient presents to a hospital that can perform a primary PCI with stent implantation, this is the preferred reperfusion strategy (Answers B and C are incorrect). Answer A is incorrect because an anticoagulant agent must be administered in addition to antiplatelet therapy. Answer D—reperfusion with primary PCI, DAPT with aspirin and prasugrel, and dosing of bivalirudin as an anticoagulant strategy—is correct.

4. Answer: C

Unlike the patient in case 3, this patient presents with a STEMI to a rural community hospital where the nearest hospital with catheterization laboratory facilities is more than 120 minutes away (i.e., lytics are indicated). He presents within the window for fibrinolytic therapy consideration (less than 6 hours after chest pain onset) and has no obvious contraindications. Because he is still having ischemic chest pain and ST-segment elevation, he should benefit from reperfusion therapy. He is experiencing complete heart block and bradycardia, which could indicate an occlusion above the area perfusing his sinoatrial or atrioventricular nodes. Enoxaparin (Answer A) is a treatment option for anticoagulant therapy given in conjunction with fibrinolytics, but the patient is at higher risk of bleeding from impaired enoxaparin clearance and needs a dosage adjustment. Furthermore, he is older than 75 years, beyond the age at which the intravenous bolus should be given, and the alteplase dosing is incomplete. Simply treating this patient conservatively with UFH alone (Answer B) in the setting of ongoing chest pain, shortness of breath, and pulmonary edema is not optimal. Diagnostic catheterization and possible PCI to determine whether an artery can be reperfused (Answer D) may be desirable, but is complicated because the patient's SCr is elevated

(2.5 mg/dL), and he is in a rural hospital, where he cannot be assessed quickly enough (within 90–120 minutes). Because of the shorter half-life and ease of administration of tenecteplase, it may be preferable to alteplase. Clearance of UFH with tenecteplase is not as altered as with enoxaparin, and it would be a more appropriate therapy than enoxaparin in combination with a thrombolytic (Answer C is correct).

5. Answer: C

This patient, who has ADHF, is receiving a β-blocker. Although long-term β-blockers can improve HF symptoms and reduce mortality, they can also worsen symptoms in the short term. It is recommended to keep the maintenance β-blocker therapy at the same or slightly lower dose compared with the outpatient therapy in patients with ADHF; increasing the β-blocker dose before reaching euvolemia might acutely worsen his clinical picture (Answer A is incorrect). In patients admitted with volume overload without substantial signs of reduced CO, it is reasonable to try intravenous loop diuretics initially (Answer C is correct). As gut edema increases, oral loop diuretics (notably furosemide) become less effective because of decreased absorption. Nesiritide is a vasodilatory drug that is FDA approved for the symptomatic relief of acute HF; however, because of its lack of evidence for benefit, adverse effects, and substantial cost, nesiritide is not recommended for routine use in the broad population of patients with acute HF (Answer B is incorrect). Milrinone is an inotropic drug. Because of their adverse effects, inotropes are recommended in cold and wet exacerbations only after vasodilatory medications have failed (Answer D is incorrect).

6. Answer: A

Intravenous vasodilators such as nitroglycerin (Answer A) and sodium nitroprusside (Answer B) are reasonable options if intravenous diuretics fail and the patient progresses to acute pulmonary edema. Both agents rapidly cause venous vasodilation and reduce pulmonary filling pressures, which can relieve acute shortness of breath. Answer A, nitroglycerin, is the optimal choice for this patient, given his declining renal function and the concern about increased risk of thiocyanate toxicity with sodium nitroprusside in this setting (Answer B is incorrect). Dobutamine is typically used in states of low CO decompensation and is counteracted by concomitant β-blocker therapy, making it a poor choice in patients receiving β-blockers (Answer C is incorrect). Although milrinone is a more acceptable inotropic agent in a patient receiving β-blockers, the dosing strategy is inappropriate as an initial dose (Answer D is incorrect). Finally, inotropes are generally reserved for patients when other therapies have failed.

7. Answer: A

Signs of a decreased CO state in HF (e.g., increased SCr, decreased mental status, cool extremities) suggest a cold and wet state, and adjunctive therapy is indicated. Positive inotropic agents such as milrinone will increase CO to maintain perfusion to vital organs. Milrinone will also vasodilate the peripheral vessels to unload the heart (lower SVR). Although dobutamine would be a potential choice in this patient, it is not recommended in patients receiving β-blockers (Answer B is incorrect). Although this patient has low blood pressure, his elevated SVR suggests that he will tolerate the vasodilatory effects of milrinone (Answer A is correct). Although nesiritide would provide venous and arterial vasodilation, it is relatively contraindicated in patients with a systolic blood pressure less than 100 mm Hg and is absolutely contraindicated in patients with a systolic blood pressure less than 90 mm Hg (Answer C is incorrect). Phenylephrine has no positive beta effects; therefore, it will not augment contractility. In addition, it will cause vasoconstriction through alpha stimulation, which will further increase SVR and probably worsen CO (Answer D is incorrect). Vasoconstrictors are reserved for patients in cardiogenic shock. Although this patient has signs of significant hypoperfusion, his blood pressure is not so low that it warrants vasopressor therapy.

8. Answer: A

Treatment options for sustained VT depend on concomitant disease states, particularly LVEF (40% cutoff). In a patient with LV dysfunction, class I agents such as procainamide are contraindicated (Answer D is incorrect). In a patient whose CrCl is less than 60 mL/minute/1.73 m^2, sotalol requires a considerable dose reduction to avoid excess risk of torsades de pointes. Sotalol is not an effective cardioversion drug but is more useful for preventing future episodes of arrhythmias (maintaining sinus rhythm) once sinus rhythm is achieved (Answer B is incorrect). Dofetilide is indicated only for AF, not

for ventricular arrhythmias; similarly, cardioversion rates with dofetilide are low (Answer C is incorrect). Amiodarone is first-line therapy for sustained VT in patients with severe renal insufficiency, HF, and structural heart disease (Answer A is correct).

9. Answer: C

With the prolonged half-life of amiodarone and extensive fat tissue volume of distribution, it would be expected that hyperthyroid adverse effects would last for 3–5 half-lives of the drug, which is anywhere from 5 to 8 months (Answer C is correct; Answer A is incorrect). Although therapeutic concentrations may fall off substantially by then, 1 month is too soon to expect the effects to subside (Answer B is incorrect). Although some iodine and amiodarone molecules will probably remain absorbed in fat stores for years, if not for life, therapeutic concentrations should not exist for longer than what is predicted by the half-life (Answer D is incorrect).

10. Answer: D

This patient is experiencing QT prolongation with sotalol, placing her at an elevated risk of developing life-threatening torsades de pointes. Sotalol should be discontinued immediately (Answer A and B are incorrect). Given the QT prolongation that occurred with sotalol, the same will probably occur with dofetilide (Answer C is incorrect). Amiodarone is associated with minimal risk of torsades de pointes and therefore would be an appropriate alternative agent to prevent ventricular arrhythmias (Answer D is correct).

11. Answer: A

Hypertensive emergency should be treated immediately by a 25% reduction in MAP, followed by a slow reduction to goal for 5–7 days. The patient's comorbidities guide the optimal therapy. His dialysis and SCr of 11.4 mg/dL are a contraindication to sodium nitroprusside (Answer C is incorrect) because of possible thiocyanate toxicity. Labetalol (and β-blockers in general) is controversial in patients who have taken cocaine, but its nonselective nature makes it an option; however, a reduction of 50% initially is too rapid a decrease in blood pressure for safety (Answer B is incorrect). Clonidine is not an appropriate drug for a hypertensive emergency because its oral form is difficult to titrate and can lead to precipitous drops in blood pressure beyond the goal 25% reduction and possibly stroke or worsening MI (Answer D is incorrect). Nitroglycerin is an optimal choice, considering the patient's lack of contraindications to this therapy and his evolving MI (Answer A is correct).

12. Answer: C

In the setting of asymptomatic hypertensive crisis (without acute target-organ damage), giving intravenous medications, as in Answers A and B, and admitting the patient to the hospital are unnecessary (Answer A and B are incorrect). This patient is probably presenting because of a history of nonadherence. Resuming her home medications (Answer C is correct) at this time would be most appropriate, with close follow-up to ensure that her prescribed regimen is working. Adding a fourth agent (Answer D is incorrect) at this time is unnecessary, considering that she could be controlled on her current drug regimen if she were adherent. Follow-up should occur within the first few days rather than waiting 1 week.

13. Answer: C

This patient is already receiving therapy with CCBs to control her heart rate caused by AF. She is taking a large dose of diltiazem, and her heart rate is unlikely to tolerate further increases in therapy (Answer A is incorrect). Sildenafil is indicated for patients to improve symptoms or for patients whose other therapies have failed (Answer B is incorrect). Although bosentan is an attractive oral option to manage her PAH, her liver enzymes are elevated more than 3 times the upper limit of normal. Therefore, in this setting, administering bosentan is not recommended (Answer D is incorrect). If liver transaminases are elevated transiently because of hepatic congestion, bosentan can be reconsidered later. Because this patient is currently in functional class IV with advanced symptoms at rest, epoprostenol is indicated for a survival benefit (Answer C is correct).

14. Answer: A

Epoprostenol (Answer A is correct) is warranted to manage this patient's underlying disease because he has not responded to two oral PAH therapies; he is considered high risk because of his right ventricular dysfunction and low CI. He has normal filling pressures for a patient with right ventricular dysfunction, and diuresis with furosemide might only worsen his low CI (Answer

B is incorrect). The underlying cause of his low CI is not elevated arterial resistance; therefore, nitroprusside would probably worsen his hypotension (Answer C is incorrect). Correcting the elevated pulmonary pressures should correct the low CI; therefore, dobutamine is not indicated at this time because it would probably worsen his tachycardia (Answer D is incorrect).

ANSWERS AND EXPLANATIONS TO SELF-ASSESSMENT QUESTIONS

1. Answer: C

In this patient, the presence of chest pain, ST-segment depression on ECG, and positive biomarkers for myocardial necrosis suggests NSTE-ACS. Because of his presentation characteristics, he is at a high enough risk to warrant cardiac catheterization (invasive strategy). This invasive strategy is used to determine whether occluded or partly occluded epicardial arteries exist, which ones can be intervened on, and whether to perform PCI (percutaneous transluminal coronary angioplasty with or without stenting). Initial therapy for ACS usually consists of morphine, oxygen, nitroglycerin, and aspirin therapy, but only aspirin has been shown to reduce mortality from these initial treatments. Aspirin should be given as soon as possible after hospital presentation and continued indefinitely, if tolerated. According to clinical trials, guidelines, and experience, an initial dose of 162–325 mg is recommended (Answers B and D are not the best choices of dosing for an acute episode). Aspirin, together with a $P2Y_{12}$ receptor antagonist, is indicated for an early invasive strategy in the management of UA/NSTEMI, improving outcomes. The 2014 NSTE-ACS guidelines give a class I recommendation for clopidogrel, ticagrelor, and prasugrel in the ACS setting for patients undergoing PCI. The choice of which $P2Y_{12}$ receptor antagonist to use in the ACS setting depends on patient presentation, contraindications, and whether PCI is involved; in this case, any of the three $P2Y_{12}$ antagonists would be appropriate. The anticoagulation strategy treatment for ACS generally includes one anticoagulant (UFH, low-molecular-weight heparin, fondaparinux, or bivalirudin). When UFH is chosen as an anticoagulant strategy, the dose used for ACS is a 60-unit/kg bolus and a 12-unit/kg/hour infusion (Answer A is an incorrect dosing strategy). Regarding dosing, bivalirudin (Answer D) would be an appropriate anticoagulation strategy; however, the initial aspirin dose should be higher, and a nitroglycerin drip would not be the best choice, given his right-sided MI (low blood pressure, low heart rate). Intravenous β-blocker therapy (Answer A) is reasonable in patients without contraindications when hypertension or ongoing ischemia is a concern; however, initiating oral therapy within 24 hours is preferred in most patients as long as the patient has no signs of HF, evidence of low output state, increased risk of cardiogenic shock, or other contraindications to β-blockade. β-Blockers should initially be avoided in this patient, given his blood pressure and heart rate. An intravenous ACE inhibitor (Answer B) should not be given to patients within the first 24 hours of ACS because of the increased risk of hypotension. Answer C includes DAPT and an appropriate dose of anticoagulant (Answer C is correct).

2. Answer: A

The NSTE-ACS guidelines recommend the use of one anticoagulant during an acute event. Enoxaparin, UFH, and bivalirudin are all recommended as class I agents for the invasive management of NSTE-ACS. However, fondaparinux (Answer C) is not optimal because increased risk of catheter-related thrombosis has been associated with fondaparinux use in the catheterization laboratory. The NSTE-ACS guidelines advise the use of additional heparin if fondaparinux was chosen as an initial anticoagulant when the patient underwent intervention, whereas the PCI guidelines give fondaparinux a class III or harmful recommendation. Of the remaining three options, UFH (Answer A) is preferred because of its rapid clearance. Both enoxaparin (Answer B) and bivalirudin (Answer D) are appropriate options but would need to be dose adjusted, given this patient's CrCl of less than 30 mL/minute/1.73 m^2. Doses listed in Answers B and D would be appropriate for patients with a normal CrCl, however.

3. Answer: B

Given that this patient had a significantly low platelet count with his most recent heparin exposure and is believed to have HIT, using any of the GP IIb/IIIa inhibitors (Answers A and C) would be unwise for ACS treatment because these agents must be combined with UFH. Thrombolytic therapy (Answer D) is not recommended for treating NSTE-ACS and would be inappropriate in this patient. Bivalirudin (Answer B), a direct thrombin inhibitor, would be the treatment of choice in patients with HIT undergoing PCI.

4. Answer: D

Administration of β-blocker therapy carries a risk of causing HF decompensation, particularly when the β-blocker is titrated too quickly or initiated in

patients who are not euvolemic. Although administering β-blockers within the first 24 hours is beneficial in STEMI, this patient has several risk factors that would be considered contraindications to initial β-blockade. The clinical condition of this patient suggests he is not euvolemic, and aggressive diuresis should be attempted before initiating a β-blocker for him. In addition, intravenous β-blocker therapy (Answer B) would place him at an even greater risk of cardiogenic shock. Answers A and C are inappropriate because the doses are too aggressive for a patient with an EF of 25%. Answer D is correct; however, before discharge, this patient should be reevaluated for the initiation of low-dose β-blocker therapy.

5. Answer: C

This patient is well perfused and can be classified in Forrester hemodynamic subset II (warm and wet). Because the patient has pulmonary congestion (shortness of breath, dyspnea at rest), intravenous diuretics are first-line therapy. Nitroglycerin (Answer C) is the best choice in this setting because vasodilatory agents can be used in conjunction with intravenous diuretics to improve acute pulmonary edema. When adjunctive therapy is needed in addition to loop diuretics, intravenous vasodilators should be considered over inotropic agents. Dobutamine (Answer A) and milrinone (Answer B) primarily increase CO, which is not a problem in warm and wet exacerbations. In addition, the adverse effects of these agents (increased mortality, proarrhythmia) limit their use. Intravenous metoprolol (Answer D) should be used extremely cautiously because of its negative inotropic effects and because this patient is not in a euvolemic state.

6. Answer: D

This patient has a depressed LVEF less than 40%; therefore, her drug therapy options are limited. Procainamide (Answer A) is indicated only in secondary prevention of sustained VT in patients with a normal LVEF greater than 40%; if given to this patient, it could worsen her HF. Metoprolol (Answer B) is indicated for treating patients with asymptomatic nonsustained VT and SVT associated with CAD. This patient had an episode of sustained VT; therefore, therapy beyond β-blockade is warranted. Her QTc interval is not prolonged at 380 milliseconds, and her serum magnesium concentration is within normal limits, so she does not need intravenous Mg^{2+} therapy (Answer C). Amiodarone (Answer D) is a first-line treatment of patients without contraindications because of its efficacy and safety in patients with an LVEF less than 40%.

7. Answer: B

This patient has target-organ damage from poorly controlled hypertension in the form of a cerebrovascular accident. Although fenoldopam (Answer A) is indicated for treating hypertensive emergencies, its use is cautioned in patients with stroke symptoms because its dopamine agonist activity can cause cerebral vasodilation and potentially reduced blood flow to the ischemic areas of the brain. Nicardipine (Answer B) is an appropriate choice for this patient because its calcium channel blocking effects will reduce blood pressure and potentially decrease vasospasm in the cerebral arteries, which can lead to further ischemia or seizure activity. Although labetalol (Answer C) is an effective option for treating this patient's hypertensive emergency, she has a history of asthma and a low heart rate, making labetalol a less-than-ideal option for treating her symptoms. The antihypertensive effects of enalaprilat (Answer D) depend on a patient's renin activity, which is unknown in this case. Therefore, the blood pressure–reducing effects may be more difficult to control than with a drug having a more consistent effect in individuals. In addition, the bolus nature of the drug is not ideal for tightly controlling blood pressure with no more than a 25% reduction in MAP. Continuous infusion drugs are preferable for easier titration to effect in a hypertensive emergency.

8. Answer: C

This patient is experiencing hypertensive urgency, considering that he has no evidence of target-organ damage. Thus, his blood pressure may be reduced over 24 hours using oral medications. Given this patient's concomitant comorbidities, HF, and microalbuminuria, an ACE inhibitor (Answer C) would be considered appropriate. Sublingual nifedipine (Answer A) is no longer recommended for management of hypertensive urgency because of acute blood pressure lowering and association with life-threatening adverse events, such as MI and stroke. Clonidine (Answer B) and labetalol (Answer D) are acceptable options; however, the patient has compelling indications for an ACE inhibitor. Although the patient should receive a β-blocker in addition to an

ACE inhibitor for HF management, labetalol is not one of the three β-blockers recommended for chronic HF management.

9. Answer: C

The Cardiac Arrest Study Hamburg trial compared ICD with AAD in survivors of cardiac arrest for secondary prevention of SCD. The propafenone (Answer A) study arm was discontinued early because of a significantly (61%) higher mortality rate than in the ICD arm (Answer A is incorrect). Although this trial had a small sample size that prevented a statistically significant difference in total mortality in ICD-treated patients versus patients treated with either amiodarone or metoprolol, the incidence of sudden death was significantly lower in patients with an ICD (Answer C is correct; 33% vs. 13%; p=0.005). The Antiarrhythmics Versus Implantable Defibrillators trial also evaluated ICD implantation versus AAD therapy (primarily amiodarone) in survivors of SCD. Patients with ICDs had a significantly higher rate of survival than those treated with drug therapy (89% vs. 82%; p<0.02), making Answer C preferable to all the other options (Answers B and D are incorrect).

10. Answer: C

The number needed to treat can be calculated as 1/Absolute risk reduction. Because the absolute risk reduction in mortality at 60 months was 7.2% with ICD versus placebo, 1/0.072 would be used to calculate the number of patients needed to treat to prevent one death during this time. About 14 patients (Answer C) would need to be treated with ICD to prevent one death in 60 months versus placebo. Other calculations in this fashion, including relative risk reduction and 100% minus the absolute or relative risk reduction, do not provide useful information for interpreting the trial results and yield an incorrect number of patients (Answers A, B, and D are incorrect).

11. Answer: D

International Pharmaceutical Abstracts (Answer A) is a database of primarily pharmaceutical abstracts in more than 750 journals, including foreign and state pharmacy journals, in addition to key U.S. medical and pharmacy journals. Many of the citations are not included on Medline, so a broader search can be performed; however, subject descriptors are not consistently defined in a uniform way, and multiword terms are often cited backward. The Iowa Drug Information Service database (Answer B) offers full-text articles from 1966 to the present in about 200 medical and pharmacy journals (based primarily in the United States). It is updated monthly, and newly available articles may take longer to access from this service. The Clin-Alert database (Answer C) contains more than 100 medical and pharmacy journals focused on adverse events, drug interactions, and medical-legal issues. It is used primarily to look up adverse events (especially recent reports) associated with medications. Excerpta Medica (Answer D) is a comprehensive database of more than 7000 journals from 74 countries dating from 1974 to the present. Recently published articles appear in the system within 10 days of article publication, and it often contains data not found in a typical Medline search.

12. Answer: B

MedWatch is a post-FDA approval program established by the FDA for health care professionals to report the adverse events that occur after a drug is approved. Although it is commonly used only for reporting serious reactions to the FDA and would not be mandatory in this case (Answer A is incorrect), it can be used to report any adverse event. Information recorded on these forms is reported to the manufacturer and used to determine whether black box warnings are necessary or whether new adverse effects are seen with a drug. The Joint Commission requires that all institutions have a definition of an ADR for the institution that can be understood and remembered by all health care professionals (Answer B is correct). In addition, The Joint Commission requires that each drug dose administered be monitored for adverse effects, that each institution have a system in place for reporting ADRs, and that the institution ensure that the reporting mechanism identifies all key ADRs. The Naranjo algorithm is used to determine the likelihood of cause and effect from a presumed drug-induced event, but is not required (Answer C is incorrect). Answer D is incorrect as serious adverse effects are reportable to the FDA, as are severe and life-threatening events.

13. Answer: B

Because the pharmacy and therapeutics committee wants to discover whether the new drug is worth the extra cost for the added mortality benefits it can provide for patients with decompensated HF compared

with available therapies, a cost-effectiveness analysis (Answer B is correct) is the best pharmacoeconomic analysis to perform. Cost-minimization analysis (Answer A is incorrect) is used to determine whether a therapeutically equivalent drug within a class that provides the same therapeutic outcome as other available drugs can be used for less cost. Cost-utility analysis (Answer D is incorrect) is used to determine whether a drug can improve the quality of a patient's life more than other available therapies. Cost-benefit analysis (Answer C is incorrect) is used to evaluate new programs or services to determine whether they provide enough benefit to justify the cost of running the program.

Learning Objectives

1. Describe cardiovascular anatomy, inherent physiologic function, and circulation in relation to hemodynamic assessment.
2. Evaluate patients and devise a treatment strategy for patients with cardiogenic shock, considering pharmacodynamic response to vasopressors/inotropes.
3. Identify cardiovascular disease states associated with cardiogenic shock.
4. Understand the fundamentals in management of cardiovascular diseases in critically ill patients.
5. Recognize the options for and roles of mechanical circulatory support and heart transplantation as advanced therapies for heart failure and/or cardiogenic shock.

Abbreviations in This Chapter

ABG	Arterial blood gas
ACE	Angiotensin-converting enzyme
ACS	Acute coronary syndrome(s)
ACT	
AF	Atrial fibrillation
ARB	Angiotensin receptor blocker
AV	Atrioventricular
BNP	Brain natriuretic peptide
CABG	Coronary artery bypass grafting
CAD	Coronary artery disease
$CHADS_2$	Congestive heart failure, hypertension, age older than 75, diabetes, and prior stroke or transient ischemic attack
CVP	Central venous pressure
ECHO	Echocardiography
ECMO	Extracorporeal membrane oxygenation
HIT	Heparin-induced thrombocytopenia
HOCM	Hypertrophic obstructive cardiomyopathy
ICU	Intensive care unit
LV	Left ventricle/ventricular
LVAD	Left ventricular assist device
LVEF	Left ventricular ejection fraction
MAP	Mean arterial pressure
MCS	Mechanical circulatory support
MI	Myocardial infarction
NSTEMI	Non–ST-segment elevation myocardial infarction
OLH	Outlying hospital
PCI	Percutaneous coronary intervention
PVR	Pulmonary vascular resistance
RV	Right ventricle/ventricular
SA	Sinoatrial
STEMI	ST-segment elevation myocardial infarction
SVR	Systemic vascular resistance
VAD	Ventricular assist device
VT	Ventricular tachycardia

Self-Assessment Questions

Answers and explanations to these questions may be found at the end of this chapter.

Questions 1–8 pertain to the following case.

A 58-year-old man (height 71 inches, weight 106 kg) was transferred to the intensive care unit (ICU) from an outlying hospital (OLH) after 24 hours of progressively worsening chest pain and shortness of breath. He arrives on 6 L of oxygen by high-flow nasal cannula, with a heparin infusion at 16 units/kg/hour and dopamine infusing at 15 mcg/kg/minute by peripheral line. Notes show that he was bradycardic (heart rate [HR] ranging from 50 to 58 beats/minute) and hypotensive (78/49 to 86/55 mm Hg) on presentation to the OLH. His 12-lead electrocardiogram (ECG) at the OLH showed ST-segment depression in leads V2 and V3. Given his chest pain and ECG findings, aspirin 324 mg (chewed and swallowed), clopidogrel 600 mg, and morphine 4 mg intravenously once were administered before transfer. Notes also show that β-blockers and nitroglycerin were held because of bradycardia and hypotension.

His medical history is significant for medical nonadherence, hypertension, diabetes, hyperlipidemia, and heart failure with preserved ejection fraction (HF*p*EF), with a last-reported left ventricular ejection fraction (LVEF) of 65% 1 year ago.

- Vital signs on transfer: BP 87/52 mm Hg, HR 85 beats/minute, respiratory rate 19 breaths/minute, temperature 37.6°C
- The team's assessment indicates ongoing distress, radiating chest pain 7 of 10, evidence of rales, absence of any cardiac murmurs, and presence of a right radial arterial line.

- A preexisting urinary catheter with 20 mL of urine in the reservoir is also present (the patient reports that his last void was yesterday morning). According to OLH records, only 30 mL of urine was reported before time of transfer.
- His chest radiography reveals evidence of diffuse patchy opacities; however, the report indicates that an infiltrate cannot be ruled out.
- His serum chemistry panel results are as follows: sodium 132 mEq/L, potassium 4.2 mEq/L, chloride 102 mEq/L, carbon dioxide 22 mEq/L, blood urea nitrogen (BUN) 34 mg/dL, serum creatinine (SCr) 1.9 mg/dL, and glucose 163 mg/dL.
- Results of the complete blood cell count (CBC) are as follows: white blood cell count (WBC) 11.3×10^3 cells/mm^3, hemoglobin 10.9 g/dL, hematocrit 31.1%, and platelet count 213,000/mm^3.
- Additional laboratory values include troponin 3.9 ng/mL, aspartate aminotransferase (AST) 14 IU/L, alanine aminotransferase (ALT) 46 IU/L, hemoglobin A1C (A1C) 8.3%, and brain natriuretic peptide (BNP) of 1423 pg/mL.

1. Which is the most likely cause of this patient's admission and transfer?
   A. Septic shock caused by suspected pneumonia with subsequent myocardial depression and demand ischemia.
   B. Cardiogenic shock caused by acute on chronic decompensated systolic heart failure.
   C. Cardiogenic shock caused by a suspected posterior ST-segment elevation myocardial infarction (STEMI).
   D. Cardiogenic shock caused by a suspected non–ST-segment elevation myocardial infarction (NSTEMI) affecting the lateral wall.

2. Given this patient's presentation, which coronary artery is most suggestive of a culprit lesion?
   A. Left main coronary artery.
   B. Left anterior descending artery.
   C. Left circumflex coronary artery.
   D. Right coronary artery.

3. The interventional cardiologist who is evaluating the patient for potential revascularization asks the ICU team to place a central venous catheter. Which changes/interventions regarding this patient's hemodynamic support would be best to recommend?
   A. Increase dopamine to achieve a mean arterial pressure (MAP) greater than 65 mm Hg.
   B. Convert the patient to norepinephrine, and titrate the dose to achieve a MAP greater than 65 mm Hg while weaning off dopamine.
   C. Initiate milrinone at 0.375 mcg/kg/minute, and continue dopamine at 15 mcg/kg/minute.
   D. Administer 1000 mL of normal saline as a bolus because of low urine output.

4. The patient has been taken to the cardiac catheterization laboratory, and a "code blue" is called overhead for immediate emergency response to this patient's procedural area. On arrival, chest compressions have just been paused for defibrillation, and a single dose of epinephrine has been administered. The interventional team indicates that, when attempting visualization of the right coronary artery, the patient went into ventricular tachycardia (VT). The patient's telemetry monitor now shows a sinus tachycardia with noted ectopy—HR of 113 beats/minute and blood pressure (BP) of 84/52 mm Hg. The cardiologist asks for recommendations for an antiarrhythmic because he is concerned about a VT relapse, given the bigeminy revealed on telemetry. Which agent would be best to recommend?
   A. Lidocaine 100 mg intravenous push over 2–3 minutes, followed by an infusion at 1 mg/minute.
   B. Amiodarone 300 mg intravenous push over less than 1 minute.
   C. Metoprolol 10 mg intravenous push over 1–2 minutes.
   D. Diltiazem 20 mg intravenous push over 2 minutes, followed by a continuous infusion at 5 mg/hour and titrated to maintain a HR less than 110 beats/minute.

5. The patient returns to the ICU after his left heart catheterization, which was performed through the femoral artery. In addition to his acute decompensation, which major procedural complication is of greatest concern during the next 12 hours?
   A. Bleeding (particularly retroperitoneal bleeding).
   B. Dissection/rupture.
   C. Stent thrombosis.
   D. Papillary muscle rupture.

6. The patient is currently on dopamine at 12 mcg/kg/minute and norepinephrine at 0.08 mcg/kg/minute with an HR of 108 beats/minute, a BP of 82/51 mm Hg, a cardiac index of 2.0, a central venous pressure (CVP) of 26 mm Hg, and a pulmonary artery pressure of 29/21 mm Hg. The physician would like to augment management of this patient's hypotension but asks for your recommendation out of concern for the patient's right ventricular (RV) function, as evidenced by the rising CVP despite only mildly elevated pulmonary artery pressures. Moreover, the physician's goal is to wean the dopamine while increasing the patient's systemic vascular resistance (SVR) without affecting the pulmonary vascular resistance (PVR) much, if at all. Which strategy would be best to recommend?
   A. Keep the current infusions and reevaluate later.
   B. Initiate phenylephrine at 1 mcg/kg/minute and wean the dopamine off if MAP is greater than 65 mm Hg.
   C. Initiate vasopressin at 0.04 unit/minute and wean the dopamine off if MAP is greater than 65 mm Hg.
   D. Administer a 1-L bolus of normal saline and wean the dopamine off if MAP is greater than 65 mm Hg.

7. Hours later, this patient goes into atrial fibrillation (AF) with an HR of 126 beats/minute; however, the patient's BP remains 86/56 mm Hg according to the regimen selected in the previous question. Which agent would you most likely administer to manage the patient's AF?
   A. Amiodarone 150 mg intravenous push, followed by a continuous infusion at 1 mg/minute.
   B. Amiodarone 150 mg intravenous infusion over 10 minutes, followed by a continuous infusion at 1 mg/minute.
   C. Metoprolol 5 mg intravenous push once, followed by 5 mg intravenous push every 6 hours.
   D. Diltiazem 20 mg intravenous push, followed by a continuous infusion at 5 mg/hour and titrated to maintain an HR of less than 110 beats/minute.

8. If this patient did have a myocardial infarction (MI) during his stay (regardless of intervention or medical management) with an LVEF greater than 40%, which most accurately depicts the medication-related quality metric that would not require initiation or documentation of contraindications at this time?
   A. $P2Y_{12}$ contraindication.
   B. Statin contraindication.
   C. β-Blocker contraindication.
   D. Angiotensin-converting enzyme (ACE) inhibitor/angiotensin receptor antagonist (ARB) contraindication

I. CARDIOVASCULAR FUNDAMENTALS OVERVIEW

A. The myocardium has five functions and distinctive properties:
   1. *Chronotropy*: Ability to generate an electrical impulse at an intrinsic rate
   2. *Dromotropy*: The speed and ability to facilitate electrical impulse conduction
   3. *Inotropy*: Ability to contract in relation to a given preload, afterload, and HR
   4. *Bathmotropy*: Demonstration of an intrinsic excitatory threshold
   5. *Lusitropy*: Relaxation of the myocardium, independent from termination of contraction
   6. Other related terms:
      a. *Preload*: Volume of blood (represented in most cases by a pressure) in a *ventricular cavity* at the end of diastole immediately before contraction, imparting stretch on a resting myocardial sarcomere
      b. *Afterload*: The pressure that a *ventricle* must overcome to generate cardiac output. The greater the afterload (vascular resistance or impedance), the greater the amount of energy and force required to enable ejection of blood from a ventricle and vice versa

B. Coronary Artery Circulation
   1. Myocardial perfusion occurs through the coronary arteries during diastole.
   2. Coronary artery anatomy and perfusion are not the same in everyone.
   3. ECG defects, hemodynamic assessment, and patient symptoms may assist with coronary artery disease (CAD) localization.
   4. Circulatory dominance:
      a. Right dominant: Posterior descending artery and atrioventricular (AV) nodal artery arise from the right coronary artery (85% of the population).
      b. Left dominant: Posterior descending artery arises from the circumflex artery (8% of the population).
      c. Codominant: Posterior descending artery arises from branches of the circumflex and the right coronary artery (7% of the population).
      d. Other notable variations: The sinoatrial (SA) node may have variation in the vessels that supply it; it is most commonly perfused by the right coronary artery (about 70%), circumflex (about 25%), and right coronary artery and circumflex (about 5%).

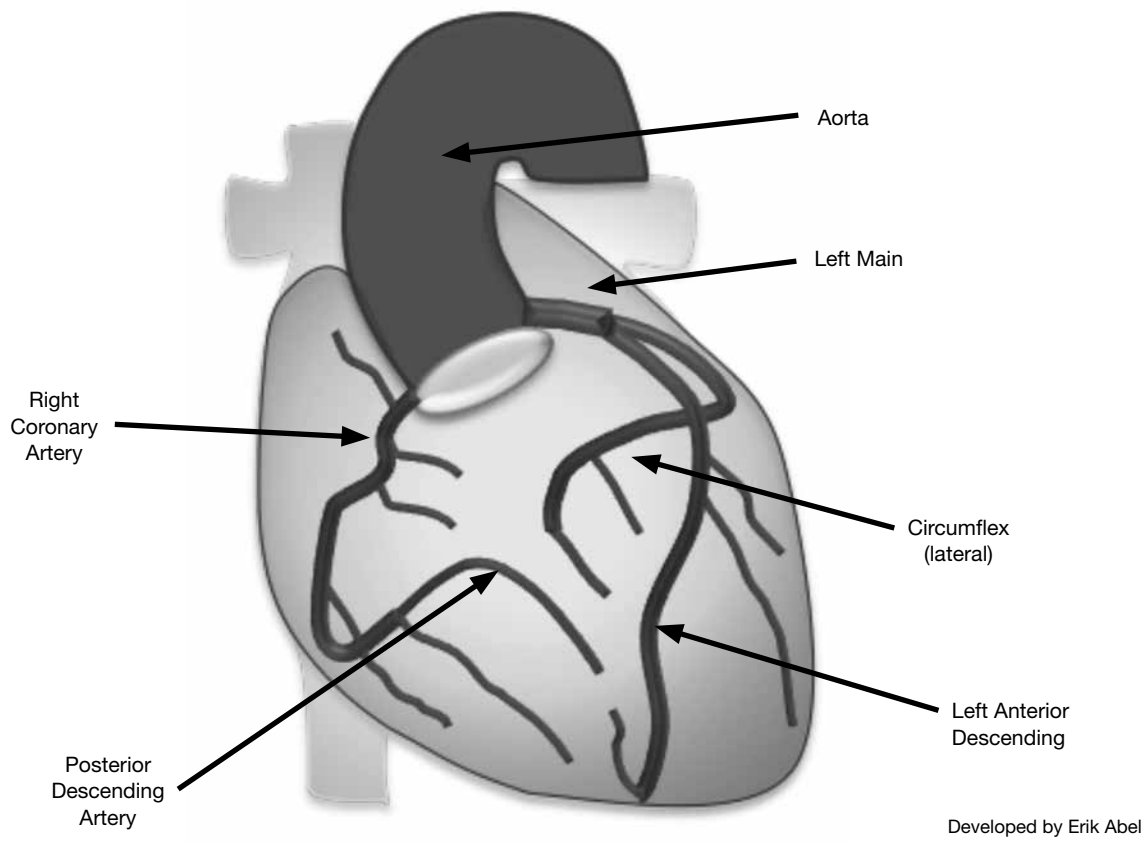

Figure 1. Coronary artery circulation.

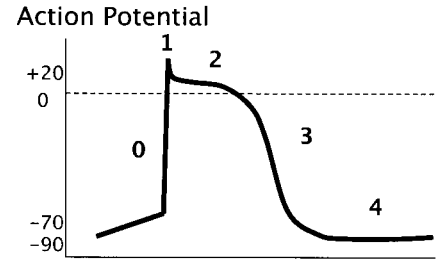
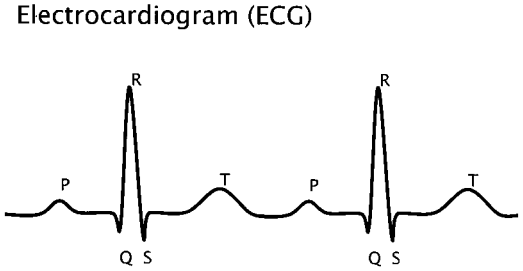
C. Anatomy in Relation to the ECG
   1. A single lead of an ECG tracing is a summative representation of the action potentials occurring from a single cell, facilitating myocardial conduction, contraction, and relaxation.
   2. A 12-lead ECG can provide a geographic representation of conduction within the myocardial tissue. Conduction abnormalities within specified leads may indicate perfusion defects in some clinical scenarios (i.e., acute coronary syndromes [ACS]).



Phase	Electrolyte movement	Conduction change
0	Na+ influx into cell	Depolarization
1	Rrefractory Ca^{2+} and C^{l-} into cell	Effective Refractory Period
2	Ca^{2+} into cell and K^{+} out of cell	
3	K+ out of cell	Repolarization
4	Resting Membrane Potential	



ECG point	Representation
P	Sinoatrial (SA) node impulse generation
PR interval	Duration for conduction to occur from the SA node through the AV node, bundle of His, bundle branches and Purkinje fibers
QRS	Concurrent atrial repolarization and ventricular depolarization
ST segment	Ventricular refractory period
T	Ventricular repolarization
QT interval	Duration for atrial and ventricular repolarization
RR interval	Duration between ventricular depolarizations (represents heart rate)
U	No listed or commonly visualized; may be more prominent in hypothermia or in severe electrolyte depletions

12 — Lead Electrocardiogram (ECG)

Limb leads				Precordial Leads			
I	Anterolateral (Circumflex)	aVR		V1	Anteroseptal (LAD)	V4	Anteroapical (Distal LAD)
II	Inferior (RCA)	aVL	Anterolateral (Circumflex)	V2	Anteroseptal (LAD) Posterior (RCA)	V5	Anterolateral (Circumflex)
III	Inferior (RCA)	aVF	Inferior (RCA)	V3	Anteroapical (Distal LAD) Posterior (RCA)	V6	Anterolateral (Circumflex)

Figure 2. Anatomy in relation to the ECG.

II. HEMODYNAMIC MANAGEMENT AND THE HEART

A. Hemodynamic Assessment Relies on the Clinician's Clinical Interpretation to:
   1. Understand cardiovascular circulation (Figure 3) and pathophysiology contributing to the hemodynamic parameters in isolation and in the context of other hemodynamic parameters
   2. Account for trends in the values in light of end-organ function and surrogates of oxygen delivery, and use VO_2 mismatch
   3. Understand the roles of hemodynamic tools, limitations in use, and interpretation of the devices/technology.
   4. Identify appropriate therapeutic targets (Figure 4), and apply the pharmacologic/pharmacodynamic principles (Table 1) to initiate, modify, or discontinue therapy depending on clinical response

B. Advantages and Disadvantages of Invasive Hemodynamic Monitoring for Assessing Cardiac Output and/or Volume Status
   1. Hemodynamic monitoring techniques facilitate diagnosis, but they should not be mistaken for therapeutic interventions.
   2. Very little evidence has shown improved outcomes with advanced hemodynamic monitoring of any type, likely because patient management is dependent on clinician interpretation and reaction.
   3. Diligent use and skilled interpretation of these technologies, together with patient assessment, can be used to guide therapeutic interventions.
   4. See comparisons of invasive and minimally invasive hemodynamic monitoring devices (see table 2 in the Shock and Resuscitation chapter).

C. Pharmacologic Support in Cardiovascular Critical Illness (see Table 1 and "Shock Syndromes" for hemodynamic basic principles)

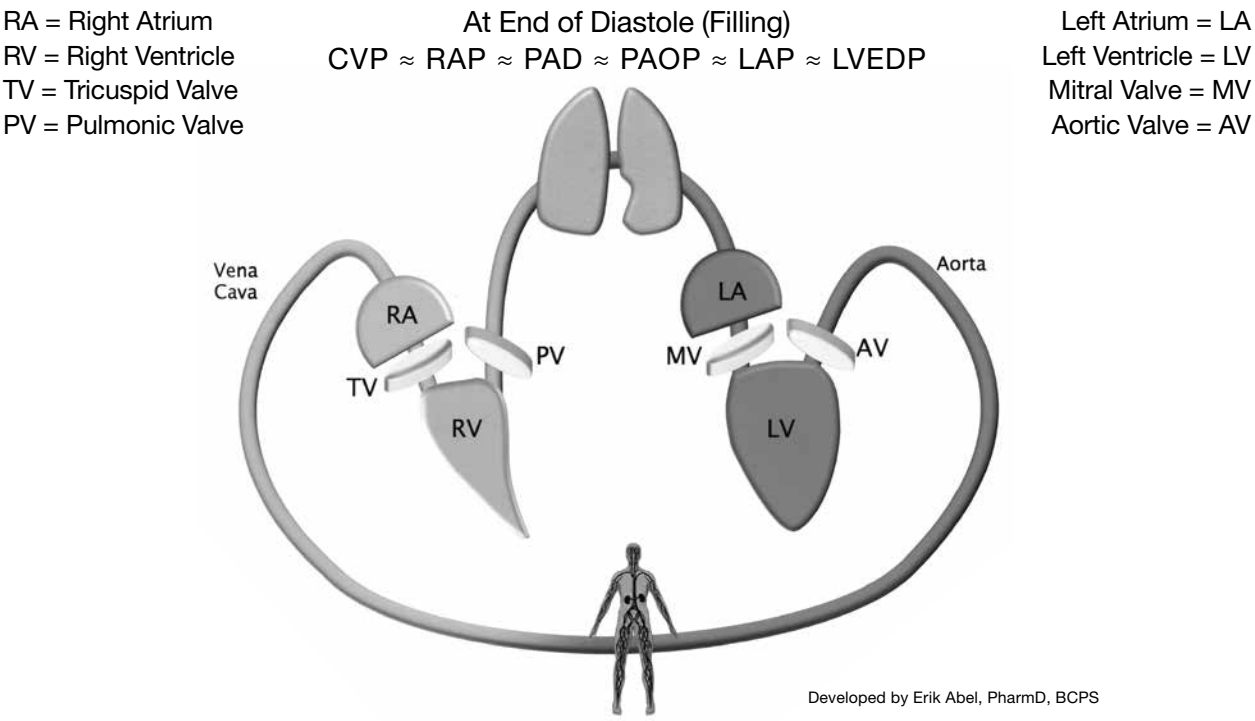

Figure 3. Cardiovascular systemic circulation.

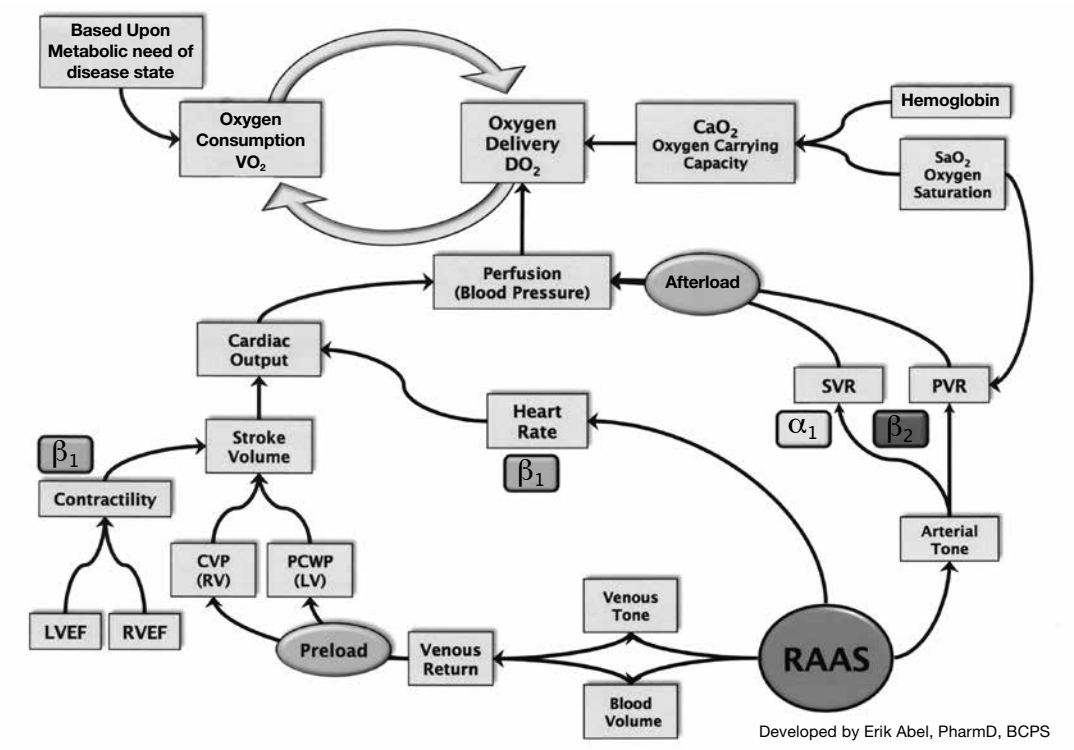

Figure 4. Integrated model of the hemodynamic parameters and therapeutic targets.

Table 1. Pharmacologic Support in Cardiovascular Critical Illness (Br J Pharmacol 2012;165:2015-33; J Am Coll Cardiol 2014;63:2069-78; 2011;xiv, 461 p.; Circulation 2008;118:1047-56; 2014;xix, 1490 p.; J Pharm Pract 2011;24:44-60)

Vasopressors	Dopa	α_1	β_1	β_2	Other Mechanism	HR	CVP	CO	SVR	PVR
Dopamine[a]	+++++	+++	++++	++		↑	↔	↑	↔ or ↑	↔ or ↑
Epinephrine[a]		++++	++++	+++		↑	↔	↑	↑	↑
Norepinephrine[a]		+++++	+++	++		↑	↔	↑	↑	↑
Phenylephrine		+++++				↔ or ↓	↔	↑	↑	↑
Vasopressin	N/A				V_1 and V_2 agonism	↔ or ↓	↔	↔ or ↓	↑	↔ or ↓
Inotropes										
Dobutamine		+	++++	++		↑	↔	↑	↔ or ↓	↔ or ↓
Isoproterenol			+++++	+++++		↑	↔	↑	↔ or ↓	↔ or ↓
Milrinone[b]	N/A				PDE_3 inhibition	↔ or ↑	↔	↑	↓	↓
Vasodilators										
Nitroglycerin					cGMP	↔ or ↑	↔ or ↓	↔ or ↑	↔ or ↓	↔ or ↓
Nitroprusside					cGMP	↔ or ↑	↔ or ↓	↔ or ↑	↔ or ↓	↓
Nesiritide					cAMP	↔ or ↑	↔ or ↓	↔ or ↑	↓	↓
Nitric oxide (inhaled)					cGMP	NA	↔	↔ or ↑	↔	↓
Epoprostenol (inhaled)					cAMP	N/A	↔	↔ or ↑	↔	↓

[a]High doses associated with increasing α1 activity.

[b]Normal half-life is 2.5 hours but is eliminated renally. Loading dose rarely used in routine management.

CVP = central venous pressure; cAMP = cyclic adenosine monophosphate; cGMP = cyclic guanosine monophosphate; N/A = not applicable; PDE3 = phosphodiesterase type 3; PVR = pulmonary vascular resistance; SVR = systemic vascular resistance.

III. CARDIOGENIC SHOCK

A. Characterized by Three Hallmark Attributes:
   1. Sustained hypotension unresponsive to fluid administration alone (SBP less than 90 mm Hg for at least 60 minutes)
   2. Evidence of myocardial dysfunction with reduced cardiac index (less than 2.2 L/minute/m^2)
   3. Signs and symptoms of malperfusion in the setting of elevated cardiac filling pressures (e.g., pulmonary capillary wedge pressure [PCWP] greater than 18 mm Hg)

B. Signs and Symptoms: See Heart Failure section.

C. Epidemiology: Without appropriate diagnosis and management, in-hospital mortality rates as high as 60% have been described Semin Respir Crit Care Med 2011;32:598-606.

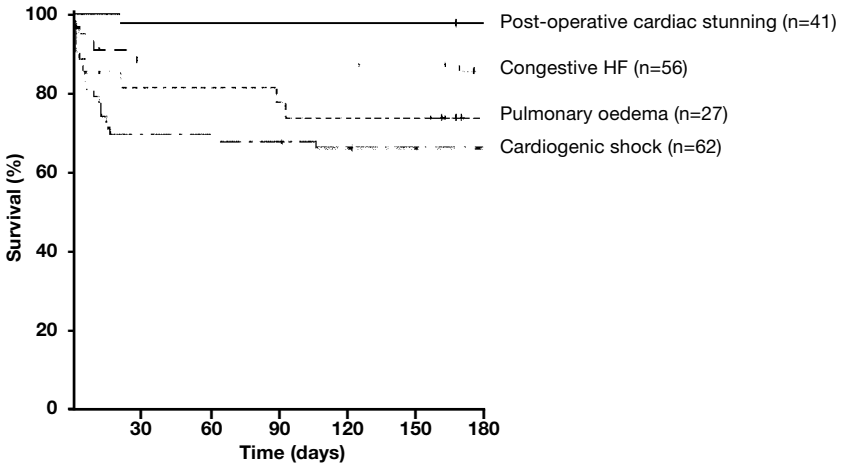

Figure 5. Survival rates of ICU patients over time presenting with different acute heart failure syndromes (Crit Care 2010;14:201).

D. Etiology
   1. Usually caused by left ventricular (LV) failure secondary to an acute MI, but a list of other potential causes can be found in Box 1
   2. May be multifactorial, including one or more of the causative etiologies; however, can also coexist with other types of shock syndromes

Box 1. Potential Causes of Cardiogenic Shock (2014;xix, 1490 p.; Semin Respir Crit Care Med 2011;32:598-606; Cardiol Clin 2013;31:567-80, viii; Cardiol Clin 2013;31:519-31, vii-viii)

Left Ventricular Failure
- Large MI
- Small MI with preexisting systolic heart failure
- Reinfarction
- Septic shock with severe myocardial depression

RV Failure
- RV infarction
- End-stage pulmonary hypertension

Acute Mechanical Dysfunction
- Papillary muscle rupture or chordal rupture with subsequent severe mitral regurgitation
- Free-wall rupture
- Ventricular septal rupture
- Cardiac tamponade

Cardiomyopathy
- End-stage heart failure
- Myocarditis
- Peripartum cardiomyopathy
- Left ventricular outflow tract obstruction
- Stress-induced cardiomyopathy (i.e., takotsubo)

Box 1. Potential Causes of Cardiogenic Shock *(continued)*

Valvular Disease
- Acute aortic regurgitation
- Ischemic mitral regurgitation
- Aortic or mitral stenosis with tachyarrhythmia or other condition causing decompensation
- Infectious endocarditis
- Prosthetic valve dysfunction or thrombosis

Arrhythmia

Other Conditions
- Prolonged cardiopulmonary bypass and/or coronary air embolus
- Cardiac trauma (blunt or penetrating)
- Heart transplant rejection
- Pulmonary embolism
- Medical nonadherence

E. Resuscitation/Treatment
   1. Treatment largely depends on managing underlying chronic or acute cardiovascular disease(s) outlined in Box 1, with consideration given to chronicity of clinical changes before onset of shock.
   2. Means of management will be primarily discussed under the Major Contributing Etiologies heading in sections III–VI.
   3. Hemodynamic management and pharmacotherapeutic considerations
      a. Because cardiogenic shock may have different underlying, contributing etiologies, hemodynamic management requires careful interpretation of clinical values. Treatment strategies could be devised according to the algorithm in Figure 6.
      b. Sepsis Occurrence in Acutely Ill Patients (SOAP) II landmark trial (N Engl J Med 2010;362:779-89)
         i. International multicenter trial (n=1679) that compared the 28-day mortality of norepinephrine with that of dopamine in the management of shock
            (a) Included if signs of malperfusion and MAP less than 70 mm Hg or SBP less than 100 mm Hg, despite adequate fluid challenge (at least 1000 mL of crystalloids or 500 mL of colloids unless the CVP was greater than 12 mm Hg or the pulmonary artery occlusion pressure was greater than 14)
            (b) Allowed titration to maximums of norepinephrine 0.19 mcg/kg/minute versus dopamine 20 mcg/kg/minute, after which open-label norepinephrine was allowed (open-label norepinephrine doses did not exceed 1.1 mcg/kg/minute during the study period)
            (c) Epinephrine and vasopressin were permitted as rescue agents (similar use in both groups).
            (d) Dobutamine use was greater in the norepinephrine group (19.4% vs. 14.8%).
         ii. Showed that dopamine was associated with a significantly higher mortality rate than was norepinephrine with or without dobutamine in patients with cardiogenic shock in subgroup analysis
         iii. Specifically, dopamine was associated with more adverse events than norepinephrine in the management of all shock subtypes, predominantly driven by the incidence of arrhythmias (24.1% vs. 12.1%, $p<0.001$). Tachyarrhythmias with dopamine had the greatest incidence within the first 36 hours after randomization.

Figure 6. Shock management and treatment considerations based on hemodynamic indices.

Patient Cases

Questions 1–6 and Question 8 pertain to the following case.

J.M. is a 58-year-old man with a history of CAD, type 2 diabetes mellitus, hyperlipidemia, gastroesophageal reflux disease, hypertension, obstructive sleep apnea, and ischemic cardiomyopathy after a STEMI 2 years ago left him with two drug-eluting stents in his proximal and mid-left anterior descending artery. Records indicate an LVEF of 30–35% and moderate mitral regurgitation from 6 months ago. He is admitted to the cardiac care unit for severe shortness of breath and altered mental status, where he is currently on CPAP (continuous positive airway pressure). He has gained 13 kg during the past 2 weeks (now weighs 121 kg) and has had decreased urine output, despite having had his diuretic dose increased. Home medications include the following: aspirin 81 mg once daily, ticagrelor 90 mg every 12 hours, pantoprazole 40 mg once daily, metoprolol tartrate 25 mg every 12 hours, atorvastatin 40 mg once daily, insulin glargine 10 units every night, metformin 500 every 12 hours, furosemide 40 mg twice daily, and potassium chloride 20 mEq twice daily. His wife states that he was taking clopidogrel until 1 month ago but could not afford it, so his primary care physician provided ticagrelor samples. A physical examination reveals rales throughout his lung fields. He is afebrile, anxious, and alert.

1. Given J.M.'s comorbidities, some drugs or drug classes have proven mortality benefits. Which group of added or modified medications, not on the patient's home medication profile, might best have helped slow the progression of his disease and confer mortality benefits?
   A. Amlodipine, clopidogrel, and sitagliptin.
   B. Spironolactone, lisinopril, and carvedilol.
   C. Pravastatin, amlodipine, and aspirin 325 mg.
   D. Prasugrel, sildenafil, and atenolol.

Patient Cases *(continued)*

2. Given the patient's presentation, which group of diagnostic tests would be most helpful to guide your recommendations to the team for J.M.'s current management? (Assume that a basic metabolic panel [Chem 7], a pulse oximetry, and a capillary blood glucose have already been completed.)

   A. Urine culture, respiratory culture, lactate and procalcitonin.
   B. Chest radiography, arterial blood gas (ABG), liver function tests, and serial troponins.
   C. Chest radiography, echocardiogram (ECHO), lactate, and BNP.
   D. Chest radiography, arterial line, ABG, and lactate.

3. All tests mentioned above have been ordered, and the following results are available. J.M.'s BP is 110/76 (MAP 87) mm Hg and HR is 56 beats/minute.

   - Chest radiography reveals diffuse patchy opacities; however, infiltrate cannot be ruled out; lines are all in appropriate positions.
   - Serum chemistry panel results are as follows: sodium 126 mEq/L, potassium 4.8 mEq/L, chloride 102 mEq/L, carbon dioxide 21 mEq/L, BUN 32 mg/dL, SCr 1.6 mg/dL, and glucose 134 mg/dL.
   - Results of the CBC are as follows: WBC 9.8 × 10^3 cells/mm^3, hemoglobin 11.1 g/dL, hematocrit 32.6%, and platelet count 173,000/mm^3.
   - Additional laboratory values include the following: troponin 0.9 ng/mL, AST 114 IU/L, ALT 102 IU/L, and BNP 1936 pg/mL.
   - Invasive hemodynamic parameters include CVP 28 mm Hg, pulmonary artery pressures 46/22 mm Hg, cardiac index 1.8 L/minute/m^2, and central venous oxygen saturation ($ScvO_2$) 53%; pulmonary artery occlusion pressure is not yet available.
   - ABG results are as follows: pH 7.36, P_{O_2} 93.7, P_{CO_2} 43.2, bicarbonate 23.9, O_2 saturation 89%, and lactate 6.9.
   - ECHO results are pending.

   The patient's physical examination reveals that his extremities are cold to the touch, and capillary refill is poor. The team has ordered furosemide 80 mg intravenously once and discontinued metoprolol; the team would like to initiate a vasopressor or inotrope for this patient. Which would be best to recommend at this time?

   A. Norepinephrine 0.08 mcg/kg/minute.
   B. Epinephrine 0.08 mcg/kg/minute.
   C. Milrinone 0.25 mcg/kg/minute.
   D. Dobutamine 5 mcg/kg/minute.

IV. ACUTE CORONARY SYNDROMES

A. Pathophysiology
   1. Manifestation of prolonged cessation of oxygenated blood supply to a portion of the myocardium that is most commonly caused by an acute thrombus at the site of coronary atherosclerotic stenosis leading to local or regional myocardial ischemia and necrosis
   2. Other disease states leading to an elevated myocardial oxygen demand with a concurrent inability to meet such demands may result in a scenario where "demand ischemia" is considered versus a diagnosis of ACS.

B. Presentation and Diagnosis (Circulation 2013;127:e362-425; Circulation 2014;130:e344-426) – Although other cardiac enzymes assays are available for clinical use, cardiac troponins are usually used as sensitive markers indicative of myocardial necrosis. Troponin is eliminated renally.

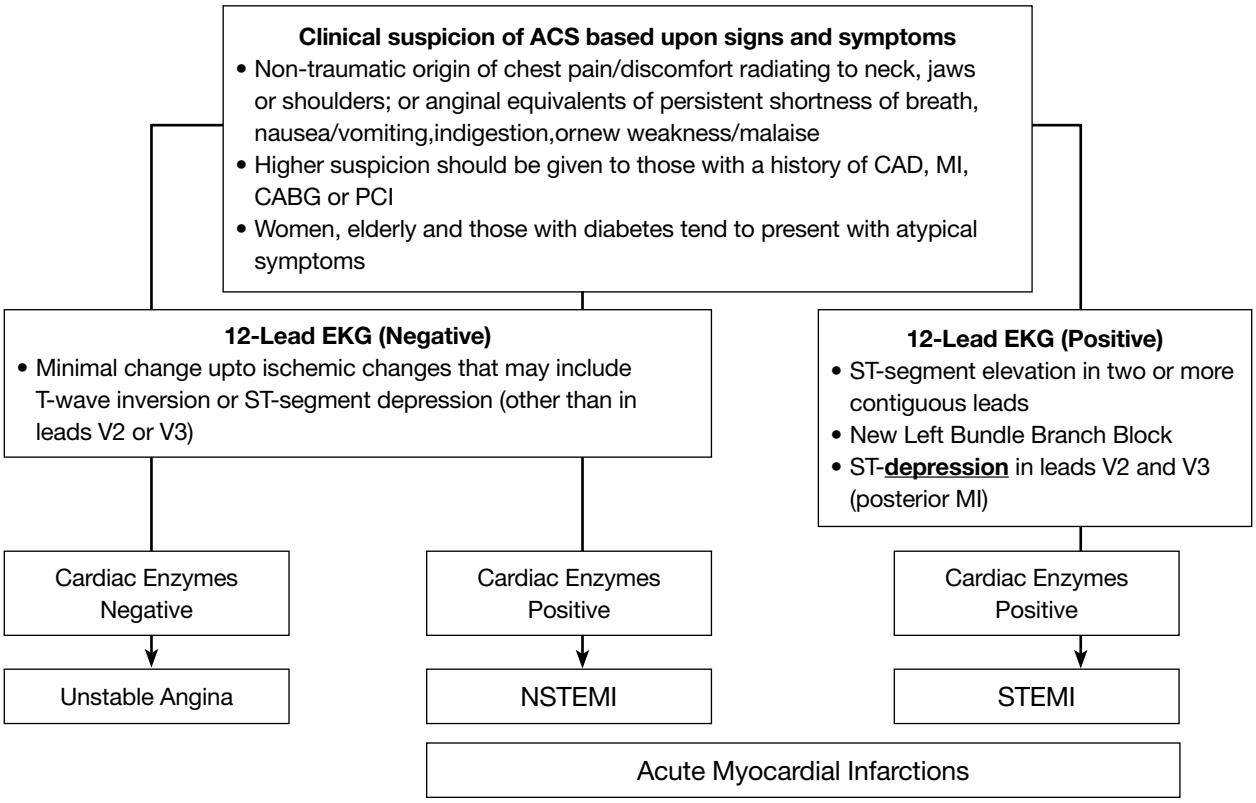

Figure 7. Presentation and diagnosis.

Box 2. Causes of Troponin Elevation (Heart 2006;92:987-93)

Acute MI	Chronic heart failure
Post-PCI	Acute decompensated heart failure
Early post-cardiac surgery	Chest wall trauma
Acute pulmonary embolism	Severe strenuous exercise
Rhabdomyolysis	Cardiotoxic chemotherapy
Tachyarrhythmia	Direct current cardioversion/defibrillation
Aortic stenosis	Cardiac amyloidosis
Pericarditis	Heart transplantation
Myocarditis	Sepsis
Type A dissection	

PCI = percutaneous coronary intervention.

C. Acute Management of MI

Table 2. Acute Management (Circulation 2013;127:e362-425; Circulation 2014;130:e344-426)

MI Type	STEMI	NSTEMI
Goals of care	Reperfusion therapy as soon as possible • Primary PCI preferred if it can be performed within 90 min of medical contact • If primary PCI is unavailable within 90 min of medical contact, thrombolytics should be administered within 30 min of presentation unless contraindications exist • Surgical revascularization may be indicated, depending on severity of CAD, complexity of anatomy, or development of other complications	Prevent total occlusion of the vessel • Decision and need for revascularization (PCI or surgery) vs. medical management should be made on the basis of risk stratification, symptom resolution, and indicators of ongoing myocardial damage/ischemia

PCI = percutaneous coronary intervention.

Table 3. Predominant Interventions on Presentation/Onset for Stabilization – Any ACS (Circulation 2013;127:e362-425; Circulation 2014;130:e344-426)

Predominant interventions on presentation/onset for stabilization – Any ACS	
Oxygen	• Can help facilitate anginal pain secondary to tissue hypoxia • Supplemental oxygen considered if Sa_{O_2} less than 90%, respiratory distress, or other high-risk features for hypoxemia
Aspirin	• Inhibit platelet activation • Four aspirin 81 mg each (324 mg total) or one 325-mg tablet (non–enteric coated) should be chewed and swallowed immediately
Nitrates	• Can facilitate coronary vasodilation and may also be helpful in scenarios of severe cardiogenic pulmonary edema caused by increased venous capacitance • Nitroglycerin (NTG) 0.4 mg sublingually every minute for total of THREE doses; afterward, assess need for IV NTG • Intravenous NTG is indicated in the first 48 hours after treatment of persistent ischemia, HF, or hypertension but should not preclude therapy such as β-blockers or ACE inhibitors when indicated • **Should NOT be administered:** o If SBP < 90 mm Hg OR if SBP is ≤ 30 mm Hg below baseline o If severe bradycardia (including heart block) with HR ≤ 50 beats/minute o If tachycardia (HR ≥ 100 beats/minute) in the absence of symptomatic HF, or RV infarction o If patient has received an oral phosphodiesterase inhibitor within the past 24–48 hours
Morphine or other narcotic analgesic	• Provides analgesia and decreases pain-induced sympathetic/adrenergic tone • Morphine commonly used because it may also induce vasodilation and mediate some degree of afterload reduction • Morphine now carries a class IIbB recommendation and may be not be favored over other narcotic analgesics, given that at least two large trials have identified an association between morphine administration and risk of death (N Engl J Med 2014;371:1016-27; Am Heart J 2005;149:1043-9)

Table 3. Predominant Interventions on Presentation/Onset for Stabilization – Any ACS *(continued)*

Predominant interventions on presentation/onset for stabilization – Any ACS		
β-Blockade	• Decreases HR and myocardial oxygen demand and increases diastolic filling time of ventricles and thereby the coronary arteries • **β-Blockade should be initiated within the first 24 hr of an ACS <u>unless</u>:** o There are signs of HF o Active evidence of other shock states o If at increased risk of cardiogenic shock (SBP < 120 mm Hg), HR > 110 beats/minute or < 60 beats/minute • ***Relative contraindications* to β-blockade include:** o PR interval greater than 0.24 s, second- or third-degree heart block, and active asthma/reactive airway disease	
Loop diuretic	• May be warranted if patient is develops severe cardiogenic pulmonary edema or other concurrent symptoms of HF with volume overload	
Helpful acronyms	MONA ± BB • Morphine • Oxygen • Nitrates (unless contraindicated) • Aspirin • β-Blocker (unless contraindicated)	LMNOP + aspirin (in reverse) • Aspirin • Positioning (resting upright + ECG) • Oxygen • Nitrates (unless contraindicated) • Morphine • Loop diuretic
Other precautions	• ACE inhibitors/ARBs should be used with caution within the first 24 hours of ACS because of the risk of hypotension and potential contribution to contrast-induced nephrotoxicity • Any NSAID other than aspirin should be avoided and/or discontinued for reasons other than GI bleeding and nephrotoxicity, which may include reinfarction, hypertension, HF exacerbation, myocardial rupture, and overall increased risk of mortality associated with their use	

GI = gastrointestinal; HF = heart failure; LMNOP = lasix-morphine-nitro-oxygen-position/positive pressure ventilation; NSAID = nonsteroidal anti-inflammatory drug.

D. Revascularization
   1. Nonsurgical – Details of interventional cardiology procedures are too broad to be discussed in great detail in this chapter; however, following are some considerations of the intervention that may play a role in postprocedural management during a left heart catheterization and percutaneous coronary intervention (PCI):
      a. Access site
         i. Radial artery (and rarely, brachial artery) (Catheter Cardiovasc Interv 2011;78:840-6)
            (a) Easily accessible
            (b) Increased risk of vasospasm during procedure
            (c) Easily compressible vessel when hemostasis is needed postprocedure
            (d) Does not prevent patient mobility postprocedure
         ii. Femoral artery
            (a) Easily accessible
            (b) More difficult to compress vessel when hemostasis is needed postprocedure and also associated with increased bleeding complications
            (c) Limits patient mobility postprocedure for at least 12–24 hours (bleeding risk after sheath removal)

b. Common interventions performed:
    i. Thrombectomy: Thrombus aspiration generally followed by placement of a stent at site of lesion
    ii. POBA (plain old balloon angioplasty): Balloon expansion and at least temporary displacement of occlusion at site of lesion
    iii. Stent placement
        (a) Important to note the number of stents placed, the types of stents, and the locations of placement
        (b) Bare metal stent
            (1) Requires aspirin for life and a P2Y12 antagonist for at least 1 month (12 months preferred) to allow adequate time for endothelialization of the stent(s)
            (2) Longer therapy durations may be considered, depending on the number of stents and/or location(s) of the stent(s).
            (3) Higher risk of in-stent stenosis over time as reendothelialization occurs
        (c) Drug-eluting stent
            (1) Requires aspirin for life and a P2Y12 antagonist for at least 12 months. Longer therapy durations may be considered, depending on the number of stents and/or location(s) of the stent(s). Ongoing investigations are evaluating the optimal duration of dual antiplatelet therapy, but many questions are currently unanswered.
            (2) Associated with a higher risk of stent thrombosis; the rate of endothelialization over the stent is slowed by the drug coating on the stent, thus leaving metal exposed that can potentiate thrombus formation
    iv. Ventriculogram: Means of assessing the ejection fraction using a larger volume of intravenous contrast dye delivered directly into the ventricle to estimate the volume of blood ejected during systole

2. Surgical revascularization – Details of coronary artery bypass grafting (CABG) procedures, including conduit type and use of cardiopulmonary bypass (or performing off-pump), are too broad to be discussed in greater detail in this chapter. According to the STS/ACC/AHA CABG guidelines, emergency CABG is recommended in patients with an acute MI in the following scenarios: (J Am Coll Cardiol 2011;58:e123-210)
    a. Primary PCI has failed or cannot be performed
    b. Coronary anatomy is more suitable for CABG
    c. Persistent ischemia of a significant area of myocardium at rest and/or hemodynamic instability refractory to nonsurgical therapy is present
    d. Requirement of surgical repair of a postinfarction mechanical complication of MI (i.e., ventricular septal rupture, mitral valve insufficiency caused by papillary muscle infarction and/or rupture, or free wall rupture)
    e. Patients with cardiogenic shock who are suitable for CABG, irrespective of the time interval from MI to onset of shock and time from MI to CABG
    f. Patients with life-threatening ischemic ventricular arrhythmias in the presence of a left main stenosis of 50% or more and/or three-vessel CAD
    g. CABG use is reasonable as a revascularization strategy in patients with multivessel CAD with recurrent angina or MI within the first 48 hours of STEMI presentation as an alternative to a more delayed strategy
    h. Early revascularization with PCI or CABG is reasonable for select patients older than 75 years with ST-segment elevation or left bundle branch block who are suitable for revascularization irrespective of the time interval from MI to onset of shock

3. Medical management – No revascularization:
    a. Less invasive strategies may be opted for rather than revascularization in some patients. Considerations reinforce a patient-centered approach driven by evidence of ongoing/recurrent ischemia and feasibility of revascularization, including myocardial viability, patient frailty, and comorbid disease states.
    b. Ongoing care outlined in section E remains the focus of optimizing aggressive medical management.

E. Antithrombotics in MI
1. The roles and combinations of antithrombotics continue to be refined in select populations (those with NSTEMI/ACS, STEMI, and PCI). For the most current guidelines and landmark trials, please see www.acc.org/guidelines.
2. Oral antiplatelet therapy
    a. Platelets can be activated by several different mechanisms, only some of which can be inhibited by medications.
    b. In the critically ill, our ability is currently limited to assess and interpret the adequacy of antiplatelet therapies. Clinical evidence with platelet function testing has not been well-studied with durable clinical endpoints such as cardiac events and/or mortality.
    c. Common clinical obstacles in the critically ill are without evidence-based solutions at this time; these include variability in drug response that could be owing to absorption and metabolism variability in patients with hepatic insufficiency. Furthermore, therapeutic alternatives are limited and without evidence when enteral administration is not an option.

Table 4. Oral Antiplatelet Therapy[a] (Circulation 2013;127:e362-425; Circulation 2014;130:e344-426; J Am Coll Cardiol 2011;58:e123-210; J Am Coll Cardiol 2011;58:e44-122; Br J Clin Pharmacol 2011;72:647-5)

Medication	Aspirin	Clopidogrel	Prasugrel	Ticagrelor
Role/mechanism of inhibition	Inhibits thromboxane A_2–mediated platelet activation and aggregation	Inhibits ADP-mediated platelet aggregation ($P2Y_{12}$ receptor) to prevent conformational change of GPIIb/IIIa receptor	Inhibits ADP-mediated platelet aggregation ($P2Y_{12}$ receptor) to prevent conformational change of GPIIb/IIIa receptor	Inhibits ADP-mediated platelet aggregation ($P2Y_{12}$ receptor) to prevent conformational change of GPIIb/IIIa receptor
Loading dose	324–325 mg	600 mg	60 mg	180 mg
Maintenance dose	81 mg	75 mg QD	10 mg QD	90 mg BID
Route	Oral	Oral	Oral	Oral
Prodrug	No	Yes	Yes	No
Reversible platelet binding	No	No	No	Yes
Onset	30 min	2 hours	30–60 min	30–60 min
% Platelet inhibition	~20	40	70	95
Recommended holding duration before CABGb	Do not hold	5 days	7 days	7 days
Other notable adverse effect(s) or clinical pearls		• Pharmacogenomic variance has been noted and may contribute to drug response	• Black box warning against use in patients with a history of stroke or TIA, and warning of use in patients > 75 years or weight < 60 kg	• Adenosine-induced bradycardia and dyspnea • Elderly patients and patients with moderate or severe hepatic impairment may be at increased risk of bleeding • Concomitant doses of ASA > 100 mg should be avoided

[a]Note: Ticlopidine is not widely used in therapy anymore or discussed in the most current ACS guidelines.

[b]Decisions to hold these agents before other invasive procedures must consider indications for use, risk of thrombosis (i.e., stent type, locations, and number), and risk of bleeding associated with intended procedure/surgery. (J Am Coll Cardiol 2011;58:e44-122; JAMA 2013;310:1451-2; Catheter Cardiovasc Interv 2013;82:1113-4; JAMA 2013;310:189-98; J Am Coll Cardiol 2007;49:734-9; N Engl J Med 2013;368:2113-24; Reg Anesth Pain Med 2010;35:64-101).

ADP = adenosine diphosphate; ASA = acetylsalicylic acid; BID = twice daily; GP = glycoprotein; QD = once daily; TIA = transient ischemic attack.

3. Parenteral antithrombotics
   a. Use of these agents is most intensive in the procedural setting, although may continue for a finite period postprocedurally
   b. The selection and use among the agents in Table 5 may depend on presentation, timing/dose of preprocedural antiplatelet medication administration, clot burden during procedure, and estimated bleeding risk of the procedure.

Table 5. Parenteral Antithrombotics (Circulation 2013;127:e362-425; Circulation 2014;130:e344-426; J Am Coll Cardiol 2011;58:e123-210; J Am Coll Cardiol 2011;58:e44-122; Br J Clin Pharmacol 2011;72:647-57)

Medication	Heparin (UFH)[a]	Bivalirudin	Abciximab	Eptifibatide	Tirofiban
Role in therapy	Indirect thrombin inhibition mediates decreased propagation of clot	Direct thrombin inhibitor – mediates decreased propagation of clot	Binds to GPIIb/IIIa platelet receptor, preventing platelet binding to fibrinogen	Binds to GPIIb/IIIa platelet receptor, preventing platelet binding to fibrinogen	Binds to GPIIb/IIIa platelet receptor, preventing platelet binding to fibrinogen
Loading dose	50–100 units/kg bolus	0.75 mg/kg	0.25 mcg/kg	180 mg/kg	25 mcg/kg
Continuous infusion	Variable (if used)	1.75 mg/kg/hr	0.125 mcg/kg/min (max 10 mcg/min)	2 mcg/kg/min	0.15 mcg/kg/min
Platelet inhibition	N/A	N/A	Irreversibly inhibits for the life of the platelet (7–10 days)	Restoration of platelet function within 6–8 hours of discontinuation	Restoration of platelet function within 6–8 hours of discontinuation
Elimination	• Hepatic and reticulo-endothelial system	• 80% plasma proteolysis • 20% renal	• Plasma elimination	• 50%–71.4% renal	• Renal
Removed by dialysis	No	Yes	No	Yes	Yes
Other notable adverse effect(s) or clinical pearls	• Cannot be used in patients with a history/suspicion of heparin – induced thrombocytopenia (HIT) • Target activated clotting time (ACT) or 200–250 s during procedure	• Requires renal dose adjustment • Can be used in patients with or without a history or suggestion of HIT • May be preferred in patients with higher bleeding risk • Target ACT or 200–250 s during procedure	• Murine monoclonal antibody – may produce antigenicity	• Requires renal dose adjustment	• Requires renal dose adjustment

[a]Enoxaparin may be used rather than UFH.

HIT = heparin-induced thrombocytopenia; UFH = unfractionated heparin.

- o If age younger than 75 years: 30 mg intravenous push within 15 minutes, followed by 1 mg/kg subcutaneously, followed by every 12 hours (max 100 mg for the first two doses)
- o If 75 years or older: 0.75 mg/kg subcutaneously every 12 hours (max 75 mg for the first two doses)

F. Postintervention Complications
   1. Bleeding (particularly retroperitoneal bleeding)
      a. Several antithrombotic agents are used during PCI to inhibit both the platelets and the clotting cascade, causing potential coagulopathies.
      b. In addition to antithrombotic use, the catheterization access site (radial vs. femoral) has been identified as a major contributor to post-PCI bleeding complications.
   2. Dissection/rupture of free wall, coronary artery, or aorta: Although this may be spontaneous, it may also be caused by vessel trauma from the catheter itself.
   3. Stent thrombosis
      a. When antiplatelet therapy is discontinued early (aspirin, P2Y12, or both), stent thrombosis may occur in up to 25% of coronary artery stents, irrespective of type of stent (drug-eluting stent or bare metal stent).
      b. Almost 1 in 7 patients may discontinue $P2Y_{12}$ inhibitors within 30 days post-PCI, thus increasing mortality risk (adjusted hazard ratio 9.0; 95% CI, 1.3–60.6). (JAMA 2013;310:189-98)
      c. Mortality rates associated with stent thrombosis can be as high as 45%.
      d. Despite bleeding risks in critically ill patients, careful consideration should be given to correlating these risks with the risk of stent thrombosis.
   4. Papillary muscle rupture and mitral regurgitation
   5. Arrhythmias (particularly after reperfusion)
   6. Contrast-induced nephropathy

G. Ongoing Care – Quality measures for NSTEMI or STEMI independent of revascularization or medical management
   1. Medications that should be initiated before discharge or contraindications should be documented in the medical record.
      a. Aspirin
      b. Statin
      c. $P2Y_{12}$ inhibitor
      d. β-Blocker
      e. If LVEF is less than 40%, ACE inhibitor or ARB and spironolactone
   2. Interventions and/or referrals
      a. LV function assessment (by imaging or during catheterization)
      b. Cardiac rehabilitation
      c. Smoking cessation counseling
      d. Measurement of a lipid profile, including the LDL (low-density lipoprotein) cholesterol, should preferably be obtained within 24 hours of admission. Any lipid profile measured between 6 months before first medical contact and hospital discharge qualifies for this quality measure.
   3. For more information on cardiology-related quality measures and registries, see https://www.ncdr.com/.

Patient Case *(see p. 1-190 for case information)*

4. J.M.'s ECG results reveal no notable evidence of ST-segment changes. The resident is still considering a diagnosis of an ACS, given the patient's shortness of breath and troponin elevation. Which would be most accurate regarding whether any other potential explanations exist for these diagnostic criteria?
   A. No, this is most likely an NSTEMI.
   B. Yes, it is likely undiagnosed chronic obstructive pulmonary disease.
   C. Yes, it is likely early sepsis.
   D. Yes, it is likely decompensated heart failure.

5. J.M. has been experiencing intermittent HR pauses on telemetry. The team has consulted the cardiac electrophysiology team. In the meantime, which statement most accurately reflects whether any other underlying correctable/contributing causes can be addressed?
   A. Ticagrelor should be discontinued, and J.M. should be switched to clopidogrel.
   B. Ticagrelor should be discontinued; only aspirin is needed for J.M.'s CAD at this time.
   C. There are no other identifiable causes, and this is likely a reflection of J.M.'s heart failure disease progression.
   D. J.M.'s hyperkalemia should be treated.

V. ARRHYTHMIAS AND ANTIARRHYTHMICS

A. Pathophysiology: Arrhythmias are generally caused by impulse formation and/or conduction abnormalities.

B. Bradyarrhythmias and Types of Heart Block (beyond sinus) (2011;xiv, 461 p.; 2014;xix, 1490 p.; BMJ 2002;324:662-5; BMJ 2002;324:415-8)
   1. Etiologies of heart block

Box 3. Causes of Bradycardias

- Drug toxicity
- CAD
- Degenerative conduction disease
- Surgery (particularly cardiac surgery)
- Endocarditis
- Electrolyte disturbances (particularly hyperkalemia)
- Vagal nerve mediated heart block
- Tumors
- Myocarditis

   2. When evaluating ECGs in the presence of heart block, QRS complex evaluation can guide some differential diagnoses to the source of conduction problems (see Table 6).
      a. Narrow QRS complexes commonly indicate AV nodal dysfunction.
      b. Wide QRS complexes may indicate dysfunction in either the AV node or the His-Purkinje system.

Table 6. Bradyarrhythmias and Types of Heart Block (2011;xiv, 461 p.; 2014;xix, 1490 p.; BMJ 2002;324:662-5; BMJ 2002;324:415-8)

Type	ECG Example	Description
First degree		• Delayed conduction from the sinoatrial (SA) node to the atrioventricular (AV) node characterized by a P-R interval > 0.2 s • Relatively benign, however underlying contributors should be evaluated and minimized (i.e., β-blockers and other agents)
Second-degree Mobitz type 1 (Wenckebach)		• Consistent P-P interval with progressive prolongation of the P-R (indicating impaired SA to AV node conduction) eventually resulting in absence of a QRS complex because of the lack of AV node conduction of atrial impulse • Of most concern in elderly patients where this may be indicative of progressive conduction disease; may be more benign in younger patients • "Longer, longer, longer, drop....must be Wenckebach"
Second-degree Mobitz type 2	 (in a post-ACS setting)	• Consistent P-P interval and consistent P-R interval duration with spontaneous absence of a QRS complex because of the lack of AV node conduction of atrial impulse • Usually indicative of more significant conduction disease and be associated with syncope, heart failure, and increased mortality rates
Third degree		• Characterized by consistent P-P intervals, R-R intervals, and variable/random P-R interval representing independent, uncoordinated atrial and ventricular conduction
Junctional rhythm		• Manifested when sinus node dysfunction allows the AV node to take over as the active cardiac pacemaker resulting in retrograde conduction through the atria

3. Management of bradyarrhythmias includes three principal strategies (see also Figure 5). Stabilize the patient, if symptomatic.
   a. Consider atropine for temporary correction to decrease vagal tone.
   b. Consider pacing strategies (temporary transvenous pacer, transcutaneous pacer, pacing pulmonary artery catheter). Interrogate permanent pacemaker for malfunction/optimization.
   c. Consider chronotropic β-agonist infusion.
      i. Isoproterenol
      ii. Dobutamine
      iii. Epinephrine
      iv. Dopamine
   d. Identify and treat underlying causes/toxidromes.

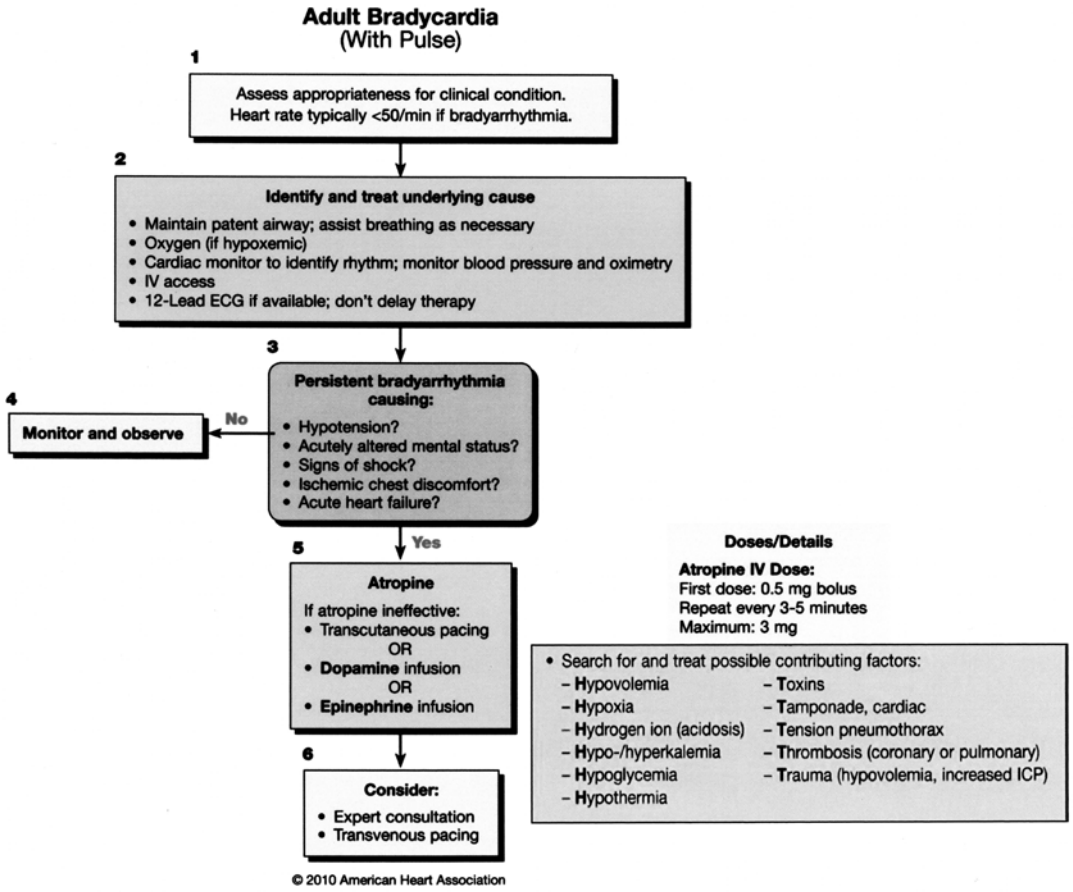

Figure 8. Advanced cardiac life support bradycardia algorithm. (Circulation 2010;122:S729-6)

C. Tachyarrhythmias (beyond sinus) – Etiologies and hemodynamic consequences
   1. Etiologies of tachyarrhythmias
      a. Usually related to enhanced automaticity, reentry, or triggered activity
      b. A history that includes ischemic heart disease or congestive cardiac failure is 90% predictive of VT.
   2. In evaluating ECGs for tachyarrhythmias, some fundamental considerations include:
      a. Evaluate for the presence of P waves.
      b. Evaluate the width of the QRS complex.

Table 7. Tachyarrhythmias (beyond sinus)[a] (Circulation 2014;130:2071-104; BMJ 2002;324:594-7; BMJ 2002;324:776-9; BMJ 2002;324:1264-7; BMJ 2002;324:1201-4; Circulation 2012;125:381-9; Heart Fail Rev 2014;19:285-93)

Supraventricular Tachyarrhythmias				
Type	**Rhythm**	**P-wave Attributes**	**Atrial Rate (bpm)**	**Description**
Premature atrial contractions (PACs)	Irregular	N/A	N/A	• Generally benign but may be more evident with increased sympathetic tone, stress, and pericarditis or with sympathomimetic use • In some cases, can lead to an AV block or initiate an reentrant SVT or AF
Supraventricular tachycardia (SVT)	Regular	Hidden or can be retrograde	140–250	• Usually sudden onset/offset with narrow QRS complexes • Often caused by reentry within the atrium or AV node, or by means of an accessory conduction pathway • Can be subcategorized as: o AV nodal reentrant tachycardia (AVNRT) o AV reentrant tachycardia (AVRT) o Sinus node reentry tachycardia
Atrial flutter (AFl)	Regular	Saw-tooth appearance	180–350	• Generally conducts through the ventricles in a 2:1 fashion, resulting in ventricular rates of 100–150 beats/min • In some scenarios, slowing the atrial rate may increase the number of conducted beats leading to rapid ventricular rates and potential hemodynamic compromise • Associated with increased risk of stroke
Atrial fibrillation (AF)	Irregular	No distinct P wave visible	Unable to determine	• Most common arrhythmia, characterized by irregular ECG appearance because of multiple reentry circuits and ectopic foci • Often associated with structural heart disease and potentiated by increase left atrial pressures among other influencing contributors such as age, inflammation, and sympathetic tone • Associated with increased risk of stroke
Multifocal atrial tachycardias (MATs)	Irregular	> 3 different types of distinct P waves	100–130	• Can be misdiagnosed as AF • Commonly associated with respiratory disease, heart failure, critical illness • May be exacerbated by electrolyte abnormalities or toxicity with digoxin or theophylline

Table 7. Tachyarrhythmias (beyond sinus)[a] *(continued)*

Ventricular Arrhythmias	
Type	**Description**
Premature ventricular contractions (PVCs)	• Results from an ectopic ventricular focus conduction that can be identified by the lack of a preceding P wave. Commonly benign or asymptomatic, but may be of concern if present in patterns or in patients with advanced heart disease o Bigeminy: Every other beat is a PVC o Trigeminy: Every third beat is a PVC o Couplets: Patterns of two consecutive PVCs o Triplets: Patterns of two consecutive PVCs
Ventricular tachycardia (VT)	• Potentially lethal wide QRS complex tachycardia characterized according to morphology and duration. Can degenerate into VF or asystole o *Monomorphic VT:* When every QRS complex appears the same and the rate is regular (100–200 beats/min). Commonly caused by reentry circuit related to myocardial scar or fibrosis o Polymorphic: When the QRS complexes continually vary in shape and rate. May be related to multiple ectopic foci, myocardial ischemia, or torsades de pointes o *Non-sustained VT:* Self-terminating episodes lasting for < 30 s o *Sustained VT:* If VT persists for more than 30 s, produces severe symptoms, including syncope, or requires termination by administration of an antiarrhythmic drug or direct cardioversion/defibrillation
Ventricular fibrillation (VF)	• Life-threatening arrhythmia with a chaotic ECG with no discernible QRS, representing rapid disorganized conduction with no resultant coordinated ventricular contractions

[a]Other arrhythmias beyond the scope of this review include sick sinus syndrome (tachy-brady syndrome) and Wolfe-Parkinson-White.

3. Management of tachyarrhythmias with a pulse includes the following strategies:
   a. Stabilization of patient: See Figure 6 and Cardiovascular Emergencies chapter.
   b. Long-term control strategies
      i. Atrial tachyarrhythmias
         (a) HR control typically with class II agents, class IV agents, and/or digoxin (see Table 8)
         (b) Heart rhythm control
            (1) Catheter-based ablation
            (2) Surgical ablation
            (3) Antiarrhythmic therapy typically with class IC or class III agents (see Table 8)
      ii. Ventricular tachyarrhythmias
         (a) Catheter ablation
         (b) Antiarrhythmic therapy
         (c) Evaluation for implantable cardioverter-defibrillator.
   c. Overall considerations for antiarrhythmics (see Table 8) (Circulation 2014;130:2071-104; BMJ 2002;324:594-7; BMJ 2002;324:776-9; BMJ 2002;324:1264-7; BMJ 2002;324:1201-4; Circulation 2012;125:381-9; Heart Fail Rev 2014;19:285-93)
      i. Abrupt discontinuation of chronic antiarrhythmics (i.e., chronic medication before ICU admission) should be done with caution and awareness of antiarrhythmic indication as well as risks-benefits of continuation/cessation.

ii. Appropriate monitoring and potential adjustment may be warranted with many of these agents in the critically ill patient.
   (a) QT/QTc prolongation increases the risk of torsades de pointes. This risk can be influenced not only by the absolute duration of the QT/QTC, but also by the rate at which the QT/QTc is changed (i.e., faster change may also increase risk).
   (b) The class III antiarrhythmics sotalol and dofetilide can be used for both atrial and ventricular tachyarrhythmias and, because of some notable characteristics, should be watched closely when used in the critically ill.
      (1) Both are renally eliminated.
      (2) Both have notable interactions with several other medications in addition to their effect on the QT/QTc interval.
      (3) ECG monitoring should be performed for safety and tolerability 2–3 hours after the first five doses when initiating, reinitiating, or introducing another interacting or QT-prolonging agent.
      (4) Electrolyte abnormalities may place a patient at increased risk of torsades de pointes (particularly magnesium and potassium).

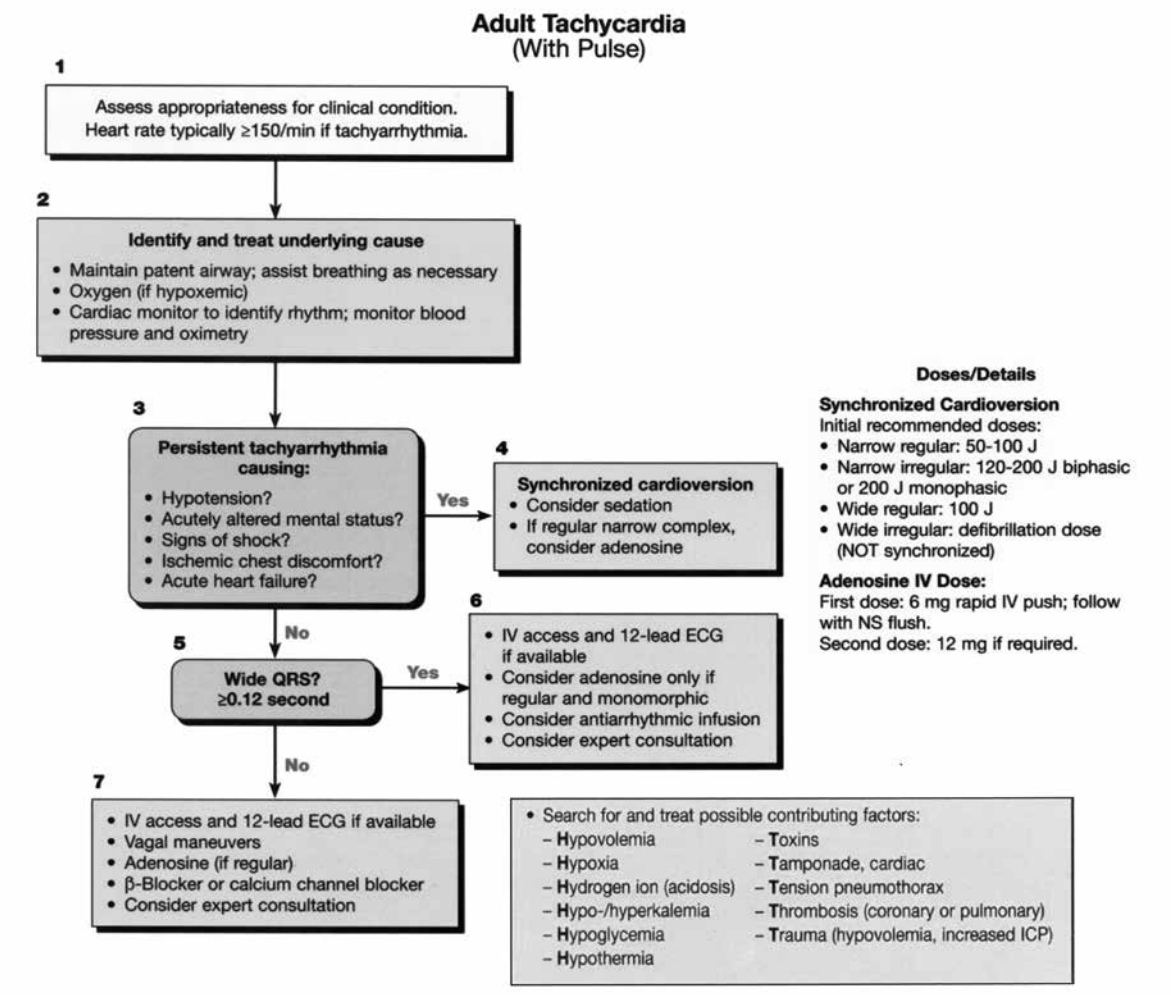

Figure 9. Advanced cardiac life support tachycardia algorithm (Circulation 2010;122:S729-67).

iii. Common agents in the ICU
  (a) β-Blockade
    (1) May be of limited use in patients receiving vasopressors, but can be used for both atrial and ventricular tachyarrhythmias
    (2) Esmolol has the shortest half-life (cleared by plasma esterases), and administration rates commonly coincide with high volumes of fluid.
    (3) Agents with combined α_1-antagonism and non-selective β-antagonism will have greater effects on BP compared with their β_1-specific antagonist counterparts.
      - β_1-specific antagonist examples:
        - Esmolol (intravenous), metoprolol tartrate (oral/intravenous)
      - Combined α1- and non-selective β-antagonist examples:
        - Carvedilol (oral) – 1α:10β receptor activity
        - Labetalol (intravenous) – 1α:7β receptor activity
        - Labetalol (oral) – 1α:3β receptor activity
  (b) Diltiazem
    (1) May be of limited use in patients on vasopressors, but can be used for both atrial and ventricular tachyarrhythmias
  (c) Non-dihydropyridine calcium channel blockers are not recommended in patients with heart failure with reduced ejection fraction (HF*r*EF) (systolic heart failure) (class III C). (J Am Coll Cardiol 2013;62:e147-239)
  (d) Amiodarone
    (1) Widely versatile and commonly used for both atrial and ventricular tachyarrhythmias
    (2) Affects all phases of the action potential (Na, Ca, K channel and provides some α- and β-antagonism)
    (3) Severe hypotension can occur because of the solvent polysorbate 80 (Tween 80) used in some formulations. This transient hypotension in patients with a pulse can be associated with rapid infusions, particularly of undiluted drugs, and is best avoided by dilution and slower administration. However, in pulseless patients, rapid administration of undiluted amiodarone is commonly indicated.
    (4) Among common agents used in the ICU, amiodarone has one of the largest volumes of distribution (about 60 L/kg) and prolonged half-lives (50–55 days).
    (5) In adults, common total intravenous or oral loading doses over several days are about 8–10 g before switching to a maintenance dose.
      - 7.2–12 g = (1.5–2.5 mg/L) × (60 L/kg) × (80 kg)
    (6) Extensive metabolism by CYP3A4 and CYP2C8 and enzyme inhibitor of CYP3A4, CYP1A2, CYP2C9, and CYP2D6, resulting in several drug-drug interactions
    (7) Therapeutic drug monitoring by levels of amiodarone or its metabolite, *N*-desethylamiodarone, is rarely warranted unless trying to confirm suspected toxicity
    (8) If patients are to be continued on amiodarone for a prolonged duration, thyroid and liver function tests, pulmonary function tests, chest radiographs, and ophthalmic examinations should be evaluated periodically. (Heart Rhythm 2007;4:1250-9)
  (e) Lidocaine
    (1) Indicated only for ventricular tachyarrhythmias and is particularly useful if the tachyarrhythmia is caused by active ischemic myocardial tissue
    (2) Efficacy and toxicity are both concentration-dependent.

(3) Metabolism is largely dependent on hepatic blood flow; the primary metabolites are monoethylglycinexylidide (MEGX) and glycine xylidide (GX) and are mediated by CYP1A2. Both lidocaine and MEGX contribute to therapeutic effect and toxicity, whereas GX has predominantly toxic adverse effects. Lidocaine's metabolites are eliminated renally.
(4) Concentration-dependent protein binding includes about 25% bound to albumin and about 50% bound to α_1-acid glycoprotein (AAG).
(5) As AAG increases and decreases as an acute-phase reactant within the first 12–72 after certain stresses (i.e., acute MI, heart failure exacerbation, trauma), an unsuspected variation can occur in free lidocaine levels. Because of the toxicity profile and concentration-dependent efficacy, routine levels should be monitored in most patients if lidocaine is to be continued beyond 24 hours (particularly in patients with heart failure, liver disease, and renal dysfunction).

Box 4. Lidocaine Levels and Toxicity Symptoms

Total Serum Concentration	Toxicity
< 1.5–5 mg/L	Typical therapeutic goal level with idiosyncratic reactions
> 5–8 mg/L	Increasing risk of light-headedness, confusion, dizziness, tinnitus, twitching, tremor, blurred or double vision, hypotension, and bradycardia
> 8 mg/L	High risk of seizures, respiratory depression, hypotension, bradycardia, AV nodal blockade, decreased cardiac output

(f) Digoxin
(1) Commonly, a last-line rate control therapy for patients whose rhythm control strategies have failed and who cannot tolerate, or have contraindications to, β-blockers and/or calcium channel blockers. Some interest has also been revived in its use for heart failure to avoid hospitalization.
(2) Use for AF should be done with caution. Two recently published retrospective trials have shown considerable evidence for increased hospitalization rates and risk of death.
- 71% increased risk of death (hazard ratio 1.71; 95% CI, 1.52–1.93) and 63% increased risk of hospitalization (hazard ratio 1.63, 95% CI, 1.56–1.71) (Circ Arrhythm Electrophysiol 2015;8:49-58)
- Digoxin-treated patients had higher mortality rates (95 vs. 67 per 1000 person-years; p<0.001), and use was independently associated with mortality, despite multivariate adjustment (hazard ratio 1.26; 95% CI, 1.23–1.29, p<0.001). (J Am Coll Cardiol 2014;64:660-8)
- Eliminated renally; thus, may pose risks of digoxin toxicity in patients with acute or chronic renal failure

(3) Although the volume of distribution is relatively large (7–10 L/kg in healthy adults), only a small percentage of total body stores are present in the serum.
(4) Digoxin has a smaller volume of distribution in patients with renal failure (around 4.5 L/kg); thus, loading doses are commonly lower in these patients.

(5) Digoxin efficacy and toxicity do not correlate well with drug levels.
- Common therapeutic targets for HR control are 0.8–1.5 ng/mL, although many clinical laboratories report therapeutic levels within a 0.5–2.0 ng/mL.
- Toxicity, which can present at any serum level, should be evaluated according to clinical manifestations, including mental status changes, visual disturbances, nausea, vomiting, ventricular arrhythmias, bradycardia, and hyperkalemia.
- Efficacy is largely based on clinical control of the HR; steady-state levels (more than 5–7 days after initiation) are typically used only to validate that levels are not supratherapeutic.

4. Anticoagulation for AF or atrial flutter
   a. According to the 2014 AHA/ACC/HRS AF guidelines, all patients with atrial flutter or paroxysmal, persistent, or permanent AF should be evaluated for anticoagulation needs, preferably using the CHA_2DS_2-VASc score to approximate stroke risk (Circulation 2014;130:2071-104).
      i. Patients with a $CHADS_2$ score (congestive heart failure, hypertension, age older than 75, diabetes, and prior stroke or transient ischemic attack) and a CHA_2DS_2-VASc score of 2 or greater should be evaluated for anticoagulation.
      ii. It is reasonable to omit anticoagulation in patients with a $CHADS_2$ and CHA_2DS_2-VASc score of zero.
      iii. For patients with AF and a mechanical prosthetic heart valve or valves, bridging with unfractionated heparin (UFH) or low-molecular-weight heparin (LMWH) should be performed in the context of bleeding versus stroke risk. Warfarin anticoagulation and international normalized ratio (INR) goals should be consistent with the type and location of the prosthetic valve.
      iv. Although the $CHADS_2$ and CHA_2DS_2-VASc scores are commonly used to estimate annual stroke risk, these scoring systems were not founded in the context of critically ill patients.

Box 5. $CHADS_2$ and CHA_2DS_2-VASc Stroke Risk Scores in AF (Circulation 2014;130:2071-104)

Risk Assessment	Score	Total Patient Score	Adjusted Annual Stoke Rate
$CHADS_2$		0	1.9%
• Heart failure	1	1	2.8%
• Hypertension	1	2	4.0%
• Age ≥ 75	1	3	5.9%
• Diabetes	1	4	8.5%
• Stroke, TIA, thromboembolism	2	5	12.5%
		6	18.2%
CHA_2DS_2-VASc		0	0%
• Congestive heart failure	1	1	1.3%
• Hypertension	1	2	2.2%
• Age ≥ 75	2	3	3.2%
• Diabetes	1	4	4.0%
• Stroke, TIA, thromboembolism	2	5	6.7%
• Vascular disease	1	6	9.8%
• 65–74 years	1	7	9.6%
• Sex category (female)	1	8	6.7%
		9	15.2%

TIA = transient ischemic attack.

b. Anticoagulation decisions should balance the risk of stroke versus the risks of bleeding in the context of duration of bridging and/or lack of anticoagulation. Two scoring systems for bleeding risk systems have been described to help assess bleeding risk in anticoagulation decisions for patients with AF on **warfarin** anticoagulation. Not unlike stroke risk scoring systems, these scoring systems were not founded in the context of critically ill patients.

Box 6. HASBLED or $HEMOR_2RHAGES$ Bleeding Risk Scores in AF

Risk Factor Assessment	Score	Total Patient Score	Bleeds/100 Patient-Years of Warfarin
HASBLED			
• Hypertension	1	0	1.13
• Abnormal renal or liver function (1 point each)	1 or 2	1	1.02
• Stroke	1	2	1.88
• Bleeding	1	3	3.74
• Labile INRs	1	4	8.70
• Elderly (> 65 years)	1	5	12.5
• Drugs or alcohol (1 point each)	1 or 2	6	0
		Any score	1.56
$HEMOR_2RHAGES$			
• Hepatic or renal disease	1	0	1.9
• Ethanol abuse	1	1	2.5
• Malignancy	1	2	5.3
• Older age	1	3	8.4
• Reduced platelet count or function	1	4	10.4
• Rebleeding risk	2	≥ 5	12.3
• Hypertension (uncontrolled)	1	Any score	4.9
• Anemia	1		
• Genetic factors	1		
• Excessive fall risk	1		
• Stroke	1		

c. In the critically ill, parenteral anticoagulation with UFH or LMWH may be more favorable if the benefit of anticoagulation exceeds the risk of bleeding. UFH infusions would be favored over LMWH in renal failure (creatinine clearance [CrCl] less than 30 mL/minute).

d. For anticoagulation of most critically ill patients, oral anticoagulation may be less favorable or even detrimental compared with parenteral anticoagulation.
   i. Elimination of apixaban, dabigatran, and rivaroxaban is significantly affected in renal compromise, and these agents currently lack data for safety in patients with a CrCl less than 30 mL/minute at any dose. These agents interact and are currently irreversible in a controlled, expeditious fashion if the patient needs an invasive procedure or develops an acute bleed.
   ii. Warfarin presents potential difficulty because of its influence on malnutrition, drug interactions, and unpredictable dose response in the critically ill. Complications with this agent are more predictably managed compared with those with other oral anticoagulants if a patient needs an invasive procedure or develops an acute bleed, but warfarin use is still not without risk.

e. For patients with AF/flutter for 48 hours or more (or if undetermined) without therapeutic anticoagulation, absence of thrombus on the left side of the heart should be confirmed by transesophageal ECHO before pharmacologic or direct current cardioversion.

f. If AF/flutter for more than 48 hours or an unknown duration that requires direct current or pharmacologic cardioversion for hemodynamic instability, anticoagulation should be initiated as soon as possible and continued for at least 4 weeks after cardioversion unless contraindicated

Patient Cases

Question 6 pertains to the case on 1-190.
The appropriate intervention has been made from question 5, and the patient has not required any pacing device intervention. For the next 48 hours, J.M. continues on inotrope therapy and is being diuresed (he has been 1250 and 900 mL negative, respectively, over these two days). The transthoracic ECHO results have revealed that J.M.'s ejection fraction is 15–20%, with a dilated, hypokinetic LV; severe mitral regurgitation; and dilated atria. No evidence of intracardiac thrombus is seen, but cannot be ruled out.

6. J.M. has had increasing premature atrial contractions on telemetry, and his HR has consistently been between 83 and 96 beats/minute; he is currently taking dobutamine at 5 mcg/kg/minute and a furosemide infusion at 10 mg/hour. The team is notified that J.M. has gone into AF with rapid ventricular response and an HR of 132 beats/minute (he has been in AF for about 30 minutes). His BP is now 83/52 mm Hg. Which treatment plan would be most favorable for this patient?
   A. Synchronized cardioversion.
   B. Metoprolol 5 mg intravenous push.
   C. Adenosine 6 mg rapid intravenous push through the most proximal port on the central venous catheter.
   D. Amiodarone 150 mg intravenous push, followed by a continuous infusion at 1 mg/minute.

7. M.B., a 76-year-old woman, is now in sinus rhythm with an HR of 98 beats/minute after being cardioverted this morning by direct current cardioversion for AF with rapid ventricular response and hemodynamic instability. Her medical history includes an unspecified arrhythmia, hypertension, frequent epistaxis, and diabetes. Her calculated CHA_2DS_2-VASc score is 5, and her HASBLED score is 4. The physician is considering anticoagulation with a heparin infusion while the patient is in the ICU and asks for a recommendation. Which is the most appropriate response?
   A. According to these scores, the patient's risk of bleeding exceeds her risk of stroke; thus, it would be reasonable to withhold anticoagulation.
   B. According to these scores, the patient's risk of stroke exceeds her risk of bleeding; therefore, it would be reasonable to initiate heparin anticoagulation.
   C. The HASBLED score is less relevant because it is derived from warfarin anticoagulation; however, anticoagulation is likely warranted, given the patient's CHA_2DS_2-VASc score and cardioversion this morning.
   D. The HASBLED score, CHA_2DS_2-VASc score, and cardioversion are irrelevant to this patient's current care, and because she remains in sinus rhythm, anticoagulation is not warranted.

VI. HEART FAILURE

A. Clinical Syndrome – Manifested because of congenital or acquired structural or functional myocardial dysfunction that impairs filling and/or emptying of the heart
   1. Mortality rate of 50% with 5 years of diagnosis
   2. Predominantly descriptive of LV and its pump performance and the ejection fraction
   3. Prognosis and treatment of heart failure are largely dependent on the etiology and symptomology.

Table 8. Diastolic Dysfunction vs. Systolic Dysfunction in Heart Failure

Type	Heart Failure with ***preserved*** EF (HF*p*EF)	Heart Failure with ***reduced*** EF (HF*r*EF)
Dysfunction	• Diastolic – blood filling the heart	• Systolic – blood emptying from the heart • May also coexist with impaired diastolic filling
Characteristics	• LVEF ≥ 50% • Impaired relaxation and filling of the ventricle before contraction • Commonly described as a "stiffened" ventricle • Contractility remains "normal"	• LVEF ≤ 40% • Impaired contraction and emptying of the ventricular cavity • Commonly described as a "dilated" ventricle
Clinical management pearls	• PRELOAD (volume optimization) is essential • As diastolic dysfunction worsens – ventricular PRELOAD and diastolic filling time must be maintained • Conditions acutely decreasing PRELOAD may lead to decompensation (such as tachyarrhythmias) • Keep HR "slow" and ventricles "full"	• PRELOAD optimization essential – at high risk of volume overload • As systolic dysfunction worsens, cardiac output becomes increasingly AFTERLOAD-sensitive • Conditions acutely decreasing or increasing PRELOAD or increasing AFTERLOAD may lead to decompensation • Volume overload and increasing myocardial dilation may contribute to decreased valvular coaptation and regurgitant flow
Common medications to avoid	• NSAIDS with the exception of aspirin	• NSAIDS with the exception of aspirin • Class 1C antiarrhythmics • Calcium channel blockers (in some scenarios, amlodipine may be considered – no proven morbidity or mortality effect)

EF = ejection fraction; LVEF = left ventricular ejection fraction.

B. Heart Failure Etiologies
   1. Ischemic cardiomyopathy
      a. Accounts for about two-thirds of heart failure cases
      b. Caused by myocardial damage/death owing to CAD
   2. Non-ischemic
      a. Accounts for about one-third of heart failure cases
      b. May be attributed to other causes (Table 9)

Table 9. Non-ischemic Cardiomyopathies

Non-ischemic Cardiomyopathies	
• Amyloidosis • Cardiac sarcoidosis • Drug induced o Alcohol o Anabolic steroids o Chemotherapy § Anthracyclines § Cyclophosphamide § Fluorouracil § Bevacizumab § Trastuzumab o Clozapine o Cocaine o Methamphetamine o Tricyclic antidepressants o Weight-loss agents	• Familial • Hypertension • Hyper/hypothyroidism • Hypertrophic obstructive (HOCM) • Idiopathic • Myocarditis o Autoimmune o Eosinophilic o Giant cell o Viral o Other infectious cause • Noncompaction • Peripartum • Obesity • Stress induced (takotsubo)

C. RV Dysfunction and/or Failure (J Am Coll Cardiol 2010;56:1435-46; Exp Clin Cardiol 2013;18:27-30; Circ Heart Fail 2010;3:340-6; Anesth Analg 2009;108:422-33; Anesth Analg 2009;108:407-21)
   1. Less well characterized than LV heart failure
   2. No guidelines to direct management of acute RV failure
   3. RV physiology
      a. The RV normally has only about one-sixth the myocardial mass of the LV. Primary means of compensation is HR increase.
      b. Normal right ventricular ejection fraction is about 40–45%.
      c. Conduit to a low pressure system in the pulmonary vasculature (normally)
      d. RV output should approximate LV output.
      e. Physiologic deficits:
         i. Preload-dependent
         ii. Interdependent on LV and septal contribution to contraction
         iii. Highly sensitive to acute increases in afterload. PVR elevations may be:
            (a) Drug induced (e.g., α_1 agents, protamine)
            (b) Caused by ventilator settings (high PEEP [positive end-expiratory pressure], high tidal volumes)
            (c) Caused by hypoxia
            (d) Caused by hypercarbia
            (e) Caused by pulmonary embolism
         iv. Poor elastic response to acute preload increases compared with LV
         v. Atypical geometric form contributes to:
            (a) Difficultly in objective assessment of RV function by ECHO
            (b) Increases susceptibility to further inefficiency/dysfunction when severely dilated
   4. Etiologies of RV failure

Box 7. Etiologies of RV Failure (J Am Coll Cardiol 2010;56:1435-46; Exp Clin Cardiol 2013;18:27-30)

- LV dysfunction
- Right coronary artery infarction/ischemia
- RV overload
- Pulmonary hypertension (primary or secondary)
- Hypoxia
- Sepsis
- Mitral valve disease
- Tricuspid regurgitation/stenosis
- Pulmonary regurgitation
- Hypovolemia
- Post-cardiac surgery
- Pulmonary embolism
- Cardiac tamponade
- Congenital heart disease
- Arrhythmias
- Heart transplantation (particularly if prolonged ischemic time)

D. Diagnostic Tests for New or Worsening Heart Failure – In addition to routine chemistry and CBC tests, additional testing may include:
   1. Liver function tests (may be indicative of congestive hepatopathy if elevated)
   2. 12-lead ECG
   3. Troponin
   4. Left heart catheterization if suspected new ischemic contribution
   5. BNP or NT-proBNP (N-terminal pro-brain natriuretic peptide) (elevations may help in the diagnosis of acutely decompensated heart failure in scenarios of uncertainty)
   6. Transthoracic or transesophageal ECHO
   7. Invasive hemodynamic monitoring (to guide volume optimization and dosing response to inotropes or vasopressors)
   8. For less common cardiomyopathies, noninvasive imaging (i.e., cardiac MRI [magnetic resonance imaging]) and/or myocardial biopsy may be required.

VII. VALVULAR DISEASE AND MECHANICAL DYSFUNCTION

A. Valvular heart disease is an important comorbid condition that must be considered in hemodynamic management of the critically ill. Valvular heart disease can also independently lead to the presenting critical illness.

B. Among the four cardiac valves, several etiologies[a] contribute to the manifested pathology; however, the depth and breadth of these etiologies are beyond the scope of this chapter. Nevertheless, conditions that may require repair/replacement include:

Stenosis	Narrowing at the opening of the valve(s) Can lead to concurrent regurgitation
Regurgitation	"Leaky" valve(s) resulting in less blood pumping forward through the heart
Prolapse	"Floppy" valve(s) with part of valve not working
Endocarditis	Infection of one or more valves
Malformation	Often occurs at birth when the valve (or valves) is defective

[a]Valvular disease secondary to rheumatic heart disease is a rare, but is a possible contributor

Table 10. Valvular Disease Characteristics and Management Considerations[a,b]

Valvular Disease Type	Management Considerations
Aortic stenosis (AS)	• One of the most common and serious valvular diseases seen in the ICU • As stenosis and disease progresses, severe/critical AS limits the heart to a fixed stroke volume. This inability to increase stroke volume occurs despite intrinsic or extrinsic attempts to compensate (i.e., increased chronotropy or inotropy) and often only increases myocardial oxygen demand without the improving delivery o Must be extremely cautious in approaching and reacting to invasive hemodynamic parameters (particularly cardiac output and cardiac index) – adding agents with inotropic/chronotropic effects may expedite demand ischemia and an acute MI because of the physiologic inability to increase cardiac output with a fixed partial LV outflow tract obstruction o For reasons similar to those listed above, treating hypertension with afterload-reducing agents must be done judiciously because as afterload (SVR) decreases, cardiac output cannot increase • Can coexist with concurrent aortic insufficiency/regurgitation because the stenotic or calcified valve leaflets may no longer move and come together (coapt) well • These patients may be at risk of developing mitral regurgitation and subsequent increases in left atrial pressures (increasing risk of AF) because of increased LV filling pressures • Must be cautious in decreasing HR in sinus tachycardia because this can be a primary means of compensation • Patients need adequate preload; however, they can become symptomatic, even with slight volume overload. This being understood, atrial fibrillation can be very detrimental, simply because it decreases preload to the ventricle • Patients with severe aortic stenosis and systolic heart failure (described as low output – low gradient) have a poorer prognosis
Aortic regurgitation (AR)	• Also known as aortic insufficiency (AI) • Must be cautious in decreasing HR in sinus tachycardia as this can be a primary means of compensation to maintain adequate cardiac output • Patients need adequate preload but the predominant target is to maintain decreased afterload (SVR) to facilitate forward blood flow and cardiac output

Table 10. Valvular Disease Characteristics and Management Considerations[a,b] *(continued)*

Mitral stenosis (MS)	• Contributes to decreased LV filling and increased left atrial pressures; can increase risk of AF and secondary pulmonary hypertension • Increasing diastolic filling time and avoiding tachycardias can facilitate stabilization until valve is corrected • Use of selective pulmonary vasodilators (i.e., inhaled nitric oxide or inhaled epoprostenol) may be detrimental because these agents can facilitate pulmonary congestion, given the preexisting pulmonary venous hypertension and elevated left atrial pressures
Mitral regurgitation (MR)	• Primary clinical target is to decrease LV afterload (SVR) to minimize augmentation of MR and to facilitate forward blood flow. If SVR is too high, blood will travel in the path of least resistance until an adequate LV pressure is generated to open the aortic valve (must exceed the systemic diastolic BP) • Can coexist with concurrent mitral regurgitation because the stenotic or calcified valve leaflets may no longer move and coapt well • Use of selective pulmonary vasodilators (i.e., inhaled nitric oxide or inhaled epoprostenol) may be detrimental because these agents can facilitate pulmonary congestion, given the preexisting pulmonary venous hypertension and elevated left atrial pressures
Tricuspid regurgitation (TR)	• Likely to influence pulmonary artery catheter assessments of cardiac output • Can be influenced by infectious causes and presence of indwelling transvenous catheters or leads, but moderate or severe TR is more commonly a marker of RV overload and dysfunction

[a]Infective endocarditis can cause progressive valve disease leading to regurgitant flow and impaired valve leaflet coaptation; however, it can also lead to near-obstruction in some cases.

[b]Degree of valvular disease is graded as mild, moderate, or severe, as defined by objective ECHO or catheter-based assessments.

SVR = systemic vascular resistance.

C. Procedural Correction

Table 11. Procedural Correction

Balloon valvuloplasty	• Performed by percutaneous intervention as a temporizing intervention
Valve repair	• May entail direct surgical repair of a damaged valve leaflet or other scenario may require use implantation of a ring at the valve annulus to facilitate improved coaptation of a regurgitant valve
Tissue (bioprosthetic) valve	• Made of animal or human tissue • Usually does not require long-term anticoagulation (see Table 11) • Does not last as long as a mechanical valve (may last 10–15 years)
Mechanical valve[a]	• Made of manmade materials (newer valves use ceramic or carbon) • They are durable and last a long time (unlikely to need replacement) • Require lifelong anticoagulation • Warfarin is currently the only anticoagulant approved for use by the FDA in patients with mechanical heart valves (see Table 11)
Transcatheter aortic valve replacement (TAVR)	• Made of animal tissue (bioprosthetic) and attached to a wire frame stent and placed using catheter inside the old aortic valve • This may be considered in patients who are at a higher risk of surgical aortic valve replacement or when surgery is not an option • Anticoagulation and/or antiplatelet agents are required for at least a short time after TAVR

[a]St. Jude manufactures mechanical and bioprosthetic valves.

FDA = U.S. Food and Drug Administration.

Table 12. Prosthetic Valve Anticoagulation: Levels of Evidence to Support Recommendations (Circulation 2013;127:e362-425; Circulation 2014;130:e344-426; J Am Coll Cardiol 2012;59:1200-54; Circulation 2014;129:e521-643; Chest 2012;141:e576S-600S; Arch Cardiovasc Dis 2012;105:465-7; The Ohio State University Wexner Medical Center. Clinician's Guide to Anticoagulation Recommendations Post-Valve Replacement. Available from https://evidencebasedpractice.osumc.edu. Accessed January 20, 2015)

Prosthetic Valve Anticoagulation: Levels of Evidence to Support Recommendations

Must consider relative risk of bleeding vs thrombosis given the patient's current clinical status when initiating or continuing anticoagulant therapy

Procedure		Antiplatelet Therapy		Warfarin Target INR‡		Parenteral Anticoagulation
		NO Risk Factors	With Clotting Risk Factors†	NO Clotting Risk Factors	With Clotting Risk Factors†	UFH: Unfractionated Heparin LMWH: Low Molecular Weight Heparin
Mechanical AVR		**ASA 81 mg**	**ASA 81 mg**	**2 – 3**	**2.5 – 3.5**	**Bridging until warfarin therapeutic for 2 days**
Level of Evidence	*CHEST*	1B*	1B*	2C	2C	2C for intermittent UFH subQ Q8H# or LMWH over continuous IV UFH
	ACC/AHA	I	I	I	I	B

	ACC/AHA	I	I	IIa - If less than 3 months	I	Discussed but not graded
	EACTS	IIaC	IIaC	IIaC	IC	IC
Other Statements	*CHEST*		For patients who have systemic embolism despite a therapeutic INR, the addition of ASA 81 mg/day is recommended if not previously provided and/or upward titration of warfarin to achieve a higher target INR. For a previous target INR of 2.5 (range 2 to 3), it is suggested that the warfarin dose be increased to achieve a target INR of 3.0 (range 2.5 to 3.5). For a previous target INR of 3.0, it is suggested that the warfarin dose be increased to achieve a target INR of 3.5 (range 3.0 to 4.0).			
	ACC/AHA	Discussed; Not graded				

* Except in patients with a history of GI bleeding or who are more than 80 years of age.
† Risk factors for increased risk of thromboembolism include atrial fibrillation, previous thromboembolism, hypercoagulable state, left ventricular dysfunction, older generation thrombogenic valve, mechanical tricuspid valve, greater than one mechanical valve.
# Dosing cited is UFH 15,000 units/kg subQ Q12H or 166 units/kg sub Q8H adjusted therapeutic PTT goals; Enoxaparin 1 mg/kg subQ Q12H

D. Anticoagulation
   1. Three guidelines exist regarding valve anticoagulation, with varying agreement in the recommendations.
   2. Prosthetic mitral valves have increased risk of thrombosis (blood flow across the valve is passive and occurs during diastole) versus aortic valves, where blood flow across the valve is active occurring during systole.

E. Valve Thrombosis
   1. Highest risk within the first year after replacement
   2. Most predominant risk is in mechanical prosthetic valves, but can also occur with bioprosthetic valves
   3. Treatment involves systemic thrombolytic treatment or surgical reoperation with varying success rates – Both carry significant risks of morbidity and mortality, including:
      a. Thrombolysis (predominantly recommended for right-sided valve thrombosis)
         i. Cardiac tamponade
         ii. Stoke/transient ischemic attack
         iii. Systemic embolization
         iv. Major bleeding
         v. Death
      b. Surgery (predominantly recommended for left-sided valve thrombosis)
         i. Cardiac tamponade
         ii. Stoke/transient ischemic attack
         iii. Renal failure
         iv. Heart block
         v. Systemic embolization
         vi. Prolonged ventilation
         vii. Major bleeding
         viii. Death

F. Other Cardiac Functional Defects
   1. Left ventricular outflow tract (LVOT) obstruction (Circulation 2008;117:429-39; J Am Coll Cardiol 2000;36:1344-54)
      a. Hypertrophic obstructive cardiomyopathy (HOCM)
         i. Genetic disease leading to hypertrophy of the left ventricle (particularly the ventricular septum) with or without the presence of LV outflow tract obstruction
         ii. LVOT obstruction is of greatest concern when HOCM exists with systolic anterior motion (SAM) (see below); however, in HOCM, LVOT obstruction can exist in the absence of SAM because of septal hypertrophy; nonetheless, acute clinical management is predominantly the same as outlined in 1.a.i–iii above and in 1.b.i below.
         iii. Treatment of HOCM without SAM relies heavily on the management of contributors to myocardial hypertrophy and diastolic heart failure.
            (a) β-Blockers are first-line agents in the treatment of patients with HOCM and are commonly titrated to HR goals of 60–65 beats/minute.
            (b) Dihydropyridine calcium channel blockers (particularly verapamil) are recommended in patients with contraindications to β-blockade or in those without advanced heart failure or bradycardia.
            (c) For recommendations specific to HOCM (patients also with SAM), see “b” below.
            (d) Patients with HOCM may be at increased risk of sudden cardiac death. Evaluation should consider the patient’s candidacy for implantable cardioverter-defibrillator placement by ambulatory ECG (Holter) monitoring at least biannually.
         iv. Treatment may be indicated by surgical septal myectomy or catheter-directed alcohol ablation.

b. SAM of the mitral valve
    i. SAM and LVOT obstruction results in a systolic outflow tract obstruction and is commonly associated with HOCM, but can also occur in other clinical scenarios, particularly after cardiac surgery
    ii. Can lead severe cardiogenic shock with a low (or no) cardiac output
    iii. SAM is more of a dynamic obstruction in which the degree of obstruction and flow gradient is dependent on HR (systoles per minute), cardiac contractility, and ventricular preload volume.
        (a) In an under-filled LV, there is physically less distance between the mitral valve and septum, thus generating an increased risk of obstruction because the LVOT is generally narrower at the onset of systole, particularly if the mitral valve leaflet is affected.
        (b) Increasing cardiac contractility and HR increases LVOT obstruction and gradient by inducing a stronger contraction, increasing the contact between the septum and mitral leaflets, and increasing the rate of systolic attempts.
    iv. For patients with SAM who have shown a potential for obstructive physiology, management involves maintaining normal or increased LV preload and low HRs.
        (a) Acute hypotension is best managed with phenylephrine or vasopressin (pure vasoconstrictors) to selectively increase SVR without increasing contractility or HR.
        (b) Inotropes and vasopressors that mediate increases in heart rate or contractility should be avoided, if possible, because they may be harmful and worsen the LVOT.
        (c) Afterload-reducing agents (e.g., ACE inhibitors, ARBs, non-dihydropyridines) should be used with caution (if at all).

2. Septal defects (atrial or ventricular)
    a. Septal defects can be acquired (i.e., postinfarction ventricular septal defect) or can be congenital in nature.
    b. Diagnosed predominantly by ECHO using a bubble study. If the patient presents in a seeming low cardiac output state, a left-to-right intracardiac shunt should be suspected if mixed venous oxygen saturation (SvO_2) saturations are greater than $ScvO_2$ saturations.
    c. Important principles
        i. Goals include minimizing the degree of intracardiac shunt while maintaining adequate cardiac output. It is generally favored to accept a right-to-left intracardiac shunt while recognizing that Pao2 saturations will be somewhat decreased and reflective of venous and arterial blood mixing in the LV before ejection.
        ii. Decreasing right-sided cardiac filling pressures can augment left-to-right intracardiac shunting of blood. Administration of venodilators (i.e., nitrates) or aggressive diuresis could augment left-to-right intracardiac shunts and lead to clinical deterioration.
        iii. Intravenous medications should preferably be filtered to minimize the risk of air /particulate embolus traveling through to the left side of the heart and being ejected and causing a potential stroke.
    d. Treatment may include surgical correction or percutaneous catheter placement of a closure device.

Patient Case

Question 8 pertains to patient case on p. 1-190.

8. J.W. is no longer in AF but remains in cardiogenic shock. The cardiac care unit team has consulted the cardiothoracic surgeons for evaluation of his mitral valve disease and has considered advanced heart failure therapies. In the patient's decompensated state, he would likely need additional optimization if he were to undergo surgery. Which temporary means of mechanical circulatory support (MCS) might be most favorable to help stabilize this patient's cardiogenic shock and afterload-sensitive valvular disease?

   A. Venoarterial extracorporeal membrane oxygenation (ECMO).
   B. Venovenous ECMO.
   C. Intra-aortic balloon counterpulsation.
   D. None; the patient likely needs urgent surgery.

VIII. ADVANCED THERAPIES FOR HEART FAILURE AND CARDIOGENIC SHOCK

A. The goals behind advanced therapies can be thought of as dynamic, depending on patient progression and resolution or presentation of comorbid conditions.

B. Dynamic Progression of Heart Failure Advanced Therapies

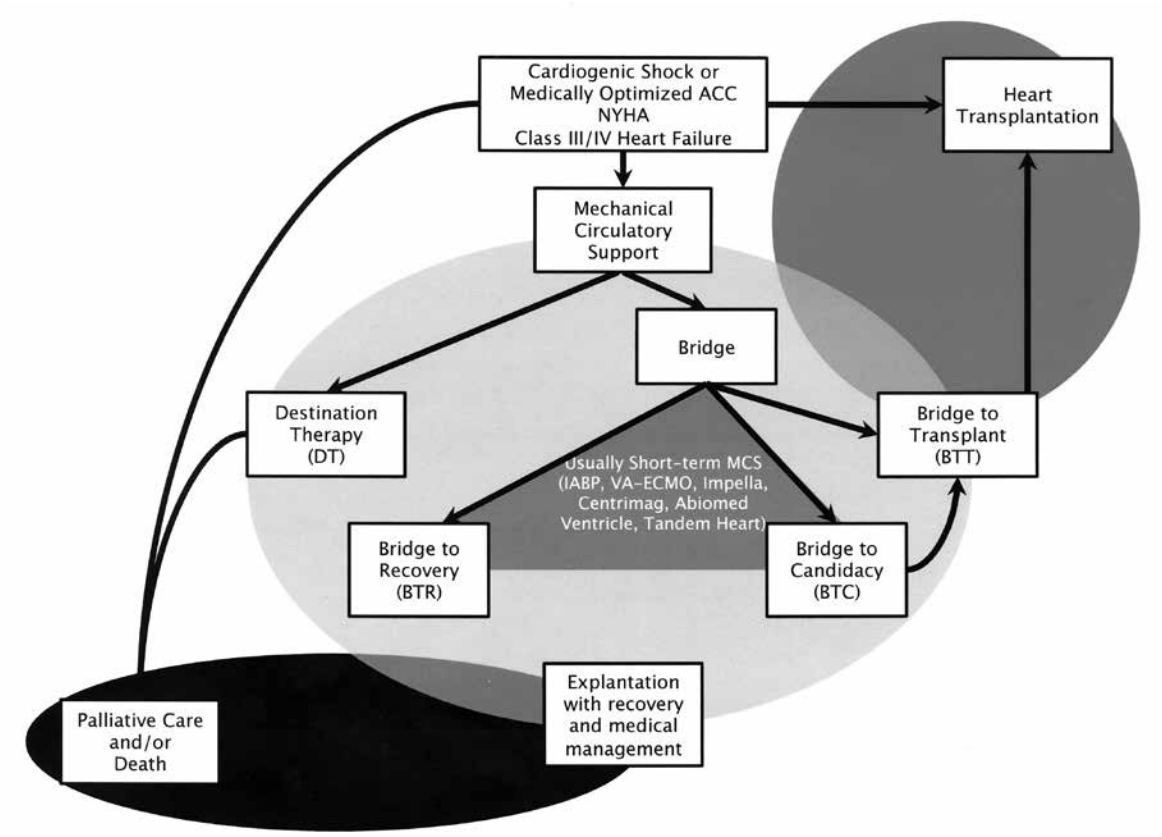

Figure 10. Dynamic progression of heart failure advanced therapies.

C. Mechanical Circulatory Support (MCS) (J Heart Lung Transplant 2013;32:157-87)
   1. Intent, duration, and type of MCS support depend on several factors, including patient acuity, comorbidities, and prognosis.
   2. Common terms
      a. Destination therapy – Formal designation for patients who meet the criteria for long-term mechanical support but who are not a transplant candidate because of relative or absolute contraindications
      b. Bridge to transplant – Formal designation for patients eligible to be listed as candidates for heart transplantation
      c. Bridge to candidacy and bridge to recovery – Used in concept and are not formally recognized abbreviations but describe the approach to temporary MCS when short-term left ventricular assist devices (LVADs) are used to support a patient until a long-term prognosis can be determined, which may include explantation with recovery, implantation of long-term durable LVAD support, heart transplantation, or palliative care.

Table 13. Short to Intermediate Term

Short to Intermediate Term	
Intra-aortic balloon pump (IABP) counterpulsation	• Placed by femoral arterial catheter and advanced up the aorta • Deflation facilitates selective afterload during systole to ease cardiac output (does not technically increase cardiac output) • Inflation enables diastolic augmentation of systemic BP to improve vital organ and coronary perfusion pressures • Can be set to trigger from ECG, pacer, or arterial line pressure or can be manually set • Tachyarrhythmias and aortic regurgitation/insufficiency are not well supported with this means of MCS • Level of support coincides with timing of inflation/deflation per related heartbeat; for example: o 1:1 = one inflation/deflation per every heartbeat (maximal support) o 1:4 = one inflation/deflation for every fourth heartbeat (less support) • When setting duration in deflated state increases (providing less support), the thrombosis risk associated with the IABP increases, commonly requiring anticoagulation
Percutaneous VAD	Example is Impella (Abiomed) • May be considered in cardiogenic shock or as temporary support during high-risk interventional cardiology procedures • Anticoagulation regimen is a common topic of debate and/or medication safety discussion • Management can be complicated by migration and/or malposition of catheter/cannula within the LV, leading to arrhythmias or hemolysis complications
Extracorporeal or paracorporeal VAD	Examples include CentriMag, TandemHeart, BVS 5000, and AB5000 ventricle

Table 13. Short to Intermediate Term *(continued)*

Short to Intermediate Term	
Extracorporeal life support (ECLS) or extracorporeal membrane oxygenation (ECMO)	• Similar cardiopulmonary bypass in which large-bore cannulas drain venous blood that is pumped through an oxygenator, where it is oxygenated and/or cleared of carbon dioxide and then actively pumped back into the body • Modality of support depends on the means of vascular cannulation o *Venoarterial:* Removal of venous blood from the vena cava with circulation through the ECMO circuit and delivery in retrograde fashion up the aorta. Potentially indicated for primary cardiogenic shock, cardiopulmonary failure, and post-cardiopulmonary circulatory shock o *Venovenous:* Removal of venous blood from the vena cava with circulation through the ECMO circuit and delivery back to the right atrium. Potentially indicated for hypoxic respiratory failure owing to any cause, hypercarbic respiratory failure with bronchospastic disease or other cause of CO_2 retention, or severe air leak syndromes
Long term	
Implantable LVADs	Examples include the Heartmate II, HeartWare
Total artificial heart	

LVAD = left ventricular assist device; VAD = ventricular assist device.

3. Anticoagulation considerations
   a. Anticoagulation strategies are specific to the proprietary device, and many institutions have standardized protocols. Comparative example approach to postoperative anticoagulation for some LVADs
   b. Safety and efficacy of apixaban, dabigatran, rivaroxaban, enoxaparin, or other anticoagulants in patients with ventricular assist devices (VADs) have not been established.

Table 14. Example of Initial Postinsertion Antithrombotic Regimen

LVAD	Aspirin	Heparin Infusion (once hemostasis achieved)	Initial Warfarin INR Goal
Long-term Devices			
Heartmate II	• POD 0: 325 mg × 1 • Ongoing: 81 mg daily	• By POD 2: – Initiate "Heparin – no dose escalation at 5 units/kg/hr" • By POD 3: – Increase to "Heparin Sliding Scale," titrating to institutional PTT goal	2–3
HeartWare	• POD 0: 325 mg × 1 • Ongoing: 325 mg daily	• Within 12 hr postop: – Initiate "Heparin – no dose escalation at 5 units/kg/hr" • By POD 1: – Increase to "Heparin Sliding Scale," titrating to institutional PTT goal	2–3

Table 14. Example of Initial Postinsertion Antithrombotic Regimen *(continued)*

Short-term Devices			
CentriMag	• POD 0: 325 mg × 1 • Ongoing: 81 mg daily	• Within 12 hr postop: – Initiate "Heparin – no dose escalation at 5 units/kg/hr" • By POD 1: – Increase to "Heparin Sliding Scale," titrating to institutional PTT goal	N/A
Abiomed ventricle	• POD 0: 325 mg × 1 • Ongoing: 81 mg daily	• Within 12 hr postop: – Initiate "Heparin – no dose escalation at 5 units/kg/hr" • By POD 1: – Increase to "Heparin Sliding Scale," titrating to institutional PTT goal	N/A
Abiomed BVS 5000	• POD 0: 325 mg × 1 • Ongoing: 81 mg daily	• Within 12 hr postop: – Initiate "Heparin – no dose escalation at 5 units/kg/hr" • By POD 1: – Increase to "Heparin Cardiac Sliding Scale," titrating to institutional PTT goal	N/A

LVAD = left ventricular assist device; POD = postoperative day; postop = postoperatively; PTT = partial thromboplastin time.

4. Complications of MCS (other than device failure)
   a. Bleeding
      i. Common sources
         (a) Nasal/upper airway
         (b) Gastrointestinal (GI)
         (c) Arteriovenous malformations in one of the above locations
         (d) Hemolysis
      ii. Workup and/or acute treatment options
         (a) Laboratory workup
            (1) Prothrombin time/INR/partial thromboplastin time
            (2) Increase frequency of hemoglobin/hematocrit evaluation.
            (3) Multimeric von Willebrand testing for acquired von Willebrand factor deficiency (some clinicians believe that all patients with prolonged continuous flow MCS develop acquired von Willebrand disease)
            (4) If no overt sign of bleeding – Consider hemolysis workup.
         (b) If suspected/confirmed bleeding, hold anticoagulation and consider reversal with caution. Consider any history of bleeding/clotting-related problems and indications for antithrombotic therapy in addition to MCS.
         (c) Obtain appropriate consults, and consider common interventions. Ear, nose, and throat:
            • Evaluate for source control and/or cauterization.
            • Mupirocin 2% (Bactroban) every 12 hours to each nostril to maintain moist nasal passages
            • Oxymetazoline 0.05% (Afrin) to each nostril every 12 hours as needed for epistaxis

(d) Gastroenterology
(1) Proton pump inhibitor continuous infusion at least until location of GI source identified
(2) Enteroscopy with or without colonoscopy; may consider one or more of the following
- Angiography and cautery
- Balloon-assisted enteroscopy
- Video-capsule enteroscopy
- Surgery

iii. Long-term management
(a) Consider decreasing anticoagulation/antiplatelet therapy intensity.
(b) Refractory bleeding despite interventions above
(1) Consider role of oral antifibrinolytics (i.e., aminocaproic acid).
(2) Consider role of desmopressin or von Willebrand factor replacement if confirmed acquired von Willebrand disease and if LVAD speed cannot be further decreased
(3) If GI arteriovenous malformations are present that are unamenable to intervention, octreotide 50 mcg subcutaneously every 8 hours may be considered.

b. Hemolysis and/or thrombosis
i. Hemolysis may be the presenting symptom of an underlying process, including infection, pump thrombosis, or other mechanical or physiologic dysfunction.
ii. Common presentation includes:
(a) Nonhemorrhagic anemia
(b) Urine color changes with appearance of hematuria or, in severe cases, can be brown or black
(c) Hyperkalemia
(d) LVAD pump alarms
iii. Workup for contributing factors:
(a) Evaluate LVAD and cardiac function for contributing factors, including documentation and alarm history for suction events, power spikes, speed changes, volume status, RV function, arrhythmias
(1) Evaluate cannula(e) position and evaluate for obstruction/thrombus by ECHO or computed tomography (CT).
(2) Evaluate RV function by ECHO.
(3) Evaluate for intra-device thrombosis by ECHO ramp testing (Echocardiography 2014;31:E5-9; J Am Coll Cardiol 2013;62:2149-50; J Am Coll Cardiol 2012;60:1764-75).
(b) Ensure adherence with anticoagulation regimen according to patient's established goals.
(c) Evaluate laboratory values to establish the presence and degree of hemolysis and to identify any other potential contributors.
(1) LDH (lactate dehydrogenase; commonly normal values are 300–600 IU/L for most forms of MCS)
(2) Haptoglobin
(3) Plasma-free hemoglobin
(4) Blood cultures (an association has been identified with bacteremia and hemolysis in patients with LVADs – in some cases, presenting as thrombosis)
(5) Urine assessment – Send baseline urinalysis, urine culture, and appearance of changes daily to assess for improvement. Likely hemolysis, as evidenced by the presence of casts and color changes (darkened tea, red, or black are highly suggestive of hemolysis)

(d) Other laboratory values/considerations
(1) Hypercoagulable states (i.e., HIT [heparin-induced thrombocytopenia])
(2) CBC with differential
(3) Reticulocyte count

iv. Treatment
(a) Address any evidence of mechanical dysfunction by adjusting speed/flow rates, if possible.
(b) Consider medical optimization of RV function.
(c) If hypovolemic, give volume challenge. Consider alkalinization of urine and optimize fluid status (sodium bicarbonate 150 mEq/1000 mL of sterile water) at 0.5-1 mL/kg/hour; treat to a goal urine pH of greater than 7.5 to avoid additional hemolysis/hemoglobinuria-related acute kidney injury.
(d) Evaluate and optimize anticoagulation strategy.
(1) Ensure therapeutic anticoagulation with heparin or warfarin.
(2) Antithrombotic therapy that is more aggressive may be appropriate. Optimal acute antithrombotic strategies, although not yet defined, may include heparin infusion, glycoprotein (GP) IIbIIa infusions, parenteral direct thrombin inhibitors, or thrombolytics.
(3) Severe hemolysis can potentiate platelet activation – Can consider GP IIbIIIa antagonist therapy (see Table 5), depending on bleeding risks and potential surgical plan
(e) Reassess long-term antithrombotic strategy.
(1) Consider augmentation of antiplatelet therapy, or increase the INR therapeutic goal range.
(2) If thought to be related to a concurrent infection, can consider acutely increasing anticoagulation goals until infection control is gained

c. Infection
i. LVAD infections are often complex and have been characterized by the International Society for Heart & Lung Transplantation in the following manner (J Heart Lung Transplant 2011;30:375-84):
(a) VAD-specific infections
(1) Pump and/or cannula infections
(2) Pocket infections
(3) Percutaneous driveline infections
- Superficial infection
- Deep infection

(b) VAD-related infections
(1) Infective endocarditis
(2) Bloodstream infections that may be VAD related or non-VAD related
(3) Mediastinitis
- Sternal wound infection: Surgical site infection-organ space
- VAD pocket infection (continuous with mediastinum or already situated in the mediastinum, depending on the device used)
- Other causes of mediastinitis, perforation of the esophagus

(4) Non-VAD infections
- Lower respiratory tract infection
- Cholecystitis
- *Clostridium difficile* infection
- Urinary tract infection

ii. Antibiotic treatment
(a) Antibiotic coverage should account for site of suspected infection, previous pathogens and susceptibilities, proximity to driveline site or VAD pocket, and any other potential exposure or bacteremia secondary to the procedure. Prophylactic antibiotic coverage for VAD-related or non–VAD-related surgical procedures should account for site of procedure, previous infections, proximity to driveline site or VAD pocket, and any other potential exposure or bacteremia secondary to the procedure. In some circumstances, this requires broader prophylactic antibiotic coverage.Interact Cardiovasc Thorac Surg 2012;14:209-14
(b) Treatment duration depends largely on the nature of the infection. However, if the infection is VAD-related or VAD-specific, prolonged antimicrobial therapy (more than 4 weeks) is commonly used.
(c) Because LVAD change-out is not without considerable risk, long-term oral antibiotic suppression therapy may be considered for some infections.

D. Heart Transplantation (J Heart Lung Transplant 2010;29:914-56)
1. Transplantation remains the gold standard treatment for end-stage heart failure.
2. Many variables limit the utility of heart transplantation, foremost of which is donor availability and donor-recipient tissue compatibility. These limitations (and potentially others) may make long-term MCS a more viable option until heart transplantation becomes an option.
3. Other limitations may include recipient characteristics of:
a. Mental health
b. Social support
c. Adherence to medication and appointments
d. Severe pulmonary hypertension
e. Cancer
f. Infection
g. Tobacco or ethanol use
h. Illicit drug use history
4. Considerations of thoracic transplantation for ICU management immunosuppression, rejection, and other complications are widely complex and beyond the scope of this review.

ANSWERS AND EXPLANATIONS TO PATIENT CASES

1. Answer: B

Given this patient's CAD, type 2 diabetes mellitus, hyperlipidemia, gastroesophageal reflux disease, hypertension, obstructive sleep apnea, and ischemic cardiomyopathy, only option B consists of the three agents shown to reduce morbidity and mortality among these comorbidities: carvedilol (heart failure and potentially diabetes), spironolactone (heart failure progression post-MI), and lisinopril (heart failure and diabetes). Thus, Answer B is correct, and Answers A, C, and D are incorrect.

2. Answer: C

Although many of these tests might be helpful in this patient's differential diagnosis, the most likely consideration would be respiratory decompensation or a heart failure decompensation, given the patient's presentation; thus, a chest radiograph, ECHO, BNP, and lactate would be most appropriate, making Answer C correct. Answer A is incorrect; although an infectious etiology cannot be ruled out, it is less likely than non-infectious cardiorespiratory differentials. Answer B is not the best answer; although serial troponins and an ABG could be argued for, liver function tests are unlikely to provide additional insight into this patient's differential. Answer D also is not the best answer; although it provides additional information for hemodynamic assessment, it is lacking in an assessment of cardiac function, which is a likely contributor to the patient's presentation. Answer C is correct, and Answers A, B, and D are incorrect.

3. Answer: D

Dobutamine would be the ideal choice, given the patient's acutely worsening cardiac index and malperfusion and its rapid onset; this would facilitate β_2 arterial vasodilation (both SVR and PVR reduction) as well as increase chronotropy and inotropy. Milrinone, although likely benficial for both cardiac index and PVR reduction, would be less favorable given that its time to peak effect will exceed 6 hours (the time required to achieve greater than 87.5% of steady state, even in normal renal function). Neither norepinephrine nor epinephrine would be favored (particularly at these doses) because the patient's MAP is currently elevated, and these agents would contribute to increased α_1-mediated afterload increases, causing increased myocardial workload in a patient who already has decompensated systolic heart failure. Answer D is correct, and Answers A, B, and C are incorrect.

4. Answer: D

The patient's troponin elevation is most likely a result of the patient's decompensated heart. Given the patient's chemistry and ABG results, chronic obstructive pulmonary disease is highly unlikely. Although this presentation could be attributed to the patient's NSTEMI, his presentation is more consistent with a heart failure exacerbation. Sepsis is also a potential contributor to troponin elevation; by comparison, an infectious etiology is less likely in this patient's case. Answer D is correct, and Answers A, B, and C are incorrect.

5. Answer: B

Ticagrelor has been associated with adenosine-mediated dyspnea and bradycardia and should therefore be evaluated as a contributing cause. According to the current ACC/AHA guidelines, this patient no longer has a direct indication for $P2Y_{12}$ therapy because his stent was placed more than 12 months ago, but the patient should continue aspirin therapy indefinitely. The patient has no evidence of hyperkalemia. Answer B is correct, and Answers A, C, and D are incorrect.

6. Answer: A

Because of this patient's hypotension and ongoing cardiogenic shock, synchronized cardioversion would be preferred. Metoprolol would be unfavorable because of the patient's concurrent dobutamine use and his hypotension; likewise, amiodarone 150 mg intravenous push could contribute to further hypotension. The primary of role of adenosine is to slow AV nodal conduction when patients are tachycardiac with a regular rhythm (i.e., supraventricular tachycardia) to break the arrhythmia or to differentiate atrial from ventriclular sources. However, adenosine plays only a small role in this scenario. Answer A is correct, and Answers B, C, and D are incorrect.

7. Answer: C

The physician is considering heparin anticoagulation while the patient is in the ICU. While valuable to consider for long-term anticoagulation the HASBLED

score is not validated for bleeding risk specific to heparin anticoagulation. Nonetheless, given the patient's CHA_2DS_2-VASc score (annual stroke risk of 6.7%) and cardioversion, anticoagulation should be considered. Answer C is correct and Answers A, B, and D incorrect.

8. Answer: C

The patient is unlikely to remain stable without intervention, given his ongoing cardiogenic shock. To help stabilize this patient, intra-aortic balloon counterpulsation would best facilitate selective afterload reduction during systole (augmenting cardiac output in a patient with a low ejection fraction and severe mitral regurgitation) while providing augmented diastolic pressures. Venovenous ECMO is unlikely to help because this means of MCS is dependent on a functional LV and RV to provide forward blood flow. A venoarterial ECMO would stabilize the patient; however, it would increase afterload on the aortic valve, which could worsen the patient's mitral regurgitation. Furthermore, this degree of MCS may not be warranted at this time unless the patient develops progressive hypoxic cardiopulmonary failure.

ANSWERS AND EXPLANATIONS TO SELF-ASSESSMENT QUESTIONS

1. Answer: C

A diagnosis of cardiogenic shock is most likely, given the patient's history, presentation, and ongoing vasopressor requirement; elevated BNP; and lack of infectious symptoms. Furthermore, this patient has positive troponins and ST-segment depression in leads V2 and V3 (anterolateral or posterior leads), which may represent ST-segment elevation equivalent if evaluated in the context of the posterior part of the heart. The SA and AV nodes are usually supplied by the right coronary artery (in 70% and 85% of the population, respectively); thus, the patient's significant bradycardia and hypotension further increase the suggestion of a posterior infarct. Answer C is correct, and Answers A, B, and D are incorrect.

2. Answer: D

The SA and AV nodes are most commonly supplied by the right coronary artery (in 70% and 85% of the population respectively); thus, the patient's significant bradycardia and hypotension further increase the suggestion of a posterior infarct. Answer D is correct, and Answers A, B, and C are incorrect.

3. Answer: B

According to the SOAP II investigation, dopamine is associated with increased rates of adverse events in patients with cardiogenic shock compared with norepinephrine. Milrinone, although helpful in some patients with heart failure, would not be favored, given the patient's current hypotension and acute renal failure. Normal saline administration would likely be detrimental because of the patient's signs of fluid overload, including BNP elevation, hyponatremia, and rales on examination. Answer B is correct, and Answers A, C, and D are incorrect.

4. Answer: A

Lidocaine would be most favorable in patients with ischemia-mediated ventricular arrhythmias, and although the patient is not currently in VT, he is having persistent premature ventricular contractions (bigeminy), further increasing concern for ongoing ischemia and myocardial irritability. Metoprolol and diltiazem would be contraindicated because of ongoing cardiogenic shock and vasopressor requirements. Amiodarone 300 mg intravenous push is no longer appropriate because the patient has a pulse and BP and is currently not in VT. Furthermore, rapid administration of amiodarone may lead to worsening hypotension. Answer A is correct, and Answers B, C, and D are incorrect.

5. Answer: A

The patient's heart catheterization was performed through the femoral artery, a vessel that it much harder to compress to facilitate hemostasis. Hematomas can occur at the access site; however, the most serious bleeding complication associated with this access site is a retroperitoneal bleed. Answer A is correct, and Answers B, C, and D are incorrect.

6. Answer: C

Vasopressin would be favored because when administered at normal physiologic doses because it mediates predominant increases in SVR while minimally affecting the PVR. Phenylephrine, however, will increase both PVR and SVR by the α_1-receptors. Given the patient's ongoing hypotension, low cardiac index, and rising CVP, inaction would be inappropriate, and additional volume administration would be detrimental in this already volume overloaded and failing RV. Answer C is correct, and Answers A, B, and D are incorrect.

7. Answer: B

Amiodarone boluses would be safest if administered slowly over 10 minutes to avoid additional hypotension, followed by a continuous infusion. Metoprolol and diltiazem would be contraindicated because of ongoing cardiogenic shock and vasopressor requirements. Answer B is correct, and Answers A, C, and D are incorrect.

8. Answer: D

Regardless of the means of medical management or revascularization, current quality registries and measures would require initiation or documentation of contraindication, except for ACE inhibitors/ARBs because the patient still has an LVEF greater than 40%. Answer D is correct, and Answers A, B, and C are incorrect.

APPENDIX A

Class	MOA	Drug (available dosage forms)	ECG Effects: AV Conduction PR	ECG Effects: Ventricular Conduction QRS	ECG Effects: Repolarization QT/QTc	Management Considerations and Pearls	Notable Drug Interactions	Therapeutic Levels (mcg/mL)	Defibrillation Threshold	TdP risk (%)
IA	High-potency vs. fast sodium channel blockade	Quinidine (PO)	↑ ↓	↑	↑	• Different formulations available (no exact conversions) • α-Blockade may contribute to hypotension • Prolonged half-life in CHF and hepatic dysfunction • May require dose adjustments in renal and/or hepatic dysfunction • Enhanced AV node conduction usually requires combination with AV node-blocking agent • > 85% protein bound	• CYP2D6 (inhibitor) • CYP3A4 (substrate and inhibitor)	2–6	↑	2–8
		Procainamide (IV)	↑	↑	↑	• Only available in intravenous form • May contribute to hypotension • Metabolized by hepatic acetylation • Active metabolite (NAPA) renally eliminated and has increased class III properties • Dialyzable	• QT-prolonging drugs	Procainamide: 4–8 NAPA: 10–20	↑ ↓	
		Disopyramide (PO)	↑ ↓	↑	↑	• May require dose adjustments in renal and/or hepatic dysfunction • Potent anticholinergic adverse effects	• CYP3A4 (substrate)	2–8	↑	1–3
IB	Least-potent vs. fast sodium channel blockade	Lidocaine (IV)	N/A	N/A	N/A or ↓	• **Ventricular arrhythmias only** • Increased risk of toxicities in hepatic dysfunction • Binds to AAG (acute-phase reactant) - increased levels of unbound drug present, leading to risk of toxicity as AAG dissipates • Enhanced efficacy in ischemic tissue	• CYP3A4 (substrate)	Total: 1.5–5 Free: 0.5–2	↑	
		Mexiletine (PO)				• **Ventricular arrhythmias only** • Prolonged half-life in CHF and hepatic dysfunction • Decrease dose in CrCl < 10 mL/min	• CYP2D6 (substrate) • CYP1A2	0.5–2	↑	
IC	Most-potent vs. fast sodium channel blockade	Flecainide (PO)	↑	↑	N/A or ↑	• May require hepatic dosing or renal dosing at CrCl < 35 mL/min • Increased risk of mortality post-MI (CAST) • Avoid in CHF because of its potent negative inotropic effects • Combine with AV node blocker to prevent rapid atrial flutter	• CYP2D6	0.2–1	↑	
		Propafenone (PO)				• Hepatic dosing • Increased risk of mortality post-MI (CAST) • Avoid in CHF because of its potent negative inotropic effects • Combine with AV node blocker to prevent rapid atrial flutter • SR and IR formulations not equivalent	• First-pass metabolism • CYP2D6, CYP3A4 CYP1A2 substrate	0.06–1	↑ ↓	
II	β-Blockade	Ex. Carvedilol (PO) Labetalol (PO/IV) Metoprolol (PO/IV) Esmolol (IV)	N/A or ↑	N/A	N/A or ↓	• Sinus bradycardia • AV block • Hypotension more likely with nonselective agents • Continuous infusions of esmolol or labetalol may contribute to large amounts of fluid	• Predominantly CYP2D6		N/A	

APPENDIX A *(continued)*

III	Potassium channel blockade ± other means	Dofetilide (PO)	N/A or ↑	N/A or ↑	↑	• Requires ECG monitoring for initiation, dose titration, reinitiation, or introduction of new interacting agents • Requires renal dosing adjustments	• CYP3A4 (mild) • Trimethoprim, verapamil, and thiazide diuretics contraindicated • QT-prolonging drugs	——	↓	1–8
		Ibutilide (IV)				• Only indicated for cardioversion of AF or enhancement of electrical cardioversion	• QT-prolonging drugs	——		1–8
		Sotalol (PO/IV)				• Requires renal dosing adjustments • Bradycardia	• QT-prolonging drugs	1–3.2	↓	1–6
		Amiodarone (PO/IV)				• Monitor liver and thyroid function tests • Average half-life 53 days; highly lipophilic • Bradycardia • High protein binding	• Inhibits CYP3A4, CYP2D6, CYP2C9	1–2.5+	↑	< 1
		Dronedarone (PO)				• Avoid in persistent AF • Monitor hepatic function tests • Avoid in CHF, particularly NYHA class III/IV • Bradycardia	• Inhibits CYP3A4, CYP2D6, CYP2C9			< 1
IV	Calcium channel blockade	Verapamil (PO/IV)	↑	N/A	N/A	• Hepatic dosing • Sinus bradycardia • Negative inotrope – avoid in patients with systolic heart failure	• CYP3A4 (substrate and inhibitor)	——	↑	
		Diltiazem (PO/IV)				• Decreased dosing in elderly patients and patients with hepatic dysfunction • Bradycardia • Negative inotrope - avoid in patients with systolic heart failure	• CYP3A4 (substrate and inhibitor)	——	N/A	
Misc.	Others	Digoxin (PO/IV)	↑	N/A	N/A	• Junctional rhythms • Decreased dosing in elderly patients and patients with HF, renal dysfunction	• Many interactions	AF: 0.8–2 ng/mL CHF: 0.5–1 ng/mL Toxic > 2.5 ng/mL		
		Adenosine (IV)	↑			• Half-life < 10 s • Used for acute treatment of AV node reentrant tachycardias	• ——	——		
		Magnesium (IV)				• Used to treat TdP and cardiac glycoside-induced arrhythmias				

AF = atrial fibrillation; AV = atrioventricular; CHF = congestive heart failure; HF = heart failure; IR = immediate release; IV = intravenous(ly); MI = myocardial infarction; MOA = mechanism of action; N/A = not applicable; NYHA = New York Heart Association; PO = oral(ly); SR = sustained release; TdP = torsades de pointes.

For more than a decade, cardiologists have relied on the Contemporary Cardiology series to provide them with forefront medical references on all aspects of cardiology. Each title is carefully crafted by world-renown cardiologists who comprehensively cover the most important topics in this rapidly advancing field. With more than 75 titles in print covering everything from diabetes and cardiovascular disease to the management of acute coronary syndromes, the Contemporary Cardiology series has become the leading reference source for the practice of cardiac care.

Preface to the Second Edition

For any cardiovascular care provider, an understanding of physiology is absolutely essential for delivering patient care. Whether sitting in the echocardiography reading room, performing procedures in the catheterization laboratory, or rounding in the coronary care unit, such an understanding is equally vital. While the underpinnings of cardiovascular physiology from a systems perspective have changed little in recent time, there have been substantial advances in the ability to apply these concepts to newer technologies.

Our primary goal for this second edition of *Cardiovascular Hemodynamics: An Introductory Guide* is not only to expound on the fundamental education of cardiovascular physiology but also to focus additionally on the clinical application of these hemodynamic principles. In order to achieve this, we have updated all of the first edition chapters and have added a new section, "Effects of Selected Interventions on Cardiovascular Hemodynamics."

Born out of the huge economic burden of heart failure is an increased pressure on the healthcare system to decrease the often-avoidable readmissions for those patients with heart failure. We believe that a solid knowledge of heart failure physiology will arm those charged with the care of these patients with the tools necessary to decrease these costly readmissions. In addition, we have added another chapter, "Objective Evaluation of Hemodynamics in the Outpatient," that aims to familiarize the reader with the recent advancements (medical and technological) that have proven helpful with regard to optimizing patient care.

Of course, an emphasis on the basic tenets of cardiovascular physiology remains our central focus, and we use numerous figures, hemodynamic tracings, tables, board style review questions, and hemodynamic "pearls" in order guide our readers. We believe this manual will be of immense value and interest to every student and practitioner of cardiovascular medicine who wishes to fully learn the hemodynamic foundation of cardiovascular medicine.

Acknowledgment

We would like to acknowledge the authors, who, in many cases, were also mentors.

Contents

Part I Components of Myocardial Performance

1 Preload 3
Amanda R. Vest

2 Afterload 23
Amanda R. Vest

3 Contractility 41
Jordan S. Thomas and Justin M. Dunn

4 Cardiac Output 51
Daniel H. Katz, Frederick Heupler Jr., and Marwa A. Sabe

Part II Effects of Selected Interventions on CV Hemodynamics

5 Renin–Angiotensin–Aldosterone Axis Modulators and Other Vasodilators 61
Chirag Bavishi, Roberto Ramirez, and Franz H. Messerli

6 Beta Blockers and Calcium Channel Blockers 73
Alexandra-Maria Neagoe, Emrush Rexhaj, Ehud Grossman, and Franz H. Messerli

7 Pressor Agents, Pure Inotropes, Mixed Function Agents 89
Paul Anaya and Tracy E. Macaulay

8 Recently Approved Pharmacologic Agents to Improve Outcomes in Heart Failure 105
David C. Booth and Navin Rajagopalan

9 Mechanical Circulatory Support 117
Daniel H. Katz and Marwa A. Sabe

Part III Methods of Hemodynamic Evaluation

10 Key Clinical Findings 137
Sachin S. Goel and William J. Stewart

11 Echocardiography 155
Omeed Zardkoohi and Richard A. Grimm

12 CT and MRI Cardiovascular Hemodynamics 183
Andrew O. Zurick

13 Objective Evaluation of Hemodynamics in the Outpatient Setting 205
Gbolahan Ogunbayo and Ahmed Abdel-Latif

14 Cardiac Catheterization: Right- and Left-Heart Catheterization 221
Michael D. Faulx and Khaled M. Ziada

Part IV Specific Hemodynamically Compromised Situations

15 Tamponade 237
Olcay Aksoy, Begum Sezer, and Leonardo Rodriguez

16 Constrictive Pericarditis and Restrictive Cardiomyopathy 251
Chun Pong Wong and Allan Klein

17 Valvular Heart Disease 271
Amar Krishnaswamy and Brian P. Griffin

18 Pulmonary Hypertension 289
Jordan D. Awerbach and Richard A. Krasuski

19 Acute Decompensated Heart Failure 309
Andrew D. M. Grant, Michael A. Hanna, and Mazen A. Hanna

20 Intracardiac Shunts 325
Olcay Aksoy, Alper Ozkan, and E. Murat Tuzcu

21 Shock 337
Jose Mariano T. Tan and Michael P. Brunner

22 Intracoronary Hemodynamics 351

List of Figures

Fig. 1.1 Factors determining preload. (From Norton [*1*]) 4
Fig. 1.2 The cardiac cycle. (From Wikipedia: DanielChangMD revised original work of DestinyQx; Redrawn as Xavax) 5
Fig. 1.3 Average pressures within the chambers and great vessels of the heart. (From Iaizzo [*48*]). 6
Fig. 1.4 Example of a typical central venous pressure waveform. (From Atchabahian and Gupta [*49*]). The base of the "c" wave represents the onset of right ventricular contraction and is therefore the best estimate of the final right ventricular filling pressure and preload. 7
Fig. 1.5 Characteristic intracardiac pressure waveforms derived from the pulmonary artery catheter. (From Anesthesia UK, frca.co.uk) 9
Fig. 1.6 Example of a typical pulmonary capillary wedge pressure waveform. (From The ABCs of A to V: Right Atrial/Left Atrial (PCW) Pressures, CathLabDigest.com). Note the occurrence of the "*a*" wave of left atrial contraction shortly after the electrocardiographic "*P*" wave and the occurrence of the "*v*" wave after the electrocardiographic "*T*" wave. The "*v*" wave falling after the "*T*" wave can be of help when distinguishing a prominent "*v*" wave in pulmonary capillary wedge profile from the systolic deflection of a pulmonary artery waveform, which occurs before the "*T*" wave and means the catheter is not in the wedge position 10
Fig. 1.7 Examples of two patients with similar left ventricular end-diastolic pressures, but differing pulmonary capillary wedge pressures, with patient 1 showing better left atrial compensation for the elevated LVEDP. (From Reddy et al. [*50*]) 12
Fig. 1.8 Pressure–volume loop for a single cardiac cycle. (From Loushin et al. [*51*]). 13
Fig. 1.9 Effects of acutely increasing preload on the pressure–volume loop, to the point of maximal preload reserve. (From Ross [*52*] and Kaplan [*53*]). When the ventricle reaches the limit of preload reserve, it is unable to distend any further and the preload is fixed; at this point (loop 4), any further increases in afterload will lead to a reduction in stroke volume. 14

Fig. 2.1 The inverse relationship between afterload and cardiac performance. (Adapted from Sagawa [*31*]) 24
Fig. 2.2 Pressure-diameter relations for elastic and muscular arteries. (From Nichols and Edwards [*5*]). 26
Fig. 2.3 The effects of wave reflection on the systolic pressure profile. (From Chirinos and Sweitzer [*32*]). Wave separation analysis showing the contributions of the forward (green dashed line) and backward (red dotted line) pressure waves to the systolic pressure profile 27
Fig. 2.4 Factors determining afterload. (From Norton [*33*]) 28
Fig. 2.5 Effects of acutely increasing afterload on the pressure–volume loop. . *A* mitral valve opens, *B* mitral valve closure, *C* aortic valve opens, *D* aortic valve closure, *e* end-systolic pressure–volume relationship, *f* end-diastolic pressure–volume relationship (or ventricular elastance). The dotted loop represents the effect of increasing afterload. Panel b demonstrates the impact of afterload plus (dotted loop) increased preload, increased end-diastolic volume, and therefore preservation of stroke volume. (From Iaizzo [*19*]) 31
Fig. 2.6 The pressure–volume relationship and elastance. Increased elastance, as illustrated by the steeper diagonal slope, leads to smaller stroke volume. (From Bashore [*35*]). 32
Fig. 2.7 Conditions for afterload mismatch in systolic heart failure. (From Ross [*15*]). The stroke volume is seen to decrease (decreased width of the pressure–volume loop) as afterload increases 35
Fig. 3.1 Left ventricular pressure curves with tangents drawn to the steepest portions of the ascending limbs to indicate maximal dP/dt values. *Red*: Control. *Blue*: Hyperdynamic heart, as with norepinephrine administration. *Black*: Hypodynamic heart, as in cardiac failure. (Adapted from Berne and Levy [*1*], p. 313, Fig. 16.9) 42
Fig. 3.2 Left atrial, aortic, and left ventricular pressure pulses correlated in time with aortic flow, ventricular volume, heart sounds, venous pulse, and the electrocardiogram for a complete cardiac cycle. (Adapted from Berne and Levy [*2*], p. 313, Fig. 16.10). 43
Fig. 3.3 Schematic diagram of the movements of calcium in excitation–contraction coupling in cardiac muscle. The influx of calcium (Ca^{2+}) from the interstitial fluid during excitation triggers the release of Ca^{2+} from the sarcoplasmic reticulum. The free cytosolic Ca^{2+} activates contraction of the myofilaments (systole). Relaxation (diastole) occurs as a result of uptake of Ca^{2+} by the sarcoplasmic reticulum, by extrusion of intracellular Ca^{2+} by Na^{+}–Ca^{2+} exchange, and to a limited degree by the Ca^{2+} pump. (Adapted from Berne and Levy [*2*], p. 365). 44

Fig. 3.4 Organization of the thin filament in both the relaxed and excited states. In the relaxed state, the myosin-binding site on actin is covered by the troponin–tropomyosin complex. In the presence of elevated calcium (Ca^{2+}), the troponin–tropomyosin complex is pulled away from the myosin-binding site when Ca^{2+} binds to troponin, allowing the myosin cross-bridge to interact with actin. Hydrolysis of ATP causes a conformational change in the myosin molecule, which pulls the actin filament toward the center of the sarcomere. A new ATP binds to myosin causing the release of the cross-bridge. If Ca^{2+} levels are still elevated, the cycle repeats. If Ca^{2+} are low, relaxation results 45
Fig. 4.1 Relationship between cardiac output, preload, and contractility. (*SV* stroke volume, *LVEDP* left ventricular end-diastolic pressure, a measure of preload). (Adapted from http://scisense.com/education/cv-application.html) 52
Fig. 4.2 Thermodilution cardiac output curves. (Adapted from Braunwald et al. [*3*]) 55
Fig. 5.1 The renin–angiotensin–aldosterone system. Mechanism of action of ACEIs, ARBs, and DRIs 62
Fig. 5.2 Mean left ventricular pressure-volume loops at baseline and 1 year in patients randomized to placebo (panel A) and to enalapril (panel B) in SOLVD trial. At 1 year, there was a rightward shift in placebo group and leftward shift in enalapril group. (Reprinted from Konstam et al. with permission of the publisher) 63
Fig. 5.3 Plots showing ascending aorta pressure waveforms (top) along with their forward (bottom left) and backward (bottom right) components in a representative normotensive (solid line) and hypertensive patient (dashed line). After captopril infusion (dotted line), attenuation of the higher backward wave and prominent late systolic peak in hypertensive patient was seen. (Reprinted from Ting et al. with permission of the publisher) 64
Fig. 5.4 Sequential left ventricular pressure-volume loops after administration of sodium nitroglycerine showing with leftward and downward shift due to changing loading conditions. (Reprinted from McKay et al. with permission of the publisher) 68
Fig. 5.5 Schematic diagram of mechanism of action of hydralazine and Isosorbide dinitrate 69
Fig. 6.1 Evolution of CCBs 79
Fig. 6.2 Effect of CCBs on hemodynamics 79
Fig. 6.3 Odds ratios for fatal and nonfatal stroke (left) and fatal and nonfatal myocardial infarction (right) in relation to corresponding differences in systolic blood pressure. Odds ratios were calculated for the amlodipine group vs placebo or other classes of antihypertensive drugs including ARBs

(dots) or for the angiotensin receptor group vs placebo or other classes of antihypertensive drugs including amlodipine (squares). Blood pressure differences were obtained by subtracting the mean change in the amlodipine or ARB group from the corresponding mean change in the reference group. When a group of trials was pooled, the blood pressure difference was calculated by averaging the between-group blood pressure difference within each trial with the number of randomly assigned patients as weighting factor. Positive values indicate tighter blood pressure control in the experimental group. The regression line was drawn for trials involving an amlodipine group and weighted by the inverse of the variance of the individual odds ratios [*105*] 82

Fig. 7.1 The Frank-Starling curve as it applies in cardiac hemodynamics depicts the relationship between preload and stroke volume or cardiac output 89

Fig. 7.2 The effects of afterload and intrinsic LV contractility on the Frank-Starling relationship 90

Fig. 7.3 The pressure-volume relation depicts the volumetric and pressure changes that occur through a single cardiac cycle. As is illustrated, the phases of the cardiac cycle include diastole (or filling phase) which begins at the time of mitral valve opening, isovolumetric contraction defined as the time from mitral valve closure until aortic valve opening, systole (or ejection phase) which begins at the time of aortic valve opening, and isovolumetric relaxation defined by the time between aortic valve closure until mitral valve opening heralds the next diastolic phase. Stroke volume is defined as the difference between the volume contained within the ventricle at end diastole and the volume contained at the end of ejection 90

Fig. 7.4 By altering preload, a series of pressure-volume loops can be generated. These can be used to define ventricular end-systolic elastance (LV E_{es}). This end-systolic pressure-volume linear relation is generally accepted as a measure of LV contractility with steeper slopes indicating greater contractility and less steep slopes indicating reduced contractility. Similarly, a linear relationship between the end-systolic pressure-volume point and the end-diastolic pressure–volume point defines arterial elastance (Ea) from which the LV afterload is derived. Black = diastolic and systolic phases of the cardiac cycle; blue = isovolumetric phases; red = LV elastance (LV contractility); green = arterial elastance (afterload) 91

Fig. 7.5 Hemodynamic effects of vasodilators. A reduction in afterload is depicted as a downward shift in the arterial elastance ($E_{a1} \rightarrow E_{a2}$) and a decrease in the end-systolic pressure. This results in an increase in the stroke volume

(SV2 > SV1). Vasodilators do not affect the LV contractility. Black = baseline hemodynamic profile; red = hemodynamic profile after intervention 91
Fig. 7.6 The hemodynamic effect of inotropes. The net effect is a leftward shift in the end-systolic pressure-volume relation (LV end-systolic elastance ($E_{es1} \rightarrow E_{es2}$)) indicating augmented contractility, which results in improved cardiac performance as indicated by the increased stroke volume (SV2 > SV1). Black = baseline hemodynamic profile; red = hemodynamic profile after intervention 95
Fig. 7.7 Hemodynamics of catecholamine vasopressor agents. The actions of catecholaminergic vasopressors result in improved contractile function denoted by the slightly leftward shift in the end-systolic pressure-volume relation ($E_{es1} \rightarrow E_{es2}$). However, the dominant effect from these agents is peripheral vasoconstriction leading to an increase in afterload ($E_{a2} > E_{a1}$). Depending on the inotropic effect that these agents confer in comparison to the increased afterload, stroke volume might be expected to increase although to a lesser extent as compared to pure inotropic agents, remain unchanged, or in the setting of an overwhelming increase in afterload, actually decrease (SV1 ≈ SV2). These agents are therefore best suited in cases of vasodilatory shock where their effect in maintaining adequate tissue perfusion pressure is required. Black = baseline hemodynamic profile; red = vasopressor effect; pink = arterial elastance (afterload) at baseline; blue = arterial elastance (afterload) vasopressor effect. 96
Fig. 7.8 Hemodynamics of pure vasoconstrictors. These agents act primarily to increase the systemic vascular resistance resulting in an upward shift of the pressure-volume relationship. The increase in afterload does not affect intrinsic contractile function but does result in an increase in the end-systolic blood pressure, increased LV end-diastolic pressure, and an increase in the LV afterload ($E_{a1} \rightarrow E_{a2}$). The combined effects result in elevated myocardial oxygen demand and a reduced stroke volume (SV2 < SV1). Therefore, while systemic blood pressure is improved, it comes at the expense of the cardiac output. Black = baseline hemodynamic profile; red = vasoconstrictor effect; pink = arterial elastance (afterload) at baseline; blue = arterial elastance (afterload) vasoconstrictor effect 97

Fig. 8.2 Ivabradine's primary mechanism of action on cardiac tissue is on the sinoatrial (SA) node, which occupies a predominantly subepicardial position at the junction of the superior vena cava (SVC) and the right atrium (RA). (**a**) Heart with position of the Sinoatrial (SA) node. (**b**) In the sinoatrial node, ivabradine blocks the intracellular aspect of the hyperpolarization-activated cyclic nucleotide-gated (HCN) transmembrane channel, which is responsible for the transport of sodium (Na^+) and potassium (K^+) ions across the cell membrane, in the open state. This results in the inhibition of the inward funny current ($\mathbf{I_f}$), which is specifically activated at hyperpolarized membrane potentials. (**c**) By selectively inhibiting $\mathbf{I_f}$, there is a reduction in the slope of diastolic depolarization of the pacemaker action potential (shaded region) and an increase in the duration of diastole, without altering other phases of the action potential. This results in heart rate reduction. Ao aorta, IVC inferior vena cava, PA pulmonary artery, RV right ventricle. (PMID:28958335) 110
Fig. 8.3 Approval timeline of ivabradine across Europe and the United States. The indications for the use of ivabradine have evolved over time and differ based on region. Since it was first approved for use in angina by the European Medicines Agency (EMA) in 2005, the findings of several randomized controlled trials have resulted in expanded indications to include select heart failure patients and only recent approval by the US Food and Drug Administration (FDA) for this indication. Fig. 9.2 (**a**) The standard pressure-volume loop for a normal heart is shown. The process from point A to point B represents isovolumic contraction where pressure increases without a change in volume. The aortic valve opens at B and ejection occurs with a drop in volume. Ejection occurs until point C when the aortic valve closes, which is followed by isovolumic relaxation to point D. The mitral valve opens at point D and the left ventricle fills. (**b**) In an acute insult, the systolic function of the heart weakens and the ESPVR decreases in slope. This results in a smaller volume of ejection and dilation of the ventricle overall. (**c**) Highlights the components of the pressure-volume area (PVA), which is made up of the stroke work (SW) and the potential energy (PE). (**d**) Shows the change in PE and SW when there is an acute insult to the heart. (Adapted from Uriel et al. JACC 2018 with permission [*2*]) 118
Fig. 9.3 (**a** and **b**) The Intra-aortic balloon pump is peripherally inserted in the descending aorta under fluoroscopy. It inflates during diastole and deflates during systole. (**c**) Diagram of the IABP's effects on systemic blood pressure. When the balloon inflates during diastole, it augments the diastolic pressure, ideally above the normal (unassisted) systolic pressure. Then, with deflation during systole, the systolic pressure is reduced slightly below what it is normally. This is referred to as the assisted systolic pressure. (**d**) Pressure-volume loop with insertion of the IABP is shown in green. Note that with reduction in the afterload, the aortic valve opens at a lower pressure and there is greater volume of ejection. (Reproduced with permission from Briceno et al. [*8*]) 120
Fig. 9.4 (**a** and **b**) The Impella is inserted fluoroscopically across the aortic valve. (**c**) The Impella directly unloads the LV into the aorta. (**d**) The resulting pressure-volume loop (purple) reflects the unloading of the Impella, as the left ventricular end-diastolic volume significantly decreases. Note that the loop reflects a lower LV stroke volume; however, overall global cardiac output is supported by the Impella. (Reproduced with permission from Briceno et al. [*8*]) 122

Fig. 9.5 (**a** and **b**) The TandemHeart is placed percutaneously under fluoroscopic guidance. (**c**) The inlet cannula advances up the femoral vein to the right atrium, and crosses to the left atrium, where it drains blood and reduces LV preload. (**d**) Hemodynamic benefits include reduction in preload and reduction in the left ventricular end-systolic volume. Note that the TandemHeart increases afterload on the LV by delivering blood to the femoral artery (Reproduced with permission from Briceno et al. [*8*]). 123
Fig. 9.6 (**a**) The CentriMag is a high flow centrifugal pump. (**b**) The CentriMag can pump blood from the right atrium to the pulmonary artery or the left atrium to the aorta. Other configurations are possible. (Images reproduced with permission from Abbott Laboratories) 124
Fig. 9.7 Three possible configurations for VA ECMO. The heart pump and the oxygenator connect a venous inflow to an arterial outflow. Configurations include (**a**) femoral vein to femoral artery, (**b**) right atrium to aorta ("central cannulation"), or (**c**) right internal jugular vein to right subclavian artery. Fig. 10.1 Hemodynamic profiles in ADHF. Evidence for *congestion* (the "yes-no" delineation of the two columns) includes orthopnea, elevated JVP, hepatojugular reflux, S3, rales, hepatomegaly, ascites, peripheral edema, and a loud P2. Evidence *for low perfusion* (the "yes-no" delineation of the two rows) includes narrow pulse pressure, cool and clammy extremities, altered mentation, and oliguria 138
Fig. 10.2 Behavior of the nonejection click (C) and systolic murmur of mitral valve prolapse. The top panel shows the first heart sound (S1), the mid-systolic click (C), and the second heart sound (S2), with the late systolic murmur of moderate mitral regurgitation while the patient is supine. With standing, (middle panel) venous return decreases, the heart becomes smaller, and the prolapse occurs earlier in systole. The click and murmur move closer to S1. With squatting, (lower panel) venous return increases, causing an increase in left ventricular chamber size. The click and murmur occur later in systole and move away from S1. (From Shaver et al. [*27*]) 139
Fig. 10.3 Jugular venous waveform patterns – (**a**) normal patients, (**b**) (constrictive pericarditis), (**c**) pericardial tamponade and (**d**) (severe tricuspid regurgitation) (TR). JVP jugular venous pressure, S1 first heart sound, S2 second heart sound. The A, C, and V positive waves, and the X and Y negative waves, are explained in the text 140
Fig. 10.4 Measurement and mechanism of pulsus paradoxus (**a**) The examiner inflates the sphygmomanometer cuff fully, listens for Korotkoff sounds as the cuff is slowly deflated, and then notes the pressure at which Korotkoff sounds are initially audible only during expiration. As the cuff is further deflated, the examiner notes the pressure at which Korotkoff sounds become audible during expiration and inspiration. The difference between these two pressures is the pulsus paradoxus, which can normally be from 0 to 10 mm Hg. In cardiac tamponade, the pulsus paradoxus measures greater than 10 mm Hg. Inspiratory diminution in the arterial blood pressure tracing represents the pulsus paradoxus. A similar phenomenon may be observed on a pulse oximeter waveform. (**b**) During inspiration in the normal heart, negative intrapleural pressures increase venous return to the right ventricle and decrease pulmonary venous return to the left ventricle by increasing the pulmonary reservoir for blood. As a result of increased right ventricular distention, the interventricular septum bows slightly to the left, and the filling and stroke volume of the left ventricle are mildly reduced. In expiration, these changes are reversed, resulting in the septum bowing to the right and a mild reduction in right ventricular filling. In the

presence of cardiac tamponade, the reciprocal changes seen in the normal heart are exaggerated when the pericardial sac is filled with fluid, thus limiting distensibility of the entire heart. This results in a more dramatic reduction in filling of the left ventricle during inspiration, exacerbating the normal inspiratory decrease in stroke volume and blood pressure. (From Roy et al. [*28*]) 142

Fig. 10.5 Relationship of murmurs to LV, aortic, and LA pressure waveforms and hemodynamics in various valve diseases. (**a**) *Aortic stenosis (AS).* The gradient between the left ventricle and aorta in AS is greatest in mid-systole and is relatively small early and late in systole. The murmur therefore has a diamond shape, i.e., starts soft and builds to a peak in mid-systole and then becomes quiet in late systole immediately before S2. In young AS patients, there may be an early ejection sound. In senile AS, A2 becomes diminished or absent. An S4 is common due to LV noncompliance. (**b**) *Aortic regurgitation (AR)*. The early diastolic murmur (EDM) begins with S2 and has a decrescendo contour. The duration of the murmur continues for a variable time in diastole, depending on severity and acuity of AR. Notice that aortic diastolic pressure is low. (**c**) *Mitral regurgitation*. There is a pansystolic murmur with a flat profile due to the regurgitant flow into the left atrium. Note that the left atrial pressure rises during systole, a "v" wave. An early diastolic S3 or flow rumble may occur. (**d**) *Mitral stenosis (MS)*. A loud S1 is heard since the mitral gradient is high and the leaflets are not very thickened or calcified. An important indicator of the severity of MS is the time interval between the S2 and opening snap (OS), which is the time it takes for LV pressure to fall from late systolic aortic pressure to early diastolic left atrial pressure. The mitral valve snaps open due to the increased gradient, causing an opening snap (OS). The diastolic murmur correlates with the gradient across the mitral valve, which is largest in early diastole, and increases again in late diastole in this patient in sinus rhythm 144

Fig. 11.1 The Doppler principle and Bernoulli equation. *Bottom right*: The echo transducer sends ultrasound waves at a given frequency (f_0) to the heart, and the sound waves are reflected back to the transducer at a different frequency (f_r). The difference between (f_0) and (f_r) is the *Doppler shift*. As shown in the equation, the Doppler shift is directly proportional to the transmitted frequency (f_0), the cosine of the angle of incidence θ (angle between the ultrasound wave and vector of the red blood cell), and the velocity of the red blood cells, however, is inversely proportional to the

speed of ultrasound in the medium (c). Rearrangement of the equation allows one to determine the velocity of the red blood cells. *Top right*: The Bernoulli equation enables one to determine the pressure gradient across a stenosis, in this case, a stenotic aortic valve. Flow accelerates just before and at the level of the stenosis. The velocity proximal to the stenosis is V_1, and the velocity distal to the stenosis is V_2. Based on certain assumptions (see text), the Bernoulli equation can be simplified to $P1 - P2 = \Delta P = 4(V_2)^2$. In this case, the peak gradient is 64 mmHg based on the peak velocity across the aortic valve (V_2) of 4 m/s. Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2011 156

Fig. 11.2 Various forms of Doppler in echocardiography. (**a**) Pulse wave (PW) Doppler of the mitral inflow with the sample volume placed at the leaflet tips. In PW, the same transducer crystal sends and receives waves to determine the Doppler shift at a particular sample volume, marked by the *white arrow*. Because PW obtains information about a particular location, it is said to have "range specificity or range resolution," but it is prone to aliasing. Note that in diastole there is early filling (E wave) and Late Filling (A wave). Diastasis is known as the period between the E and the A wave. The E velocity is 68 cm/s. (**b**) Continuous wave (CW) Doppler across the aortic valve. In CW, one crystal sends sound waves continuously and another crystal receives the sound waves. Because the CW profile represents all the velocities along the path of interrogation (represented by the *dotted line*), the peak velocity cannot be localized based on the CW signal alone. This phenomenon is known as "range ambiguity." The y axis is velocity and the x axis is time, and therefore the area under the curve is the velocity time integral (VTI), or the aortic valve VTI, in units of distance (cm). In this example, the peak velocity is 1.3 m/s and the Aortic Valve VTI is 22 cm. (**c**) Tissue Doppler of the mitral annulus characterizes annular velocities, with the corresponding annular e' and a' waves. These waves correspond temporally with the E and A waves of the mitral inflow. Because $E = 68$ cm/s and $e' = 13$ cm/s, the ratio E/e' is roughly 5, suggesting normal PCWP pressures. (**d**) Color Doppler in which the color pixels represent the mean velocity vector at a particular location 157

Fig. 11.3 Right-sided pressures. (**a**) M-mode through the IVC from the subcostal view. Note that the IVC size is <2.1 cm and collapses greater than 50%, suggesting normal right atrial pressure (0–5 mmHg). (**b**) Pulse wave (PW) Doppler of the hepatic vein showing normal hepatic vein flow. Note that

there are two antegrade waves (*S* and *D*) and one retrograde wave (*a* reversal). The representative portions on the JVP waveform are shown (*S* corresponds to the *x* descent, and *D* corresponds to the *y* descent). The onset of the *S* wave corresponds to the onset of the QRS (isovolumic contraction), although the peak occurs in mid to late systole. In this example, the velocity of the *S* wave is larger than the *D* wave, indicating normal right atrial pressures. (**c**) A plethoric IVC greater than 2.1 cm in width which does not collapse, suggesting a right atrial pressure between 10 and 20 mmHg. (**d**) Systolic flow reversal in the hepatic veins in severe tricuspid regurgitation. Notice that the *S* wave is above the baseline, indicating flow reversal. This corresponds to the blunted *x* descent and tall *v* wave in the JVP waveform. 160

Fig. 11.4 Pulmonary pressures and signs of pulmonary hypertension. (**a**) The right ventricular systolic pressure can be estimated from the peak tricuspid regurgitation velocity obtained in the right ventricular inflow view (*see Question 1*). (**b**) The continuous wave (CW) Doppler profile of the pulmonary regurgitation jet. The early peak velocity can be used to determine the mean pulmonary artery (PA) pressure by the following formula: Mean PA Pressure = $4v_{\text{EarlyDPR}}^2$. In this case, early pulmonary regurgitation (PR) jet velocity is 3.9 m/s and the end-diastolic PR velocity is 1.9 m/s. Therefore, the mean PA pressure is roughly 39 mmHg. Also, the pulmonary artery end-diastolic pressure (PAEDP) can be determined from the end-diastolic velocity and estimated right atrial (RA) pressure: PAEDP = RA + $4v_{\text{EDPR}}^2$ (*see Question 2*). Note that in pulmonary hypertension, there is absence of the typical end-diastolic dip in the pulmonary regurgitation CW profile that normally corresponds to atrial systole. (**c**) The sample volume is in the RVOT, just below the pulmonic valve. In pulmonary hypertension, there is a steep slope in early systole (acceleration phase becomes shorter, *upper left corner*) and there can be a mid-systolic dip in the RVOT profile (*yellow stars*), due to high afterload. A simplified formula to calculate the mean pulmonary artery pressure (MPAP) is MPAP = 80 − 0.5 (acceleration time (ms)). Acceleration time is roughly 90 ms, yielding a MPAP of 35 mmHg. (**d**) Note the D-shaped septum during systole, suggestive of RV pressure overload 161

Fig. 11.5 Stroke volume and aortic valve area (AVA) calculation using the continuity equation. (**a**) Based on the continuity equation, the flow through the left ventricular outflow tract (LVOT), or the volume of the *blue cylinder*, must equal the flow through the aortic valve, or the volume of

the *red cylinder*. The stroke volume (represented by the *blue cylinder*) is estimated by multiplying the LVOT area by the LVOT VTI. The LVOT area is obtained using the equation Area = πr^2 = (Diameter)^2∗0.785, with the diameter measured in the parasternal long axis view. Because the LVOT diameter in this case is 1.9 cm, the LVOT area is 2.84 cm^2. From the apical 5 chamber or apical long axis view, the LVOT VTI is obtained, which in this case is 28.1 cm (*bottom right* and (**b**)). Therefore, the stroke volume = 28.1 cm∗2.84 cm^2 = 79.8 cm^3. The product of the stroke volume and the heart rate (SV∗HR) can give an estimate of cardiac output. The volume of the *red cylinder* is the product of the AVA and the AV VTI (**c**, **d**). Because the volume of the *blue cylinder* (LVOT Area∗LVOT VTI) must equal the volume of the *red cylinder* (AVA∗AV VTI) to satisfy the continuity equation, it follows that AVA = [LVOTVTI ∗ (LVOTdia meter)^2 ∗ 0.785]/[AVVTI] = Strokevolume/AVVTI (*see Question 3*). (**b**) Pulse wave Doppler Sample volume is placed just below the aortic valve in the 5 chamber view, and the LVOT VTI is traced. (**c**) Continuous wave Doppler measures the highest velocity along its path to estimate the peak and mean gradient across the aortic valve. The peak and mean gradients are 95/55 mmHg from the 5 chamber view, which is an underestimation of peak flow in this particular patient. Multiple views are necessary to obtain the highest, most representative jet velocity, as seen in (**d**). Right sternal border view obtains peak and mean gradients of 119/74 mmHg, higher than the peak gradient of 95 mmHg from the apical 5 chamber view 164

Fig. 11.6 Shunt calculation in a patient with a secundum atrial septal defect (ASD). (**a**) Color flow Doppler demonstrates left to right flow across the ASD in this subcostal view. (**b**) Pulse wave Doppler at the level of the ASD confirms that there is left to right continuous flow. During peak systole, based on the velocity of 1.2 m/s, the pressure gradient between the right atrium (RA) and the left atrium (LA) is $4v^2 = 4(1.2)^2 = 5.8$ mmHg. The RA pressure was estimated at 10 mmHg, so the LA pressure during systole is estimated at 15.8 mmHg (LA = RA + $4v^2$). (**c**) Measurement of systemic flow (Q_s) based on the LVOT area and LVOT VTI (pulse wave Doppler from the apical 5 chamber view, *right upper corner*). (**d**) Measurement of pulmonary flow (Q_p) based on the RVOT area and the RVOT VTI (pulse wave Doppler from the basal short axis view, *right upper corner*). The Q_p/Q_s or shunt fraction is 1.3:1 (*see Question 4 for calculation of Q_p, Q_s, and shunt fraction*) 165

Fig. 11.7 Assessment of mitral stenosis. (**a**) Continuous wave Doppler across the mitral valve yields the peak and mean gradient (14/7 mmHg). Given the irregular heart rhythm, 6–8 beats are measured and averaged to obtain the peak and mean gradient. (**b**) The pressure half-time (PHT) is the time for the pressure gradient to decrease by 50%, and is equal to 0.29∗Deceleration time. Again, multiple beats are averaged (6–8) to obtain the PHT of 214 ms. The mitral valve area (MVA) is estimated by the following empiric equation: MVA = 220/PHT, giving a MVA of 220/214, or 1.0 cm^2, by the PHT method. (**c**) Calculation of MVA using the continuity equation. The flow across the mitral valve must equal the flow across the aortic valve, and therefore, MVA ∗ MVVTI = LVOTarea ∗ LVOTVTI. In this case, the LVOT diameter is 1.9 cm, the LVOT VTI is 20 cm, and the MV VTI is 56.4 cm. Therefore, the calculated MV area is 1.0 cm^2. Note that the MV VTI is measured using CW and the LVOT VTI is measured using PW in this situation. (**d**) Planimetry is another method of estimating the MVA. Note the commissural fusion and "fish-mouth" appearance of the mitral opening, characteristic of rheumatic mitral valve disease. In this example, planimetry yields a MVA of 1.0 cm^2, concordant with the PHT and continuity methods . . . 169

Fig. 11.8 PISA (proximal isovelocity surface area) method for mitral regurgitation and vena contracta. (**a**) Artistic rendition of the PISA concept. As flow converges during systole toward the regurgitant orifice, it accelerates and forms concentric hemispheres of increasing velocity and decreasing radius. For example, the velocity at the edge of the *yellow hemisphere* is higher than the velocity at the edge of the *blue hemisphere*. First the image should be optimized and zoomed. Next, the color baseline is shifted downward toward the direction of flow, from −65 to −40 cm/s, creating the *larger yellow hemisphere* with a lower velocity on the right. The velocity at the boundary between the *yellow* and *blue hemisphere* is the aliasing velocity (V_a = −40 cm/s). The flow proximal to the orifice equals the product of the hemisphere surface area ($2\pi r^2$) and the aliasing velocity (V_a). This proximal flow should equal the flow distal to the orifice, which is the product of the regurgitant orifice area (EROA) and peak MR velocity (V_{MR}). Therefore, EROA = $(2\pi r^2 * V_a)/V_{MR}$. (**b**) Similar to *panel A*, after creating a zoomed-in image, the color baseline is shifted toward the direction of flow, and a larger hemisphere with a known radius (0.8 cm) and aliasing velocity (V_a = 38.5 cm/s) is created. Based on the above equation, the proximal flow rate is 154.7 cm^3/s. (**c**) Continuous wave Doppler across the mitral valve to obtain

the peak mitral regurgitant velocity (V_{MR}) = 416 cm/s and MV VTI. The distal flow rate is V_{MR}∗EROA. The EROA, which is equal to $(2\pi r^2 * V_a)/V_{MR}$, is 0.37 cm^2, consistent with moderately-severe MR. Regurgitant volume can be calculated with the information in this figure (*see Question 5*). Using the simplified PISA formula, $r^2/2$, estimated EROA is 0.32 cm^2, likely slightly underestimated because the aliasing velocity is 38.5 cm/s, not the 40 cm/s assumed in the simplified formula. (**d**) The vena contracta, the narrowest jet width at the orifice, measured in the parasternal long axis view, is 0.6 cm, consistent with moderately-severe MR 173

Fig. 11.9 Severe aortic insufficiency (AI). (**a**) Parasternal long axis view color Doppler demonstrates a very severe, eccentric, and posterior directed jet. Note that the M-Mode across the mitral leaflet shows fluttering of the anterior leaflet due to the aortic insufficiency jet (*lower left corner inset*). Given the eccentricity, one cannot use the LVOT jet area to assess severity. (**b**) Pulse wave Doppler with sample volume in the upper descending thoracic aorta, demonstrating holodiastolic flow reversal, a sign of severe AI. (**c**) Continuous wave Doppler across the aortic valve in the apical 5 chamber view. The PHT is 253 ms, consistent with severe AI. The aortic insufficiency VTI is 232 cm based on the CW profile. (**d**) Application of the continuity equation allows for the calculation of the regurgitant AI volume. Flow across the mitral valve plus the regurgitant volume should equal the flow across the aortic valve (Stroke volume). The MVA is determined by measuring the mitral valve diameter, and this area (5.3 cm^2) is multiplied by the MV VTI at the annulus (19 cm) to yield a flow of 101 cm^3. Flow across the aortic valve is determined by the product of the LVOT VTI and LVOT area, which yields a volume of 169 cm^3, calculation not shown. Therefore, the aortic insufficiency regurgitant volume is 169 cm^3 – 101 cm^3 = 68 cm^3, consistent with severe AI. The regurgitant orifice area (EROA) of the aortic valve is calculated by dividing the regurgitant volume (68 cm^3) by the AI VTI (232 cm), which equals 0.3 cm^2, also consistent with severe AI. 175

Fig. 11.10 Summary of intracardiac pressure calculations. RA right atrial pressure, IVC inferior vena cava, RVSP right ventricular systolic pressure, V_{TR} peak tricuspid regurgitation velocity, PASP pulmonary artery systolic pressure, RVOT right ventricular outflow tract, PS pulmonic stenosis; PAEDP pulmonary artery end-diastolic pressure, V_{EDPR} end-diastolic pulmonary regurgitation velocity, PAP pulmonary artery pressure, $V_{EarlyDPR}$ early diastolic pulmonary regurgitation velocity, PVR pulmonary vascular

resistance, VTI velocity time integral, LVOT left ventricular outflow tract, D diameter, LA left atrial pressure, SBP systolic blood pressure, V_{MR} peak mitral regurgitation velocity, PCWP pulmonary capillary wedge pressure, LVEDP left ventricular end-diastolic pressure, DBP diastolic blood pressure, V_{EDAI} end-diastolic aortic insufficiency velocity, SVR systemic vascular resistance, Q_p pulmonary flow, Q_s systemic flow. Fig. 12.1 (**a**) Cardiac amyloidosis. Image at *top* are from representative phase-contrast image demonstrating manual contouring of the ascending aorta, superior vena cava, and right upper pulmonary vein. Flow curves in *upper left panel* demonstrate systolic blunting consistent with diastolic dysfunction. Images at *bottom* demonstrate tissue characterization of myocardium in cardiac amyloidosis, with associated circumferential pericardial effusion, through multiple different cardiac MRI pulse sequences. (**b**) Hypertrophic cardiomyopathy with severe systolic anterior motion of the mitral valve (SAM). Representative phase-contrast image (*top*) demonstrating manual contouring of the left ventricular outflow tract. Contours are propagated to images from multiple cardiac phases. Image at *bottom left* represents single cardiac-phase magnitude gradient echo image at end-systole. Peak left ventricular outflow tract velocity can be measured and converted to pressure gradient through utilization of modified Bernoulli equation . . 186

Fig. 13.2 Relationship between LVEDP and impedance. Data shown are for impedance recorded by left ventricular (LV) r–Can in 12 dogs. Correlation coefficient is calculated using Spearman rank order. (Adapted from Khoury et al. [*36*]). 209
Fig. 13.3 Relationship between LA pressure and Impedance. Data shown are for impedance recorded by left ventricular (LV) r–Can in 1 dog at different time points of the experiment. Correlation coefficient is calculated using Spearman rank order. (Adapted from Khoury et al. [*36*]) 210
Fig. 13.4 Tetrapolar system of electrodes, separating the current pathway from the sensing pathway. After transmitting electricity by way of the outer electrodes, the impedance to flow of the current through the thorax along the path of least resistance (i.e., the great vessels) is sensed by way of the inner electrodes. (Adapted from Summers et al. [*39*]) 210
Fig. 13.5 Definition of cardiac and impedance waveforms during the cardiac cycle. *Waveforms* Z_0 baseline impedance, A atrial wave, Baortic valve opening, Cmaximum aortic flow (dZ/dt_{max}), X aortic valve closing, Y pulmonic valve closing, O mitral valve opening, PEP pre-ejection period, VET ventricular ejection time, IVRT isovolumic relaxation time, FT ventricular filling time. (Adapted from Summers et al. [*39*]) 211
Fig. 13.6 Operational algorithm for detecting changes in impedance over time. (**a**) Differences between measured impedance (bottom; o) and reference impedance (solid line) are accumulated over time to produce fluid index (top). Threshold is then applied to fluid index to detect sustained decreases in impedance. (**b**) Example of impedance reduction before heart failure hospitalization (arrow) for fluid overload and impedance increase during intensive diuresis during hospitalization. Label indicates reference baseline (initial reference impedance value when daily impedance value consistently falls below the reference impedance line before admission). Magnitude and duration of impedance reduction are also shown. Days in hospital are shaded. (Adapted from Yu et al. [*34*]). 213
Fig. 13.7 Overview of aortic flow as a function of time and its use to measure cardiac hemodynamics. The basic principle of stroke volume (SV) estimation from changes in the bioimpedance ($\delta Z/\delta t$) or phase shift ($\delta\Phi/\delta t$). 215

Fig. 14.1 Harmonics in hemodynamic assessment. The aortic pressure waves shown at the bottom are composed of simpler sinusoidal harmonic waves. Each harmonic is a multiple of the fundamental frequency, in this case 1.5 Hz. The data contained within each harmonic contributes in some way to the reconstructed waveform, depicted in this illustration by color. Exclusion of one or more harmonics by a monitoring system can produce a distorted, inaccurate pressure tracing 222

Fig. 14.2 (**a**) Catheter whip in a pulmonary artery (PA) pressure tracing. Whip occurs when the catheter tip vibrates in response to ventricular contraction or valvular motion. Whip causes high-frequency distortion of the waveforms, particularly at the high and low points of the complex. Since the extremes of the waveform are equally affected, the mean pressure obtained from a "whipped" tracing is generally accurate. Whip can be attenuated by catheter repositioning, the use of a high-frequency filter, or increased damping. (**b**) Damping-related artifacts. Overdamping results in a flat, low-amplitude waveform that lacks contour detail. Overdamping can be caused by catheter kinking, air bubbles or blood in the transducer circuit, and the use of long, small-caliber catheters. It can be overcome by removing kinked tubing, flushing of the catheter and manifold, and use of shorter, large-caliber catheters. Under-damping produces exaggerated waveforms with overestimated amplitudes. It occurs when the natural frequency of the catheter system approximates a harmonic frequency in the pressure wave. This can be offset by lowering the natural frequency of the catheter system (longer, smaller-caliber catheters) or the patient (treat tachycardia). (**c**) Positional artifact. This is characterized by flattening of the pressure tracing with a gradual rise in pressure. It most often occurs when the catheter tip is pressed against the wall of a vessel or chamber. Gentle withdrawal and redirection of the catheter typically solves the problem. (**d**) Transducer malposition. In this example, the true mean right atrial pressure is 10 mmHg. When the transducer is zeroed at a level 5 cm below the sternal angle the catheter recording is accurate. When the transducer is zeroed at a level above the chest, the pressure is underestimated. When the transducer is zeroed at a level well below the right atrium, the pressure is overestimated. (**e**) Respiratory variation of right atrial pressure. The thin-walled right-sided chambers are subject to respiratory variation, particularly in subjects with underlying obstructive lung disease. Pressure measurements taken during a

few seconds of breath holding at the end of normal expiration (when intrathoracic pressure is theoretically zero) are much less variable 224
Fig. 14.3 Schematic representation of the major electrical and mechanical events during the cardiac cycle: (**a**) atrial contraction; (**b**) isovolumic contraction; (**c**) rapid ejection; (**d**) reduced ejection; (**e**) isovolumic relaxation; (**f**) rapid ventricular filling; and (**g**) reduced ventricular filling 228
Fig. 14.4 (**a**–**f**) Normal cardiac pressure tracings. Descriptions of each tracing are found within the chapter text. (**g**) Abnormal pressure tracing obtained during selective coronary angiography. In the presence of severe ostial stenosis, the endhole catheter transmits a distorted waveform due to the reflected coronary wedge pressure and appears as a hybrid between aortic and ventricular pressure (ventricularized pressure) waveform 228
Fig. 14.5 Diagram of the pulmonary capillary wedge technique 230
Fig. 14.6 Estimating the transaortic pressure gradient. The pressure waves produced by simultaneous catheterization of the left ventricle and proximal ascending aorta are superimposed. The shaded area under the curve (AUC) is calculated, providing the mean transvalvular gradient 233
Fig. 15.1 ECG demonstrating electrical alternans 238
Fig. 15.2 Echocardiogram with Doppler evaluation demonstrating respiratory flow variation across mitral (**a**) and tricuspid valves (**b**) 238
Fig. 15.3 Pre-pericardiocentesis (**a**) and post-pericardiocentesis (**b**). (Reprinted from modification by LeWinter [*9*]) 239
Fig. 15.4 Intrapericardial pressure that is critical in determining the transmural pressure is affected by the time course of fluid accumulation. Rapidly developing effusions reach the limits of the pericardial stretch sooner, whereas slowly developing effusions are better tolerated due to the time allowed for the pericardium to adapt to the changes imposed by the effusion. (Adapted from Spodick [*10*]) 241
Fig. 15.5 Stages of pericardial tamponade showing pressures in the right atrium, right ventricle, pulmonary capillary wedge pressure, and intrapericardium (peri pericardium, RV right ventricle, LV left ventricle, CO cardiac output, IFASP inspiratory decrease in arterial systolic pressure). Initial concept and its revision with further data are shown below detailing changes in the pressures across stages of tamponade. (Adapted from Reddy et al. [*3*]) 242
Fig. 15.6 *Top panel* showing tricuspid and *bottom panel* showing mitral valve inflow pattern 245
Fig. 15.7 Hepatic vein tracing showing flow to the atrium predominantly during systole and blunted return in diastole. After pericardiocentesis, flow to atrium during diastole is recovered . . 246

Fig. 15.8 Diastolic equalization of right atrial (mean), right ventricular end diastolic, pulmonary arterial diastolic pressures demonstrated as the PA catheter is pulled back from the pulmonary artery 246
Fig. 15.9 Right atrial pressure waveform with blunted *y* descent 247
Fig. 15.10 Pericardiocentesis can be performed using paraxiphoid approach where the needle is inserted between xiphoid process and left costal margin at a 15° angle above the skin. In apical approach, the needle is inserted 1–2 cm lateral to the apex within the fifth, sixth, or seventh intercostal space. (Adapted from Spodick [*10*]) 248
Fig. 16.1 (**a**) Normal, full-thickness parietal pericardium is shown. It consists of a layer of mesothelial cells and compact layers of dense wavy collagen (yellow) with interspersed short elastic fibers (black). (**b**) Fibroblasts with elongated nuclei and scant thin blood vessels are normally present in the parietal pericardium. CD34 immunostaining highlights the endothelial cells of capillaries. (**c**) The visceral pericardium (also called epicardium) consists of a mesothelial cell layer and a thin subepithelial layer of collagen with elastic fibers. The mesothelial cells show distinct microvilli. Beneath the visceral pericardium is epicardial adipose tissue. (**d**) In other areas of the visceral pericardium (or epicardium), only a thin layer of fibrous tissue (yellow) separates the mesothelial cells from the myocardium with absence of epicardial fat. Original magnifications 400×; (**a**, **c**, and **d**): Movat pentachrome stain; (**b**): CD34 immunoperoxidase. (From Klein et al. [*9*]) 253
Fig. 16.2 Pericardial pressure-volume curves are shown in which the volume increases slowly or rapidly over time. (Blue curve) Rapidly increasing pericardial fluid first reaches the limit of the pericardial reserve volume (the initial flat segment) and then quickly exceeds the limit of parietal pericardial stretch, causing a steep rise in pressure, which becomes even steeper as smaller increments in fluid cause a disproportionate increase in the pericardial pressure. (Red curve) A slower rate of pericardial filling takes longer to exceed the limit of pericardial stretch, because there is more time for the pericardium to stretch and for compensatory mechanisms to become activated 254
Fig. 16.3 Echocardiography of patient with amyloidosis shows (**a**) thickened myocardium with speckling or a granular pattern and (**b**) biatrial enlargement with inter-atrial septal bulging to the right. (**c**) Global longitudinal strain (GLS) study shows a pattern of apical sparing suggestive of amyloidosis. (**d**) The pulsed wave Doppler study of the mitral inflow shows high E/A ratio of ~4.1 and short deceleration time of ~134 ms. Tissue Doppler imaging (TDI) of mitral annulus

shows markedly reduced velocities in both (**e**) septal e' of 3 cm/s and (**f**) lateral e' of 4 cm/s 257
Fig. 16.4 Midventricular septal M-mode recording (parasternal long axis) in a patient with constrictive pericarditis. There is leftward ventricular septal shift in inspiration. Exp indicates expiration and Insp inspiration 257
Fig. 16.5 Echocardiography of a patient with constrictive pericarditis. (**a**) The pulse wave Doppler study of the mitral inflow shows high E/A ratio which is ~2.3 and short deceleration time of 125 ms. Tissue Doppler imaging (TDI) of mitral annulus shows "annulus reversus" with (**b**) septal e' of 10 cm/s and (**c**) lateral e' of 5 cm/s. (**d**) There is significant respiratory variation in the mitral inflow [(expiration – inspiration)/expiration; (115–84)/115 × 100% = ~27.0%]. Insp indicates inspiration and Exp, expiration. (**e**) M-mode image shows plethoric inferior vena cava (IVC) with diameter of 2.6 cm and <50% change in diameter during respiration. (**f**) Global longitudinal strain (GLS) study shows LV antero-lateral wall shortening strains were lower than the septal shortening strains 258
Fig. 16.6 Pulmonary venous flow during different phases of respiration in different conditions. S indicates pulmonary vein systolic flow; D pulmonary vein diastolic flow; AR atrial reversal; Insp inspiration; Exp expiration 259
Fig. 16.7 Pulsed-wave Doppler recording (subcostal window) within the hepatic vein in a patient with constrictive pericarditis. Note prominent diastolic flow reversals in expiration, with the diastolic reversal ratio defined as reversal velocity divided by forward velocity (~0.35 m/s reversal velocity divided by ~0.40 cm/s forward flow velocity yields a diastolic reversal ratio of 0.875). Exp indicates expiration. . . . 260
Fig. 16.8 Pericardial calcification seen on CXR (**a** and **b**) and CT scan (**c** and **d**). Red arrows indicate the location of pericardial calcification 262
Fig. 16.9 CMR free breathing sequence shows the presence of ventricular septal shift. The ventricular septum moves toward the left ventricle with inspiration during diastole (**a**) and toward the right ventricle with expiration during diastole (**b**) 263
Fig. 16.10 CMR of a patient with sarcoidosis. (**a**) There is increased myocardial signal intensity on T2-STIR imaging to suggest myocardial edema (white arrow). (**b**) Delayed-enhancement imaging reveals late gadolinium enhancement (LGE) in a non-ischemic pattern. There is near transmural LGE in the basal and mid inferoseptum (sparing the endocardium) and mid-myocardial LGE in the mid-anterolateral and transmural LGE at the inferolateral apex. 263

Fig. 16.11 Left and right heart catheterization of a patient with constrictive pericarditis. (**a**) Pressure tracing of the right atrium shows prominent x- and y-descents. v indicates v wave; a, a wave; x, x-descent; and y, y-descent. (**b**) Simultaneous recording of LV and RV pressure tracings shows "dip-and-plateau"/"square-root" sign and equalization of both ventricular diastolic pressures. (**c**) Simultaneous recording of LV and RV pressure tracings with respiratory variation shows ventricular interdependence. LV indicates left ventricle and RV, right ventricle 264
Fig. 16.12 A patient with constrictive pericarditis. During inspiration there is an increase in the area of the RV pressure curve (yellow-shaded area) compared with expiration. The area of the LV pressure curve (blue shaded area) decreases during inspiration as compared with expiration 265
Fig. 16.13 Echocardiography of a patient with effusive-constrictive pericarditis. (**a**) There is significant respiratory variation in the mitral inflow [(expiration – inspiration)/expiration; (97–72)/97 × 100% = ~25.8%]. Insp indicates inspiration and Exp expiration. (**b**) There is significant respiratory variation in the tricuspid inflow [(expiration – inspiration)/expiration; (45–66)/45 × 100% = ~ −46.7%]. Tissue Doppler imaging (TDI) of mitral annulus shows "annulus reversus" with (**c**) septal e' of 12 cm/s and (**d**) lateral e' of 9 cm/s. (**e**) Inferior vena cava is plethoric with diameter of ~2.9 cm and <50% variation in size during respiration. (**f**) Pulsed wave Doppler of hepatic vein flow showed significant end expiratory diastolic flow reversal with hepatic vein expiratory diastolic reversal ratio of ~0.9 266
Fig. 17.1 Calculation of aortic valve area (AVA) using the continuity equation. Measurement of the left ventricular outflow tract (LVOT) diameter (**panel A**), velocity time integral (VTI) in the LVOT (**panel B**), and aortic valve (AV) VTI (**panel C**) is necessary to calculate the AVA (**panel D**) 273
Fig. 17.2 Simultaneous LV and aortic pressure tracing. Peak-to-peak gradient is measured as the difference between peak LV and aortic pressures during cath; peak gradient by echocardiography is an instantaneous peak. Mean gradient is calculated as the average pressure difference between LV and aorta pressures (area between the curves) 275
Fig. 17.3 Pulsed-wave Doppler demonstrating pandiastolic flow reversal in the descending thoracic aorta in a patient with severe aortic regurgitation 278
Fig. 17.4 Pulsed-wave Doppler of mitral inflow demonstrating calculation of the mitral valve area (MVA) using the pressure half-time (PHT) method. MVA = 220/PHT 281

Fig. 17.5 Patient with moderate mitral stenosis and atrial fibrillation. The mean gradient across the mitral valve is significantly increased in the setting of decreased diastolic filling time (i.e., increased heart rate) (beat 1:12 mmHg vs. beat 2:5 mmHg) 281
Fig. 17.6 Simultaneous measurement of left atrial (LA) and left ventricular (LV) pressures in a patient with mitral stenosis before (**a**) and after (**b**) percutaneous mitral balloon valvuloplasty. Prior to PMBV, a substantial gradient is present until the end of diastole. In this patient, the pre-procedural resting gradient was 10 mmHg, and post-procedural gradient was 4 mmHg. Paper speed is faster in panel A 282
Fig. 17.7 Demonstration of the mitral regurgitation (MR) jet and calculation of the proximal isovelocity surface area (PISA). In this patient with an aliasing velocity set at 38.5 cm/sec and a MR velocity of 500 cm/sec (not shown), the simplified effective regurgitant orifice (ERO) calculation can be used ($r^2/2$), providing an ERO of 0.5 cm^2, which is consistent with severe MR. (Adapted with permission from Krishnaswamy et al., Coron Art Dis 2011). 284
Fig. 17.8 Pulmonary artery catheter pressure tracing in the wedge position (PCWP) in a patient with acute severe mitral regurgitation due to papillary muscle rupture complicating acute myocardial infarction demonstrates a large v-wave 285
Fig. 18.1 The modified Borg scale has the potential to provide quick, easy, and rapid information about a patient's subjective state of dyspnea. 291
Fig. 18.2 (**a**) Deflation of the wedged pulmonary capillary balloon catheter results in a rapid increase in the pressure recordings identifying the pulmonary artery pressure. In this case the mPAP is >25 mmHg and PCWP is <15 mmHg consistent with a diagnosis of PAH. (**b**) Identification of pulmonary venous hypertension using continuous right heart pressure monitoring during acute balloon inflation and deflation. The PA pressure is elevated but the mPCWP is well in excess of 15 mmHg with large *v*-waves, reflecting the impact of severe mitral regurgitation in this case 295
Fig. 18.3 This wedge tracing illustrates the respirophasic waveforms with the digitized means and the difference between PCWP–exp versus the automatically derived mean PCWP, thereby resulting in misclassification. (Reprinted with permission of publisher [*24*]) 296
Fig. 18.4 Initial RHC in a patient with scleroderma that suggests the presence of PVH. There is limited respiratory variation in the PCWP tracing and the tracing appears to be a hybrid (fusion of PAP and PCWP waveforms) suggesting incomplete balloon occlusion of the pulmonary artery. These

tracing were not consistent with the expected findings. In such cases multiple measurements should be obtained in different locations, and the LVEDP should then be measured for confirmation. This patient required repeat hemodynamic assessment to obtain proper measurements. . . . 299
Fig. 18.5 Repeat RHC which indicates the presence of PAH (the expected finding given the clinical history). The LVEDP confirms that the PCWP is low in this case 300
Fig. 18.6 Gentle contrast injection into the right pulmonary artery under balloon inflation (pulmonary wedge angiogram). The tip of the balloon is highlighted by the arrow. Dye is seen filling a branch pulmonary artery proximal to the balloon and suggests incomplete occlusion. In such a case, a hybrid tracing would be present and would lead to an inappropriately high PCWP recording 300
Fig. 18.7 Limited pulmonary vein angiogram (AP projection) of an anomalous right upper pulmonary vein performed via right femoral vein access (hand injection via end-hole catheter). The white arrow highlights the distal segment of the pulmonary vein which drains into the SVC at the RA junction. Samples drawn from this vein showed oxygen saturations >95%. A high CO at catheterization in the presence of right heart enlargement and a negative bubble study should prompt careful assessment for possible anomalous pulmonary venous return 301
Fig. 18.8 Collected right heart catheterization waveforms in patient with heart failure and severe mitral regurgitation leading to pulmonary hypertension after aggressive diuresis. These suggest the presence of PAH and initially supported a potential role for selective pulmonary vasodilator therapy in this patient. 302
Fig. 18.9 Collected right heart catheterization waveforms during inhalation of 40 ppm of inhaled nitric oxide. Note the dramatic increase in mPCWP to ~30 mmHg and prominent *v*-waves to >65 mmHg. The PA pressure remained essentially unchanged (73/30 with mean 46 mm Hg) compared to baseline (Fig. 18.7). In this case acute vasodilator testing unmasked the left heart pathology leading to pulmonary venous hypertension in this patient. 303
Fig. 19.1 Hemodynamic profiles in patients with left-sided heart failure 310
Fig. 19.2 Renal venous congestion: increased right atrial pressure leading to elevated pressure in the IVC and thus the renal vein (especially when coupled with low mean arterial pressure) can lead to worsening renal function by “congesting the kidney.” Decreasing right atrial pressure and thus the renal venous pressure can lead to improved renal function 315

Fig. 19.3 Treatment paradigm in patients with left-sided heart failure . . 316
Fig. 19.4 Case 1: left ventricular pressure tracing 316
Fig. 19.5 Case 2 sample hemodynamic tracings: Pressures were recorded with the catheter positioned in the right atrium (RA), right ventricle (RV), and pulmonary artery (PA) as well as with pulmonary capillary "wedging" (PCWP). The following pressures were noted: RA mean pressure of 10 mmHg (normal, 0–8 mmHg); RV, pressure of 46/10 mmHg (normal 15–30/0–8 mmHg); PA, pressure of 46/30 mmHg (normal 15–30/4–12 mmHg); and PCWP, mean pressure of 32 mmHg (normal 1–10 mmHg) 318
Fig. 19.6 Case 3: estimation of pulmonary artery systolic pressure by echocardiography. Peak velocity of the tricuspid regurgitation jet is 4.27 m/s (**a**) – this suggests a gradient from the RV to the RA of ~73 mmHg. [RV to RA gradient = $4v^2 = 4 \times (4.27)^2 = 72.9$mmHg. The IVC is dilated (**b**) with a diameter of 2.8 cm and less than 50% variation with respiration – these findings suggest an RA pressure of 15 mmHg. Estimated peak pulmonary artery pressure is 88 mmHg (assuming no pulmonary valve stenosis) (73 + 15 = 88). 320
Fig. 19.7 Case 3: parasternal short-axis echo images showing pronounced flattening of the interventricular septum during diastole (**a**) which is still present during systole (**b**). This produces a "D-shaped appearance" of the left ventricle as emphasized in the cartoon above. Severe left ventricular dysfunction is suggested by the minimal change in area of the left ventricular cavity 320
Fig. 20.1 Quantification of IC shunts using transthoracic echocardiography. Systemic stroke volume or flow (Q_s) can be calculated by using CSA of LVOT, which is derived by LVOT diameter at the end of systole (**a**), and LVOT VTI (**b**) pulmonary stroke volume or flow (Q_p) can be measured using CSA of RVOT, which is derived by RVOT diameter at the end of systole (**c**) and RVOT VTI (**d**)

$$\frac{Q_p}{Q_s} = \frac{\text{CSA RVOT} \times \text{VTI RVOT}}{\text{CSA LVOT} \times \text{VTI LVOT}}, \quad \frac{Q_p}{Q_s} = \frac{3.14 \times (2.3/2)^2 \times 21.1}{3.14 \times (1.8/2)^2 \times 17.1}, \quad \frac{Q_p}{Q_s} = \frac{87.6}{43.5} = 2.$$

CSA cross-sectional area, *LVOT* left ventricle outflow tract, *VTI* velocity time integral, and *RVOT* right ventricle outflow tract 327
Fig. 20.2 Volumetric method for the quantification of IC shunt. Diastolic (**a**) and systolic (**b**) four chamber cine MR images of both ventricles demonstrate moderately dilated RV with normal systolic function. Diastolic (**c**) and systolic (**d**) short axis cine MR images of both ventricles. The ratio of the RV to LV stroke volumes gives shunt ratio (Q_p/Q_s). LV EDV = 194 cm^3; LV ESV = 102 cm^3; LV SV = 92 cm^3;

LV EF = 48%, RV EDV = 289 cm^3; RV ESV = 124 cm^3; RV SV = 165 cm^3; and RV EF = 57%. Shunt ratio can be therefore calculated for this ASD case (*white arrows* show the defect); Q_p/Q_s = 165/92 = 1.8 (ASD atrial septal defect, EDV end diastolic volumes, ESV end systolic volumes, LV left ventricle, RV right ventricle) 329

Fig. 20.3 (**a**–**c**) Velocity-encoded (phase contrast) cine MR imaging for the quantitation of systemic flow (Q_s). (**a**) Magnitude image of the ascending aorta for the measurement of cross-sectional area of the vessel. The plane is positioned at the level of the bifurcation of the main pulmonary artery. (**b**) Phase contrast image perpendicular to the ascending aorta (*white arrow*). (**c**) Through-plane velocity mapping creates flow vs. time curves. The area under the curve represents stroke volume of the ascending aorta (Q_s), which was measured 70 mL/beat for this case. (Q_s = 70 mL). (**d**–**f**) Phase contrast cine MR imaging for the quantitation of pulmonary flow(Q_p). (**a**) Magnitude image of the main pulmonary artery. (**b**) Phase contrast image perpendicular to the main pulmonary artery (*white arrow*). (**c**) Through-plane velocity mapping demonstrates flow vs. time curves across the main pulmonary artery. The area under the curve represents stroke volume of the pulmonary artery (Q_p), which was calculated 162 mL/beat for this case. The shunt ratio was therefore calculated Q_p/Q_s = 162/70 = 2.2, which indicates significant left to right shunting 330

Fig. 20.4 Exact localization for the blood sampling in oxymetric run study. *1a* main pulmonary artery, *1b* left pulmonary artery, *1c* right pulmonary artery, *2* right ventricular outflow tract, *3* right ventricle, *4* low right atrium, *5* mid right atrium, *6* high right atrium, *7* superior vena cava, *8* inferior vena cava (sample should be obtained just below the diaphragm (*blue arrows*); hepatic vein must be taken into account while obtaining inferior vena cava blood), *9* left atrium, *10* left ventricle, *11* aorta or femoral artery 331

Fig. 21.1 Expansion of the pathophysiological paradigm of cardiogenic shock to include the potential contribution of inflammatory mediators. Part I

Components of Myocardial Performance

Preload

1

Amanda R. Vest

Understanding the Concept

The four major determinants of cardiac output are cardiac preload, myocardial contractility, heart rate, and afterload. Of these four elements, preload is the primary determinant. Cardiac preload is a semiquantitative composite assessment that is variously described in different cardiovascular physiology texts and articles as end-diastolic myocardial fiber tension, end-diastolic myocardial fiber length, ventricular end-diastolic volume, and ventricular end-diastolic filling pressure [1]. There is a general recognition that preload is not synonymous with any one of these measurable parameters, but is rather a physiological concept that encompasses all of the factors that contribute to passive ventricular wall stress at the end of diastole.

Cardiac preload may be expressed as a mathematical concept based upon the Law of LaPlace. This law states that, for a thin-walled spherical structure, $T = PR/2$, where T is wall tension, P is chamber pressure, and R is chamber radius. In the case of a thick-walled structure such as the left ventricle, the relationship is better described by $\sigma = PR/2w$, where σ is wall stress, and w is wall thickness, and where $T = \sigma w$. From the structure of the LaPlace's equation, the preload for the ventricle can be described as the left ventricular σ, whereby $\sigma\text{LV} = (\text{EDPLV})(\text{EDRLV})/2w\text{LV}$, with EDPLV representing the left ventricular end-diastolic pressure and EDR as the left ventricular end-diastolic radius. Thus, the parameters of pressure, radius (a surrogate for volume), and wall thickness are all demonstrated to contribute to this mathematical definition.

Clinically, a more tangible and measurable representation of preload has been sought from invasive hemodynamic monitoring. A measurement of end-diastolic pressure – the ventricular pressure measured after atrial contraction just before the onset of systole – is the most relevant representation of preload to many clinicians. Noninvasive assessments of end-diastolic chamber volume are also possible, but volume assessments rely on geometric assumptions that can be undermined by arrhythmias, changes in heart rate, localized wall motion abnormalities, and the chronic ventricular dilatation that occurs in many forms of heart failure. The passive pressure–volume relationship within a chamber, which is a reflection of the passive length–tension curve in isolated myocardium, is exponential and not linear. This fact poses one of the greatest limitations to the use of pressure as a surrogate for preload, with the ratio of change in chamber pressure to

volume being greater at higher volumes compared to lower volumes. In addition, the relationship between pressure and volume will also be distorted by various cardiac pathologies, such as the presence of pericardial constriction. Overall, it should be remembered that preload as a physiological concept encompasses more than just a single value on a pressure tracing (Fig. 1.1).

The concept of preload can be applied to either the atria or the ventricles. In the structurally normal heart, the preload experienced by the right atrium will determine the subsequent preloads in the right ventricle and ultimately the left side of the heart. The other determinants of cardiac output will be addressed in later chapters of this section.

Preload Physiology and Theory

Chamber Anatomy and Function

Cardiac preload will increase with a rise in total circulating volume or greater venous return, which increases myocardial wall stress and the pressure within a chamber at the end of its diastolic phase. Conversely, hypovolemia or decreased venous return will result in decreased chamber filling and wall stress and hence a decreased end-diastolic pressure. The chamber most easily and frequently accessed for invasive monitoring of cardiac preload is the right atrium. A central venous catheter, commonly employed in intensive care settings, can contribute useful

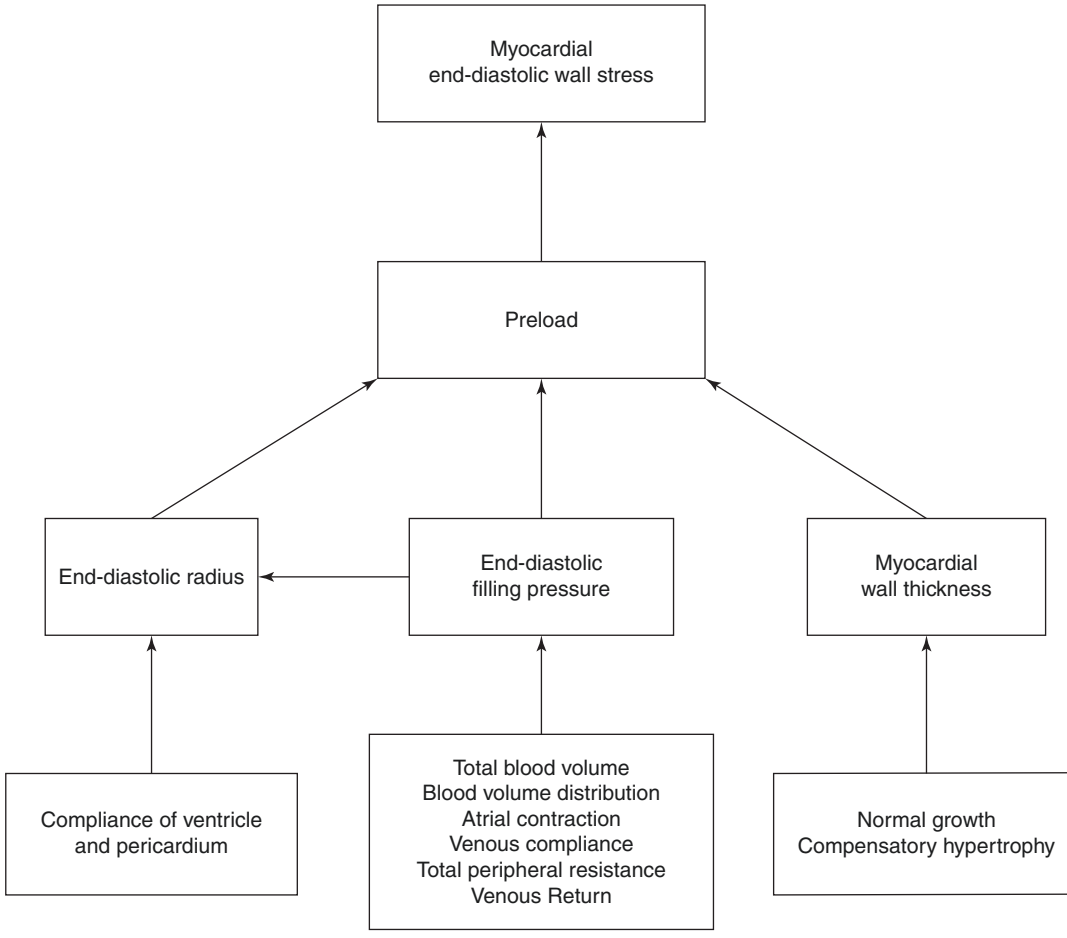

Fig. 1.1 Factors determining preload. (From Norton [1])

information for the clinician when assessing the patient's preload status.

The cardiac cycle comprises diastolic ventricular filling, augmentation by atrial systole to achieve the end-diastolic volume, isovolumic contraction, and then aortic (and pulmonary) valve opening, and stroke volume ejection. Meanwhile, atrial pressure progressively increases during ventricular systole as blood continues to enter the atrium while the atrioventricular valves are closed. Once the ventricle reaches its end-systolic volume, there is a period of isovolumic relaxation, which brings about mitral and tricuspid opening and diastolic filling from the atrium into the ventricle to begin the next cycle. Throughout the diastolic ventricular filling period, the pressure gradient between the atrium and ventricle is minimal. This is because a normal open mitral or tricuspid valve offers little resistance to flow; there is also significant passive filling of both the atrium and ventricle as blood returns from the systemic or pulmonary venous system. At a normal resting heart rate, diastole occupies approximately two-thirds of the cardiac cycle. With increased heart rate, both systolic and diastolic intervals will shorten (Fig. 1.2) [2].

The main difference between the left and right pumping systems is the pressure magnitude. In the normal heart, the pressures developed in the right heart are significantly lower than those on the left side, because resistance across the pulmonary vasculature is far less than the resistance to flow offered by the systemic vascular system. Normal pulmonary artery systolic and diastolic pressures typically do not exceed 30 mmHg and 15 mmHg respectively; the maximal right atrial pressure is generally 8 mmHg (Fig. 1.3).

The Right Atrial Pressure Waveform

A central venous catheter is correctly placed when its tip is situated in the distal superior vena cava [3]; at this position it approximates pressures within the right atrium. As illustrated above, right atrial pressure also approximates the right ventricular end-diastolic pressure, because minimal pressure gradient exists across the normal tricuspid valve. In turn, the right ventricular end-diastolic pressure reflects the right ventricular end-diastolic volume and, due to the conservation of volume passing through the right and left ventricles, will also mirror left ventricular end-diastolic pressure (LVEDP) and volume. Hence, the right atrial pressure alone can serve as a useful surrogate for cardiac preload while requiring slightly less invasive catheter insertion than pulmonary artery catheterization. However, it is also evident that abnormalities of cardiac structure and function will interfere with the assumptions by which central venous pressure monitoring can approximate left ventricular preload. Therefore, the central venous pressure has a greater role in preload assessment in the medical and surgical intensive care units for patients with structurally normal hearts, than in critically ill cardiac patients. The right atrial pressure waveform demonstrates pressure elevations concurrent with atrial contraction (the *a* wave), reflection of ventricular systole as transmitted by the tricuspid valve (the *c* wave), and venous filling of the right atrium against a closed tricuspid valve (the *v* wave). The *x* descent probably arises from right ventricular contraction pulling the tricuspid annulus downward, whereas the *y* descent corresponds to blood emptying from the right atrium into the ventricle [4] (Fig. 1.4).

As illustrated, there is generally an electromechanical delay of approximately 80 ms between the atrial depolarization of the P wave and the pressure deflection of atrial systole represented by the *a* wave. The degree of delay is dependent upon the length of tubing used for pressure transduction.

The normal right atrial pressure, or central venous pressure, ranges from 0 to 8 mmHg (approximately 0–10 cmH_2O if measured with a water manometer). The atrial pressure is usually taken to be the mean of the *a* waves on the pressure

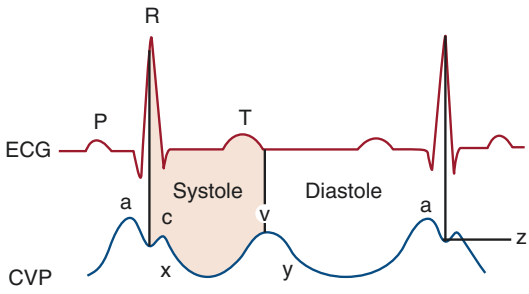

Fig. 1.4 Example of a typical central venous pressure waveform. (From Atchabahian and Gupta [49]). The base of the "c" wave represents the onset of right ventricular contraction and is therefore the best estimate of the final right ventricular filling pressure and preload.

Table 1.1 Variations of the right atrial waveform and their implications

Finding	Implication
Absence of the *a* wave	Atrial fibrillation or atrial standstill
Cannon waves	Atrioventricular dissociation – atrial contraction against a closed tricuspid valve
Elevation of all chamber pressures, with prominent *x* descent	Cardiac tamponade
Elevation of all chamber pressures, with steep *y* descent	Constrictive pericarditis
Large systolic wave	Tricuspid regurgitation

tracing. When the atrial wave is not present (due to atrial fibrillation or atrial standstill), the pressure tracing correlating with the R wave that occurs just before the *c* wave, referred to as the *z* point, is the most appropriate point for central venous pressure measurement. Because the central veins lie within the thorax, the waveform obtained will be influenced by intrathoracic pressure changes during inspiration and expiration. Inspiration is achieved by creating a negative intrathoracic pressure (by expansion of the thoracic cavity) which will be reflected by a downward shift of the central venous tracing. Exaggerated spontaneous inspirations may magnify this deviation. Therefore, it is customary to read the mean pressure at end-expiration, just before the inspiratory drop. The relationship is reversed in patients who are mechanically ventilated because inspiration is typically achieved by applying positive pressure and hence, the pressure at end-expiration is often at the low point of the respiratory nadir. The electronic transducer should always be leveled and zeroed in line with the right atrium, with the fourth intercostal space in the mid-axillary line often used as the anatomical landmark for leveling.

Other variations of the waveform that should be taken into account are listed in Table 1.1. Of particular relevance is the large systolic wave seen in tricuspid regurgitation. In the setting of significant tricuspid regurgitation, the *c* wave and *x* descent will be replaced by a prominent upward deflection (the systolic wave) occurring just before the *v* wave would be expected. This wave represents the regurgitant flow of blood back into the atrium with ventricular contraction.

Assessing Preload from the Right Atrial Pressure

The mean right atrial pressure, or central venous pressure, is primarily a reflection of venous return to the heart and thus the volume status of the patient. Lower pressures will be seen in the hypovolemic patient, as well as those in vasodilatory shock, e.g., due to sepsis or anaphylaxis. Elevated right atrial pressures are seen in cases of right ventricular failure (such as right ventricular infarction, pulmonary embolus), pulmonary hypertension (currently defined as mean pulmonary artery pressure at rest ≥25 mmHg [5]), tricuspid stenosis or regurgitation, cardiac tamponade, pericardial constriction, and hypervolemia (during anuric renal failure for example). The right atrial pressure may also be elevated in chronic or acutely decompensated left ventricular failure with either systolic or diastolic failure mechanisms.

Preload Reserve and the Venous System

In one of the early studies of preload dependence on human subjects, individuals with both normal

hearts and diseased hearts were observed to sustain a reduction in LVEDP and a reduction in cardiac index upon inflation of an occlusive balloon in the inferior vena cava, just caudal to the liver [6]. Conversely, it has been demonstrated in various settings that passive leg raising (PLR) from the horizontal plane in the supine subject increases the volume of blood returning to the right heart and, for a heart that is under filled and demonstrates preload reserve, this additional volume will boost left ventricular stroke volume. The venous system contains the major portion of circulating volume – up to 75% in some situations – because of the greater capacitance of veins than arteries. Therefore, venoconstriction has the potential to displace significant quantities of blood from the peripheral vasculature to the central circulation.

Venous return is the rate of blood flow from the periphery to the right atrium and depends upon the pressure gradient and the resistance to venous return. If blood were removed from a subject's circulating volume until there was no pressure within the venous system (i.e., no outward luminal force distending blood vessel walls), the volume of blood still contained within the system would be called the unstressed volume. The unstressed volume can be modulated by altering the contractile state of the venous smooth muscle. Venoconstriction decreases unstressed volume and, all other parameters being equal, will increase venous return and right atrial pressure. Venodilation increases unstressed volume and decreases right atrial pressure. In experiments using hexamethonium chloride, the unstressed volume has been seen to increase by almost 18 mL/kg, demonstrating the range of reflex compensation available [7]. During exercise, such as running, reflex venoconstriction of vascular beds in the spleen and skin, in combination with the action of the skeletal muscle pump, all help to increase venous return to the higher output heart and hence maintain sufficient pressure in the right atrium to support ventricular filling. In response to a sudden reduction in cardiac output, passive recoil of the veins will redistribute blood to the heart and act to restore adequate stroke volume. Conversely, sequential reductions in cardiac pump output lead to consequent decreases in arterial pressure and increases in venous pressure [8].

Movement of a volume of blood from the arterial system to the venous system will lower arterial pressure and raise venous pressure. However, due to the differing capacitances in these two systems, the arterial pressure change will be 19 times greater than that in the veins [9]. If cardiac output were to fall suddenly, the drop in pressure in the arterial system would far exceed the small rise in pressure in the venous system. Likewise, a large rise in arterial pressure will cause only a small reciprocal fall in venous pressure. All other factors being equal, the relationship venous pressure and cardiac output is reciprocal. Therefore, a constant interplay occurs between the heart and venous system to accommodate changes in posture and volume status. An equilibrium state can be reached at a right atrial pressure where venous return equals cardiac output. The reflex control of venous tone, and the signals governing this primary reservoir for cardiovascular homeostasis, are still incompletely understood.

Preload and the Respiratory Cycle

During inspiration, the negative intrathoracic cavity pressure is transmitted to the thoracic structures resulting in a decrease in the observed intravascular and intracardiac pressures. As previously described, right atrial and pulmonary wedge pressure tracings will be seen to fall. Inspiration will be followed by an increase in right atrial filling as an increased venous blood volume moves down the pressure gradient toward the heart. This leads to increased right ventricular volume and end-diastolic pressure in relation to the pleural pressure, although overall the expansion of the thoracic cavity causes the absolute right ventricular end-diastolic pressure to fall. Increased right-sided flow results in a slight increase in transmural pulmonary pressure during spontaneous inspiration. Events on the left side of the heart are inconsistent, as they are influenced by potentially contradictory changes in several parameters. However, the augmented blood volume moving through the right ventricle has been shown in closed-chest animal models to transiently decrease left ventricular stroke volume, likely due to deviation of the intraventricu-

lar septum into the left ventricular cavity which decreases its end-diastolic volume [10]. The respiratory relationship is reversed in patients who are mechanically ventilated with positive pressure during inspiration and calculation of the transmural pressure, by subtraction of the pleural pressure from the measured hemodynamic pressure, would show a more complex sequence of changes during the respiratory cycle. Intrapleural pressures can be measured with esophageal catheters, or roughly estimated based on the pressure settings of a patient's mechanical ventilation mode.

The Pulmonary Capillary Wedge Pressure Waveform

A key tenet of using the central venous pressure to assess cardiac preload is the relationship of right ventricular end-diastolic pressure to the left ventricular end-diastolic pressure. Experience has shown that there are many situations in which this pressure relationship does not hold true [11]. Pulmonary artery catheterization was previously a procedure limited to the research laboratory, but it made the transition to the bedside in the 1970s following the advent of the Swan-Ganz catheter. This is a multiple lumen catheter that permits pulmonary artery pressure measurement at the distal injection port and right atrial pressure at the proximal injection port. The balloon inflation port is used to inflate and deflate a small air-filled balloon at the distal catheter tip, which is introduced into a pulmonary artery branch. When the balloon is inflated and advanced within a pulmonary arterial branch, a column of static blood will exist between the left atrium and the catheter tip, enabling measurement of the downstream pressure in the left atrium (Figs. 1.5 and 1.6).

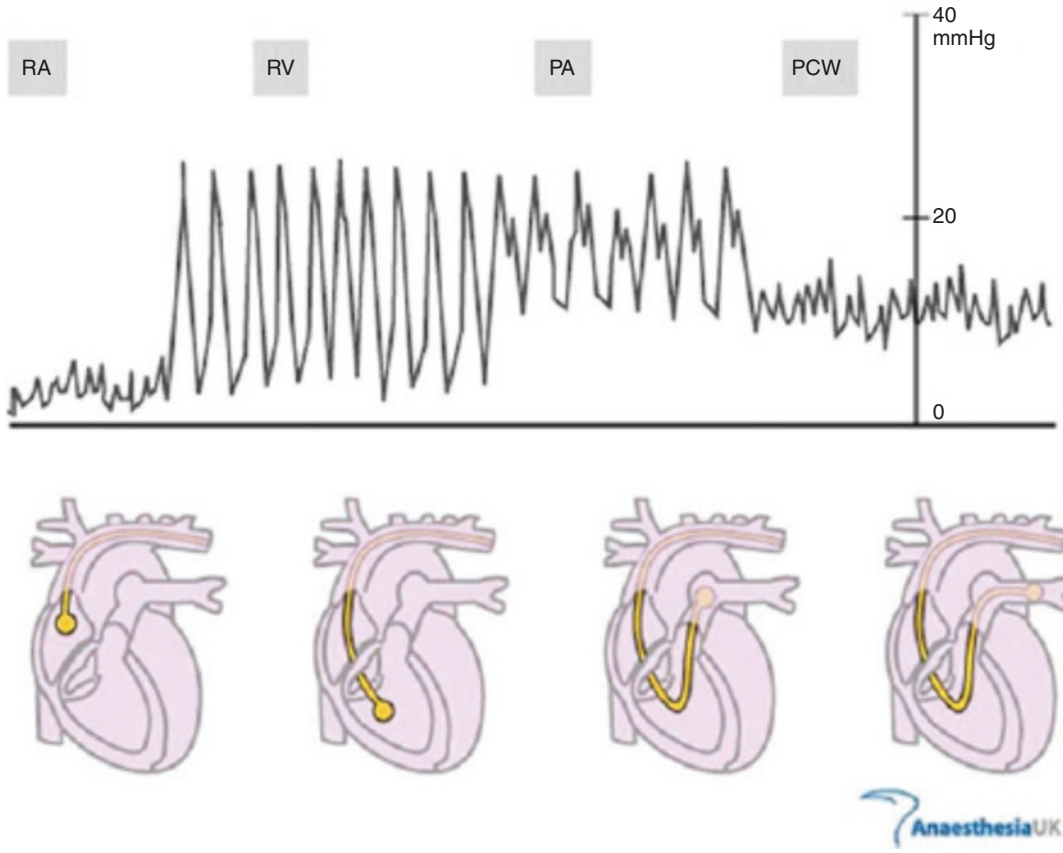

Fig. 1.5 Characteristic intracardiac pressure waveforms derived from the pulmonary artery catheter. (From Anesthesia UK, frca.co.uk)

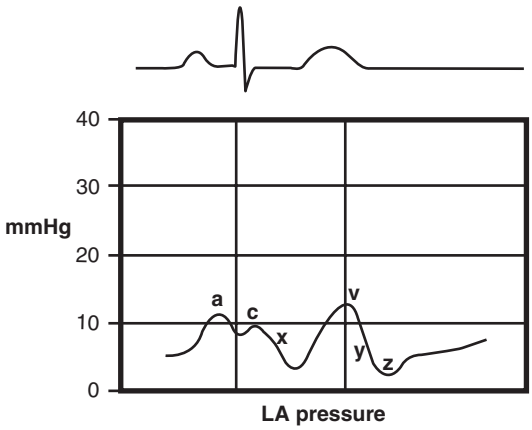

Fig. 1.6 Example of a typical pulmonary capillary wedge pressure waveform. (From The ABCs of A to V: Right Atrial/Left Atrial (PCW) Pressures, CathLabDigest.com). Note the occurrence of the "*a*" wave of left atrial contraction shortly after the electrocardiographic "*P*" wave and the occurrence of the "*v*" wave after the electrocardiographic "*T*" wave. The "*v*" wave falling after the "*T*" wave can be of help when distinguishing a prominent "*v*" wave in pulmonary capillary wedge profile from the systolic deflection of a pulmonary artery waveform, which occurs before the "*T*" wave and means the catheter is not in the wedge position

The waveform obtained at balloon inflation is a reflection of the left atrial pressure and therefore it will show a similar contour as the right atrial tracing with *a*, *c*, and *v* waves produced by the corresponding left-sided physiological events, although the wedge pressure is normally higher than the right atrial pressure. The pulmonary capillary wedge pressure (PCWP) is the key parameter in the clinical assessment of preload in heart failure patients, because in the absence of mitral stenosis, it will approximate left ventricular end-diastolic pressure (LVEDP), and therefore correct measurement technique is essential. The *a* wave will occur near the end of, or just after, the QRS complex, and the *v* wave follows the T wave. The PCWP pressure is measured as the mean amplitude of the *a* wave, or alternatively at the *z* point near the end of the QRS complex if an atrial contraction is not present. If a large systolic wave (*v* wave) is present, suggesting mitral regurgitation, a ventricular septal defect or diastolic dysfunction with impaired atrial compliance, the amplitude should also be recorded. If there is any uncertainty as to whether a true PCWP waveform has been attained, it should be ensured that the v wave falls after the T wave; in the catheterization laboratory, a blood sample can be withdrawn from the distal catheter port in the wedge position and should be the same as the arterial saturation is a true PCWP position has been attained. The PCWP should be measured at end-expiration if the waveform has respiratory variation.

The total electromechanical time delay is greater for the wedge waveform than for the right atrium as the changes in left atrial pressure have to be transmitted back through the pulmonary vasculature to the catheter tip. A balloon-tipped pulmonary artery catheter typically shows a mechanical time delay of 150–160 ms. A pressure gradient should exist between the mean pulmonary artery and the PCWP, with a gradual drop in PCWP occurring as the balloon is inflated. Indeed, there is usually a gradient of approximately 1–4 mmHg between the pulmonary artery diastolic (PAD) pressure and the mean PCWP to ensure forward movement of blood through the pulmonary vasculature, although sometimes the PAD and PCWP can be measured as almost equal [12]. However, a wedge pressure that exceeds PAD suggests an error in measurement, such as misidentification of a dampened PA tracing in place of a PCWP waveform or balloon inflation into a very small branch vessel, called overwedging. The difference between PAD and PCWP will be greater in the setting of pulmonary arterial hypertension, where elevated pulmonary artery pressures are seen without a concurrent PCWP elevation.

Assessing Preload from the Pulmonary Capillary Wedge Pressure

The value in the PCWP lies in its ability to represent (a) the volume status of the patient and (b) the adequacy of left ventricular function. If correctly obtained, the PCWP measures the capillary hydrostatic pressure that will tend to force movement of fluid out of the capillaries and into the pulmonary interstitium. This force is normally 6–12 mmHg

and is opposed by the capillary plasma colloid oncotic pressure at approximately 20–25 mmHg and acts to retain fluid in the vessel [13]. An imbalance of these opposing forces, or a change in the filtration coefficient, can promote the movement of fluid into the interstitium resulting in pulmonary edema. When the only altered parameter is hydrostatic pressure, there is a useful correlation between PCWP and the chest X-ray. From 18 mmHg, features of pulmonary edema may be seen; once hydrostatic pressure exceeds oncotic pressure around 25 mmHg, frank pulmonary edema would be expected. Therefore, a PCWP cut-off of 18 mmHg is often used as the hemodynamic numeric correlate of pulmonary edema [14]. A normal PCWP is usually quoted as 8–12 mmHg [12].

The gold standard invasive clinical assessment of cardiac preload is the left ventricular end-diastolic pressure (LVEDP), which is measured with a catheter retrogradely via the arterial system by crossing the aortic valve into the left ventricle. The correlation of PCWP with the left ventricular end-diastolic pressure, but not pulmonary artery pressures, has previously been demonstrated in settings such as acute myocardial infarction [15]. Although the PCWP is a good surrogate of left ventricular preload, one study showed that LVEDP was >5 mmHg higher than the PCWP in approximately 30% of heart disease patients [16].

It is important to understand situations in which the PCWP will not accurately assess preload. As previously mentioned, there is an exponential relationship between left ventricular end-diastolic pressure and volume. Therefore, the same volume change will cause a small pressure change at a low ventricular volume and a large pressure change in a more distended ventricle. The relationship between left ventricular volume and pressure may also be skewed in pericardial tamponade or constriction. Other scenarios where the PCWP can potentially misrepresent the LVEDP are outlined in Table 1.2. Mitral regurgitation causes a systolic regurgitant wave with onset just before the *v* wave, with similar morphology to that seen in tricuspid regurgitation in the central venous waveform. In pure mitral stenosis, the *a* wave will be prominent and elevated due to the resistance to blood flow through the narrowed valve orifice during atrial systole. The *y* descent is usually prolonged, indicative of the increased resistance to passive left ventricular filling. It is also important to remember that PCWP measured in the resting state may not adequately represent the hemodynamic etiology of dyspnea on exertion. Right heart catheterization during bicycle exercise is increasingly utilized when evaluating patients with potential heart failure with preserved ejection fraction, in whom the left atrial pressure may only rise to abnormal levels during exertion [17].

Table 1.2 Situations where pulmonary capillary wedge pressure (PCWP) may inaccurately represent left ventricular end-diastolic pressure (LVEDP)

PCWP lower than LVEDP	PCWP higher than LVEDP
Aortic regurgitation	Positive pressure ventilation
Highly compliant left atrial chamber	Mitral stenosis
	Mitral regurgitation
	Pulmonary venous obstruction between pulmonary capillary and left atrium
	Left atrial myxoma

Another recent advance in clinical heart failure management is the ability to measure ambulatory pulmonary artery pressures and attain a daily assessment of cardiac preload that guides outpatient therapies. The CHAMPION trial led to the approval of the CardioMEMS device (Abbott, St. Paul, Minnesota, USA) for which a pressure sensor is implanted into the pulmonary artery and wirelessly transmit PA systolic and diastolic measurements to their care providers. The CHAMPION trial showed a 30% reduction in heart failure hospitalizations in the 6 months following randomization to the monitoring strategy versus control, although the single-blind design of the trial and the lack of a comprehensive heart failure disease management comparator arm have left questions about the clinical impact of this approach [18]. However, the ability to assess ambulatory cardiac preload from a PA diastolic surrogate and identify an uptrend in volume status prior to clinical congestion manifestation is clearly a technological advance in the application of hemodynamic principles to clinical care.

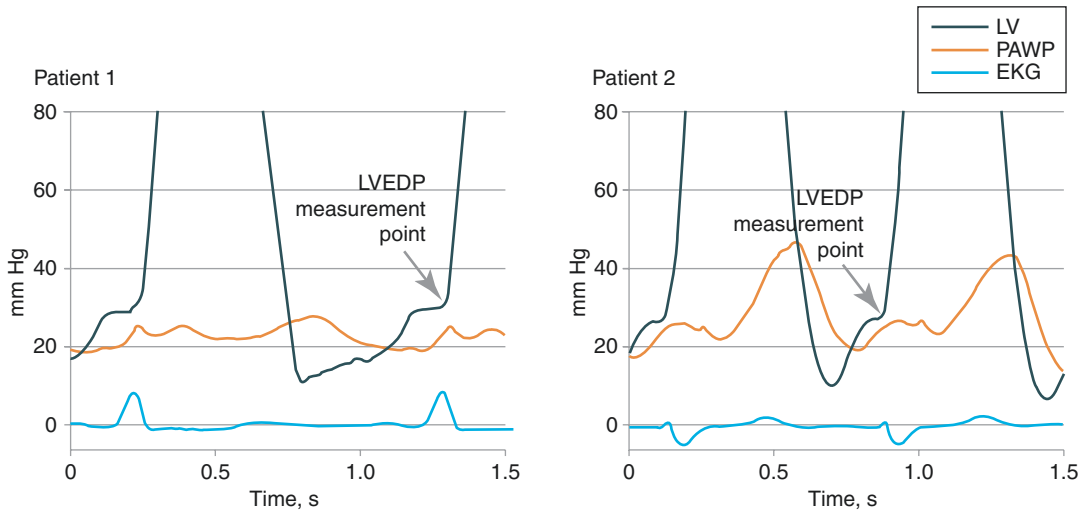

Fig. 1.7 Examples of two patients with similar left ventricular end-diastolic pressures, but differing pulmonary capillary wedge pressures, with patient 1 showing better left atrial compensation for the elevated LVEDP. (From Reddy et al. [50])

In the absence of any of these complicating factors, the wedge pressure should reflect the end-diastolic filling pressure in the left ventricle. The LVEDP is considered the gold standard single parameter in quantifying cardiac preload with the caveat that, as defined above, preload is a composite of several elements that contribute to passive ventricular wall stress at the end of diastole. In situations where it is essential to know the left ventricular preload precisely, such as in the evaluation of pulmonary hypertension etiologies, a left ventricular catheter for direct LVEDP measurement may be necessary. The downside is that the LVEDP requires arterial cannulation and retrograde passage of the catheter across the aortic valve into the left ventricle. This procedure is associated with risks and is usually performed only as a component of a more extensive left heart catheterization procedure. In addition, as the catheter enters the left ventricle for only a matter of minutes, usually only a single measurement of LVEDP is obtained during a patient's hospitalization. This is in contrast to the Swan-Ganz catheter which may remain in place for many days, with many critically ill patients having serial PCWP measurements throughout their intensive care admission. It should, however, be remembered that the LVEDP only reflects the LV operating compliance and can be higher than the PCWP if the left atrium is highly compliant and able to compensate for a chronically elevated LVEDP (Fig. 1.7).

A normal LVEDP is often quoted as 8–12 mmHg, with 16 or 18 mmHg usually being used as the threshold for significant elevation in clinical trials [19]. As illustrated in Fig. 1.3, chamber pressures on the left side of the heart are normally higher than those in the low-pressure system on the right.

Preload Dependency and Pressure–Volume Loops

Having successfully obtained an accurate hemodynamic estimate of preload, the next challenge is to interpret the impact of that parameter on overall cardiac function. The first concept is the preload dependency of ventricular performance. Carl Ludwig is reported as being the first to describe the dependence of cardiac work on diastolic filling, when he wrote in 1856 "… a strong heart that is filled with blood empties itself more or less completely, in other words, [filling of the heart with blood] changes the extent of contractile power" [20]. This relationship of preload to

performance was described in detail by Ernest Henry Starling, who published this relationship in a series of papers between 1912 and 1914 and in his 1915 Linacre Lecture at Cambridge University [21]. The relationship between ventricular pressure and volume during the cardiac cycle can be illustrated by pressure–volume loops, as depicted in Fig. 1.8. End-diastole is located at the lower right corner of the loop. The subsequent upstroke (the vertical line on the right of the graph) is isovolumic contraction. This is followed by ejection, with end-systole located in the upper left corner, and then the downstroke of isovolumic relaxation. As illustrated, increases in preload will result in a greater volume of blood ejection during systole – at least up until a point. Controversy exists as to whether the nondiseased human heart reaches a point of preload at which further end-diastolic stretch will result in decreasing blood ejection [22]. The so-called descending limb of the Frank–Starling curve is better described in the failing heart and will be discussed elsewhere in this book (Fig. 1.8).

At this point, it is valuable to reflect on the myocardial cellular mechanics that underlie the preload concept. The term preload originally arose from the isolated myofiber studies where myocytes were physically loaded with defined forces in the form of a weight applied to one end of a quiescent muscle sample, such as papillary muscle. The other end remains tethered and the force applied prior to contraction is the preload. By varying preload, the relationship between initial length and shortening (isotonic contraction), or developed force (isometric contraction), can be recorded. The maximal force developed at any sarcomere length is determined by the degree of overlap of thick and thin filaments and therefore the number of available actin-myosin cross bridges. Forces increase linearly until a sarcomere length with maximal overload (approx. 2.2 μm) is achieved [23]. Structural proteins constitute a strong parallel elastic component within the myocardium and prevent an increase in developed force beyond this maximal degree of preload. The ascending limb of the myofiber length–tension relationship, which is analogous to the increase in stroke volume with increasing preload in the whole heart, is also modulated by length-dependent increases in myofilament calcium sensitivity [24]. Proposed mechanisms include enhanced calcium binding to troponin C, narrower interfilament gaps at longer sarcomere length, and increased sarcoplasmic reticulum calcium release and uptake at longer sarcomere lengths.

Returning to the whole heart, the major determinants of the left ventricular pressure–volume relationship are the initial ventricular volume, chamber geometry, wall thickness, and myocardial stiffness. Pressure–volume loops highlight the nonlinear pressure and volume relationship during diastolic filling. The instantaneous slope of the curve in the filling phase (i.e., change in pressure/

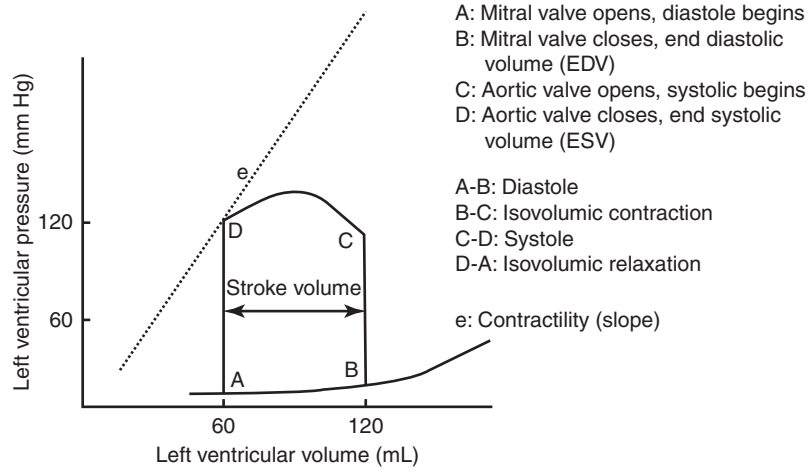

Fig. 1.8 Pressure–volume loop for a single cardiac cycle. (From Loushin et al. [51])

change in volume) represents diastolic stiffness. This parameter is correctly termed as elastance and can be conceptualized by the ventricle behaving as a spring with a stiffness (the inverse of compliance) that increases during contraction and decreases during relaxation. Elastance can be calculated at any point during the ventricle's diastole by calculating the gradient of the curve. Beyond a volume of approximately 140 mL (the exact volume will depend on individual heart dimensions), the chamber becomes progressively more difficult to fill, requiring a greater pressure increase to effect volume changes than earlier in diastole. A thicker, stiffer ventricle, for example in an individual with left ventricular hypertrophy, will show a steeper gradient to the diastolic curve, and hence a greater elastance. The mathematical inverse of elastance (i.e., change in volume/change in pressure) is compliance. The thicker, stiffer ventricle would be described as having reduced compliance. It should be remembered that diastole is an active process that consumes energy; ATP is hydrolyzed to break the actin-myosin crosslink and permit sarcomere lengthening. Therefore ventricular compliance also often falls during ischemia. In the setting of low compliance, a high LVEDP may actually reflect a relatively small LVEDV. Conversely in the normal left ventricle, compliance is high within the typical physiological range, because the chamber operates on the flatter region of the curve where reasonably small pressure rises give significant volume increases, promoting optimal stroke volume.

The importance of the physiological pressure–volume relationship is its role in modulating ventricular performance by the changes in preload. This heterometric regulation occurs on a beat-by-beat basis and ensures matching of the right and left ventricular output with changes in respiration and body posture [25]. In response to myocardial pathology, rises in end-diastolic pressure and volume can also provide a longer term compensatory increase in stroke volume due to increased myocardial fiber length in the remaining functional myocardium. However, the scope of this compensation is limited, as the dilated failing heart will also develop fibrosis, adverse remodeling, and unfavorable metabolic status. This explains the disparity between acute increases in end-diastolic volume resulting in augmented stroke volume, vs. the chronically dilated heart generating a poorer stroke volume.

These considerations illuminate the inherent difficulties in judging preload adequacy. The level of preload at which the heart will show its optimal stroke volume will be dependent on not only the intravascular volume status but also the ventricular compliance and geometry unique to the individual heart. Clinical experience has shown that some dilated, failing ventricles perform optimally at a higher wedge and LVEDP than would be judged normal. However, this cannot be assumed to be the case, as many heart failure patients show improved symptom status and cardiac output following aggressive diuresis and return of their wedge pressure to a value that would be considered to lie in the normal range (Fig. 1.9).

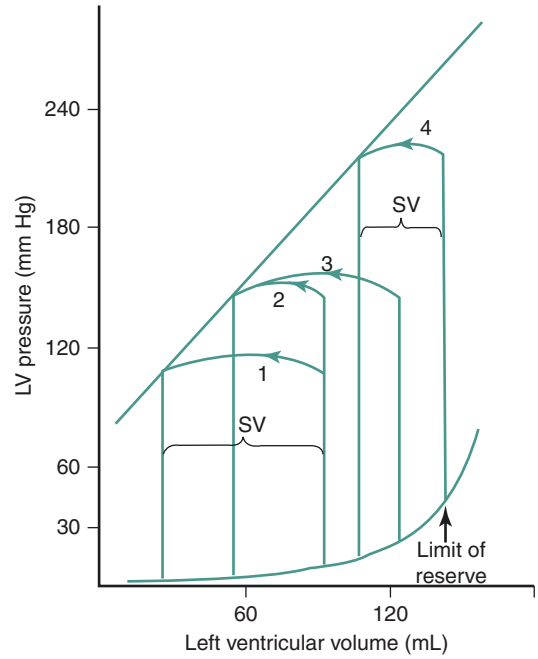

Fig. 1.9 Effects of acutely increasing preload on the pressure–volume loop, to the point of maximal preload reserve. (From Ross [52] and Kaplan [53]). When the ventricle reaches the limit of preload reserve, it is unable to distend any further and the preload is fixed; at this point (loop 4), any further increases in afterload will lead to a reduction in stroke volume

Preload in Clinical Practice

Invasive Hemodynamics

Assessment of preload reserve and preload adequacy is of particular relevance to the management of hypovolemic or septic shock patients. The use of invasive hemodynamic monitoring, with either a central venous catheter or pulmonary artery catheter, is generally the standard technique in the intensive care unit or operating room. Fluid resuscitation is titrated to right atrial or pulmonary wedge pressure, or to the central or mixed venous saturation which serves as a reflection of tissue oxygenation adequacy. Various goal-directed algorithms have been developed in the research setting and have demonstrated the value of early effective volume resuscitation in trauma, surgical, or sepsis patients [26]. However, since its introduction to clinical care almost 40 years ago, the limitations of the pulmonary artery catheter in actual clinical practice have been well documented. As described earlier, for the pulmonary wedge pressure to accurately reflect LVEDP, the following criteria must be met: (a) the catheter is correctly positioned with a valid and accurate wedge tracing obtained, (b) the wedge pressure is correctly interpreted, (c) the wedge pressure is an accurate reflection of LVEDP, and (d) there is a linear and predictable relationship between left ventricular end-diastolic pressure and volume. In an assessment of the technical adequacy of 2711 pulmonary wedge recordings, the authors reported that 31% of these recordings were technically inadequate [27]. Even if a valid waveform is obtained, it is estimated that in approximately a third of cases, data will be incorrectly interpreted by the physician making management decisions [28]. These issues, and the added difficulties brought by positive pressure ventilation, changes in myocardial compliance, and ventricular interdependence, can severely impact on the utility of the pulmonary capillary wedge pressure in accurately reflecting cardiac preload. Such factors may partially explain why randomized controlled trials have, to date, not shown improved outcomes with pulmonary artery catheterization in critically ill patients.

Noninvasive Preload Assessment Techniques

Alternative techniques for assessment of preload adequacy, and responsiveness of the stroke volume to further preload delivery, have also been trialed over recent years (Table 1.3). Various transthoracic and transesophageal echocardiographic measurements have been experimented with. One simple strategy is assessment of venal caval collapse during positive pressure ventilation, with the goal being to identify those patients with a RA pressure less than 10 mmHg who would benefit from further intravenous volume before being subjected to positive pressure ventilation [29]. Another related technique is passive leg raising (PLR) which has gained interest as a maneuver for assessing functional hemodynamic status and assessing potential fluid responsiveness. As described above, passive leg raising from the horizontal position effects a transient increase in preload and acts as an endogenous fluid challenge. Radiolabeled erythrocyte studies to determine venous blood volume in the lower extremities have demonstrated a reduction of approximately 150 mL in each leg when this maneuver is performed [30]. If the right ventricle is preload responsive, the 300 mL increase in venous return will augment right ventricular output and hence left ventricular filling. A small number of studies have proven increases in pulmonary wedge pressure and LVED dimensions with PLR, supporting the theory that the transfer of this volume of blood into the right atrium does significantly contribute to cardiac preload. However, in situations where the preload reserve of the heart is limited, meaning that further diastolic filling will not raise left ventricular stroke volume, the increased venous return will not result in greater cardiac output. The transient increase in cardiac output seen in the preload responsive heart has been observed to be greater after withdrawal of 500 mL blood [31], suggesting that the effect of this maneuver is dependent upon the volume status of the individual. The clinical utility of this observation was highlighted in a study of mechanically ventilated patients judged to be requiring volume expansion, with recording of aortic blood flow after PLR and then a 500 mL intravenous fluid

Table 1.3 Techniques for clinical assessment of cardiac preload

Technique	Pros	Cons
Pulmonary capillary wedge pressure (PCWP) [15]	Multiple right heart and pulmonary pressures, cardiac output, and index all measurable	Invasive, inaccurate with some structural diseases, requires interpretation
Left ventricular end-diastolic pressure (LVEDP) [15]	Gold standard for preload measurement	Requires arterial cannulation, traversing the aortic valve
Ambulatory pulmonary artery diastolic pressure sensor [18]	Enables ambulatory monitoring to detect preload increases	Relies on PA diastolic, further clinical validation required
Vena caval ultrasound assessment	Noninvasive and simple to perform	Sensitivity may be poor
Passive leg raising (PLR) [7]	Noninvasive and simple to perform	Requires bed that performs appropriate movements
Right ventricular end-diastolic volume index (RVEDVI) [33]	Predicts change in stroke volume in response to fluids	Requires a rapid response thermistor and PA catheterization
Left ventricular end-diastolic area (EDA) [36]	No vascular access required	Requires a transesophageal echocardiogram study
Intrathoracic blood volume assessment (ITBV) [38]	Stronger predictor of preload than PCWP or CVP	Requires femoral artery cannulation
Esophageal Doppler [41]	Esophageal probe is minimally invasive	Role in medical intensive care is still to be defined
Deuterium oxide and sodium bromide dilution techniques	Accurate estimation of total body water and extracellular water, respectively	Requires isotope ingestion or injection and blood or urine collections
Radioisotope blood volume analysis (red cell mass and plasma volume measurement) [44]	Measures intravascular volume	Requires isotope injection and blood collections
Bioimpedance spectroscopy [45]	Noninvasive	Does not differentiate intravascular fluid from total body water
Thoracic impedance measurement [46]	Noninvasive	Imperfect representation of invasive hemodynamics

challenge. The PLR was achieved by taking the patient from a semirecumbent position with 45 ° head elevation, through a negative 45 ° tilt of the bed, so that the upper body lay parallel to the horizontal with the lower extremities elevated at a 45 ° angle. An increase in aortic blood flow of at least 10% by PLR predicted a volume expansion-induced increase in aortic blood flow of at least 15% with a sensitivity of 97% and specificity of 94% [32]. Thus, an initial trial of PLR appears to offer a potentially useful noninvasive clinical tool for assessing which critically ill patients will be preload responsive and should receive further volume expansion.

Additional Invasive Preload Assessment Techniques

The use of a pulmonary artery catheter with a rapid response thermistor and an ECG electrode allows computation of the right ventricular ejection fraction, from which right ventricular end-diastolic and end-systolic volumes can be calculated. Right ventricular end-diastolic volume index (RVEDVI) is by dividing right ventricular end-diastolic volume by body surface area, and has been evaluated in surgical critical care settings in mechanically ventilated patients. One such study aimed to determine preload status in acute respiratory failure patients. The degree of positive end-expiratory pressure (PEEP) was titrated and corresponding serial measurement of RVEDVI, wedge pressure, and cardiac index were recorded. They found that, at all levels of PEEP, cardiac index correlated significantly better with RVEDVI than with wedge pressure – at high levels of PEEP, cardiac index inversely correlated with wedge pressure, but remained positively correlated with the RVEDVI [33]. The value of RVEDVI is its ability to predict the change in stroke volume in response to a

fluid challenge, and has been demonstrated to be a superior predictor of recruitable cardiac output than wedge pressure [34]. Of note, though, some authors suggest that the RVEDVI overestimates the preload in comparison to echocardiographic techniques [35].

Left ventricular dimensions have also been employed in the assessment of preload adequacy (Table 1.3). Transesophageal echocardiography is also increasingly used to assess left ventricular filling, with the LV end-diastolic area (EDA) in the transgastric mid-papillary short axis view proving to be a useful parameter that correlated with cardiac preload. In a cohort of heterogeneous medical intensive care unit patients, the left ventricular EDA was significantly lower in those patients who showed a good response to volume challenge [36]. However, the utility of EDA assessment was felt to be lower in this study than in several others evaluating EDA and preload in cardiac surgery patients. Nonetheless, at least one intensive care center has had such success with left ventricular echocardiographic assessment of preload reserve that it has become the primary method for hemodynamic [37].

Another technique that features in the anesthesiology and surgical literature is transpulmonary thermal-dye indicator dilution, which enables bedside measurement of intrathoracic blood volume (ITBV). ITBV has been shown to be a stronger predictor of preload than PCWP and CVP [38]. Transpulmonary double indicator dilution measurements of cardiac output and ITBV can be performed using a catheter positioned in the descending aorta (via the femoral artery) that simultaneously measures thermodilution and dye-dilution. The two indicators are the freely diffusible cold saline and a plasma bound indicator such as indocyanine green (ICG). When injected simultaneously, the cold indicator will equilibrate with the interstitium whereas the ICG will remain in the intravascular space. Based upon the conservation of mass, intrathoracic blood volume (ITBV) can then be calculated from cardiac output and the mean transit time of the dye tracer between the site of injection – the right atrium – and the site of detection. A study in 10 anesthetized patients observed significant decreases in ITBV after a standardized change from supine to sitting body position, which correlated with changes in the stroke volume index. This study found ITBV and EDV to be equivalent indices of cardiac preload in their small sample of anesthetized patients [39]. Another group that compared preload variables in the early phase of hemodynamic stabilization of 57 critical care patients found ITBV to be a more reliable indicator of preload than CVP or PCWP [40]. However, femoral artery catheterization is required for this technique.

An invasive technique for assessing preload adequacy that may be appropriate in high-risk surgical patients is esophageal Doppler. This is a minimally invasive method of measuring real-time descending aortic blood flow that employs the Doppler shift phenomenon as a marker for blood cell velocity. A probe situated in the esophagus is in close proximity to the descending aorta and provides an excellent window for obtaining Doppler flow signal from which cardiac output can be calculated. The left ventricular ejection time (or flow time) corrected for heart rate correlates well with left ventricular preload. In general, a corrected flow time of less than 0.35 s suggests a potential to respond to volume expansion, whereas reading above 0.45 s suggests that volume expansion will not stimulate further increases in cardiac output [41]. Esophageal Doppler has been demonstrated to be effective in guiding nurse-led, protocolized resuscitation in the early postoperative hours, resulting in reduced complications and shorter hospital stays for cardiac surgery patients [42]. Its promise has also been recognized in the medical intensive care setting, where the continuous real-time monitoring could be of use in gaining instantaneous feedback on interventions. Probe insertion takes only minutes, requires minimal technical skill, and is not associated with any major complications [43]. However, the calculations that generate measurements of aortic blood flow do depend upon aortic geometric assumptions.

Finally, a range of techniques for ambulatory assessment of blood volume, as a surrogate for cardiac preload, have been developed to inform the clinically management of heart failure patients

who are at risk of developing congestion years (Table 1.3). Techniques range from the research-only use of deuterium oxide and sodium bromide, to measure the total body water and extracellular volumes, respectively, to the radioisotope measurement of red cell mass and plasma volume in a blood volume analysis test [44]. The relationship between elevated preload and increased tissue edema is harnessed for the techniques of bioimpedance spectroscopy, which involves the placement of voltage and current electrodes at landmarks on the body [45], and for thoracic impedance measurements either via implantable pacemaker-defibrillator devices or from measurement on the chest wall [46]. There is much current interest in the potential for left ventricular assist device (LVAD) flow waveforms to offer a noninvasive assessment of preload for mechanically supported end-stage heart failure patients, with a recent publication showing correlation between the PCWP and the ventricular filling phase slope of the Heartware LVAD flow waveform [47].

Bullet Point Summary

- Preload is a composite assessment of cardiac filling that represents the primary determinant of cardiac output.
- End-diastolic left ventricular pressure and volume are common surrogates for preload.
- However, the passive myocardial length–tension relationship is exponential rather than linear, limiting the role of pressures as a direct surrogate for preload.
- Preload increases with greater circulating volume, venoconstriction, exercise, arteriovenous fistulae, increased ventricular compliance, increased ventricular filling time, left ventricular systolic failure.
- Preload decreases with volume depletion, decreased venous return, impaired atrial contraction, tricuspid or mitral stenosis, less compliant ventricles.
- The atrial pressure waveform comprises *a*, *c*, and *v* waves, with *x* and *y* descents.
- Atrial pressure is usually measured as the mean of the *a* waves.
- Inspiration normally decreases all intracardiac pressures.
- Inflation of the Swan-Ganz catheter balloon within a pulmonary artery branch enables measurement of downstream pressure in the left atrium.
- Pressure–volume loops are orientated with end-diastole located at the lower right corner of the loop.
- The instantaneous slope of the pressure–volume curve in the filling phase elastance.
- Invasive methods of assessing left ventricular preload adequacy include: central venous pressure, pulmonary artery diastolic pressure, and pulmonary capillary wedge pressure. Left ventricular end-diastolic pressure is considered the gold standard.
- Noninvasive methods of assessing left ventricular preload adequacy include vena caval collapse, right ventricular end-diastolic volume index, left ventricular end-diastolic area, esophageal Doppler evaluation of left ventricular inflow, and intrathoracic blood volume.

Review Questions

1. Which of the following has *not* been used as surrogate parameter for cardiac preload?
   (a) Left ventricular end-systolic pressure
   (b) Pulmonary capillary wedge pressure
   (c) Intrathoracic blood volume
   (d) End-diastolic myocardial fiber tension
   (e) Degree of venal caval collapse
   Answer is (a). However, left ventricular end-*diastolic* pressure is a commonly used clinical surrogate for cardiac preload.
2. Which one of the following statements is true regarding central venous pressure monitoring?
   (a) The normal central venous pressure in a healthy adult ranges from 5 to 12 mmHg
   (b) The central venous pressure should be taken to be the lowest point between the *a* and v waves as measured during inspiration
   (c) Central venous pressure rises during deep inspiration
   (d) The *x* descent is absent in cardiac tamponade

(e) Significant tricuspid regurgitation will cause a prominent upward deflection just before the *v* wave would be expected

Answer is (e). The normal central venous pressure is 0–8 mmHg, although a higher rage may well be an appropriate target for a critically ill individual in whom maintenance of preload is important. The pressure is usually read as the mean peak of the *a* waves, ideally at the end of expiration, just before the inspiratory fall in central venous pressure. Cardiac tamponade causes absence of the *y d*escent, and often results in a prominent *x d*escent.

3. Which of the following does *not* generally cause the pulmonary capillary wedge pressure to be unrepresentative of the left atrial pressure?
   (a) Pulmonary venous hypertension
   (b) Balloon inflation in a very small branch vessel
   (c) Aortic stenosis
   (d) Mitral regurgitation

   Answer is (c). Pulmonary venous hypertension, overwedging of the Swan-Ganz balloon and an atrial myxoma can all cause the pulmonary capillary wedge pressure to read higher than the actual left atrial pressure. Severe mitral regurgitation causes a large systolic regurgitant wave with onset just before the *v* wave, and so care must be taken to correctly interpret the pressure waveform and estimate the pressure as the peak of the a waves, because inclusion of the regurgitant upward deflection will cause overestimation of the true pressure. The presence of mitral stenosis and aortic regurgitation can also cause the pulmonary capillary wedge pressure to misrepresent the left ventricular end-diastolic pressure.
4. Which one of the following statements is true regarding ventricular "elastance"?
   (a) This is an expression of the ease of diastolic stretching of the myocardium.
   (b) Can be a calculated as the change in pressure divided by change in volume, which is the instantaneous slope of the pressure–volume curve in the filling phase.
   (c) Beyond a volume of 40 mL in the adult heart, the left ventricle becomes more difficult to fill, and shows lower elastance.
   (d) A heart with left ventricular hypertrophy shows lower elastance than normal.
   (e) In the setting of low elastance, a high LVEDP may actually reflect a relatively small LVEDV.

   Answer is (b). Elastance is a measure of the diastolic stiffness of the myocardium, and is the inverse of compliance. Elastance is decreased above approximately 140 mL in the adult left ventricle. Left ventricular hypertrophy results in higher elastance and lower compliance than normal. It is a higher elastance ventricle in which a high LVEDP may actually reflect a relatively small LVEDV.
5. A 74-year-old female with long-standing hypertension and diabetes presents with confusion, fever and hypotension, with a blood pressure of 88/48. She is diagnosed with urosepsis and admitted to an intensive care unit. A prior outpatient echocardiogram showed severe left ventricular hypertrophy, most marked in the upper septal region, with a left ventricular ejection fraction of 65%. Are the following statements true or false?
   (a) The concentric hypertrophy confers greater elastance, compared to a normal left ventricle.
   (b) Preload is increased in a stiffer left ventricle.
   (c) This individual may be particularly sensitive to volume depletion.
   (d) After recovery from sepsis, beta-blockers and nitrates should be included in this individual's outpatient medication regimen.
      (a) True. A stiffer ventricle has greater elastance, and lesser compliance – these two parameters are inversely related.
      (b) False. As a ventricle becomes less compliant, the preload will decrease as the end-diastolic volume achieved with the same degree of venous return and filling time will be less.

(c) True. Due to the decreasing end-diastolic volume with worsening left ventricular hypertrophy, this heart becomes more "preload dependent," meaning that the same reduction in preload will cause a greater fall in stroke volume compared to a structurally normal heart. An individual such as the one described can show significantly reduced stroke volumes in the setting of volume depletion or distributive shock, due to the development left ventricular outflow tract obstruction, with or without systolic anterior motion of the mitral valve. This patient's blood pressure will likely improve markedly when the preload is augmented, for example, by intravenous volume resuscitation.

(d) False. Beta-blockers are often indicated in patients with significant left ventricular hypertrophy, or hypertrophic cardiomyopathy. By reducing heart rate, the diastolic ventricular filling period is increased, so improving the preload. Conversely, nitrates cause venodilatation and a reduction in preload, and hence may decrease this patient's preload and induce a left ventricular outflow tract gradient.

6. A 60-year-old male with coronary artery disease, hypertension, and active tobacco use presents with chest pain and inferior ST elevations. He was also noted to be in complete heart block with a heart rate of 48 bpm. At emergent cardiac catheterization, there was an acute right coronary occlusion, which was successfully intervened upon. However, the peak troponin T was 28 ng/mL, signifying a significant inferior myocardial infarction. On arrival in the coronary intensive care unit, the blood pressure was 90/72, with a right atrial pressure of 21, PA pressure 27/17, pulmonary capillary wedge pressure 14, cardiac index 1.8 l/min/m^2. Are the following statements true or false?

(a) Passive leg raising could be used as a measure of preload dependence.

(b) Positive end-expiratory pressure will not affect the cardiac index as the pulmonary capillary wedge pressure is normal.

(c) Atrioventricular pacing would be expected to improve the cardiac index.

(d) Use of dobutamine in this setting will increase the preload.

(a) True. Passive leg raising provides an "endogenous fluid challenge" and temporarily enhanced venous return and therefore preload. If the blood pressure and/or cardiac index improves immediately after this maneuver, it suggests that the patient will be responsive to volume resuscitation. The scenario described is consistent with a right ventricular infarction. In this setting, the blood pressure and cardiac index often improve with judicious use of small fluid boluses, as the patient is highly preload dependent.

(b) False. Mechanical ventilation with positive end-expiratory pressure will hinder venous return to the thorax during inspiration and hence may decrease stroke volume, especially in the heart with inadequate preload.

(c) True. The loss of atrial contraction, which usually supplies approximately 20% of ventricular filling, may be particularly detrimental for the preload-dependent right ventricle in this individual. Restoration of atrioventricular coordination with temporary pacing wires can significantly augment ventricular performance.

(d) False. Use of dobutamine in this setting would be expected to enhance contractility and decrease the right ventricular afterload by inducing some vasodilatation in the pulmonary vasculature. The preload may be slightly decreased by systemic peripheral vasculature dilatation.

Afterload

2

Amanda R. Vest

Understanding the Concept

As discussed in Chap. 1 regarding preload, cardiac afterload is also a semiquantitative composite assessment of a determinant of cardiac output. The four major determinants of cardiac output are cardiac preload, myocardial contractility, heart rate, and afterload. Afterload is the force against which the heart pumps to expel blood into the vasculature. In isolated myofiber experiments, myocytes are physically loaded with defined forces in the form of a weight, to the lower end of a vertically mounted quiescent muscle sample. The opposing end of the myofiber remains tethered. The muscle is then electrically stimulated to contract and lift the additional weight. Once stimulated, the muscle develops tension, or force, until it meets and then overcomes the opposing force of the applied load, which is termed the afterload. Once the afterload is exceeded, the weight will be physically lifted and fiber shortening occurs. The degree and velocity of myofiber shortening is inversely related to the afterload applied. If both ends of the muscle sample are tethered and immobilized, or if the afterload applied is in excess of the myofiber's maximal force generation, the resulting contraction will remain isometric, meaning that the fiber length will be unchanged when tension is generated during contraction [1].

An alternate expression of the afterload is as a stress (defined as unit force per cross-sectional area) enabling comparison of differently sized samples of myofiber. It also permits transfer of the concept to the intact ventricle. Afterload in the whole heart can be understood as the stress encountered by left ventricular myofibers as they contract against the end-diastolic volume. Ventricular wall forces are difficult to directly measure, but the wall tension can be described by LaPlace's equation through $\sigma = PR/2w$, where σ is wall stress, P is pressure, R is ventricular radius, and w is wall thickness. This equation applies to a spherical chamber, whereas the equation is modified toward $\sigma = PR/w$ for a cylindrical vessel. More complex mathematical calculations can also be used to quantify end-systolic wall stress that take into account variations on chamber geometry. It can be seen from the law of LaPlace that, at a given intraventricular

pressure, a dilated left ventricle (increased ventricular radius) will have to develop a greater inward force than a smaller heart to generate the same systolic pressure. This makes the ventricle vulnerable to an "afterload-contractility mismatch" and explains why stroke volume may be augmented by reducing the afterload of a dilated left ventricle. Conversely, a hypertrophied left ventricular wall will achieve a lower wall stress and more easily generate a systolic pressure that overcomes ventricular afterload.

Another concept for defining afterload is in terms of the impedance to blood flow entering the aorta, known as arterial input impedance. This parameter quantifies the ratio of change in pressure to change in flow. It can be calculated using values for arterial pressure, elasticity, vessel dimension, and blood viscosity, and it requires invasive instantaneous aortic pressure and flow measurements which render it a research tool only. With the two principal determinants of ventricular afterload being systolic pressure and ventricular radius, and because the ventricular dimensions are assumed to remain relatively consistent, the systolic arterial pressure is the parameter most commonly used as a surrogate for afterload in clinical practice. In the absence of aortic or pulmonic stenosis, the maximum systolic pressure beyond the valve reflects the maximum pressure generated by the corresponding ventricle. Hence, the peak aortic pressure and peak pulmonary pressure can be measured to estimate the left and right ventricular afterloads, respectively.

An inverse relationship exists between stroke volume and the afterload [2]. As above, this is a consequence of the fact that muscle cannot shorten in excess of the length determined by the total load acting upon it. When this load is increased, sarcomere shortening will stop at a greater length, and so the extent of thick-thin filament overlap and cross-bridge formation will be diminished compared to a lower afterload (Fig. 2.1).

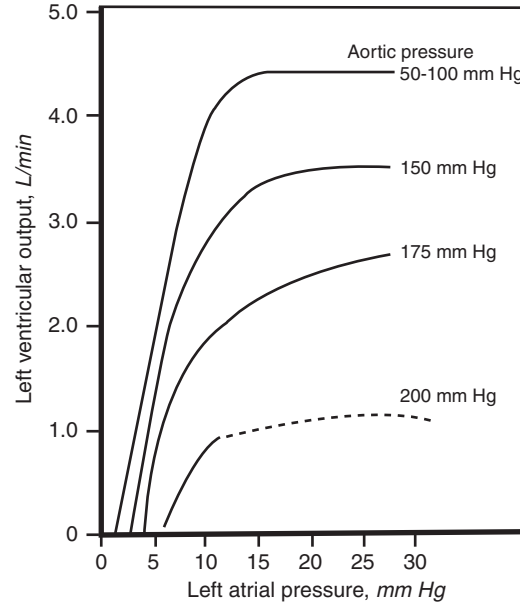

Fig. 2.1 The inverse relationship between afterload and cardiac performance. (Adapted from Sagawa [31])

Afterload Physiology and Theory

Afterload and Arterial Vasculature

The forces that oppose ventricular shortening are a summation of factors encountered throughout the arterial tree and can be referred to as arterial impedance. The total systolic load includes not only the impedance to flow from the large arteries but also the impedance provided by the medium peripheral arteries and smaller arterioles. Stephen Hales (1677–1761) suggested a simplistic model for the function of the arterial system, with the functions of cushion, conduit, and resistance being fulfilled by the proximal elastic arteries, medium-sized muscular arteries, and peripheral arterioles, respectively [3]. This classic model is useful in defining the differing properties of vessels along the arterial tree and in highlighting the peripheral arterioles as the site of the majority of peripheral resistance.

The three major determinants of arterial impedance are resistance, inertia, and compliance.

Resistance in a vessel is described by the Poiseuille equation $R = 8 \times \eta \times l/\pi r^4$, where R is resistance, η represents the viscosity of blood, l is vessel length, and r is vessel radius. Thus, it can be seen that elevated viscosity, such as in polycythemia, will increase resistance to flow. Importantly, resistance is inversely proportional to the fourth power of the radius, enabling small changes in arteriolar diameter to have profound changes on total peripheral resistance [4]. Total peripheral resistance can be expressed with regard to the ascending aorta as $R = P_o/\mathrm{CO}$, where P_o represents the mean arterial pressure, CO is the cardiac output, and R is the total peripheral vascular resistance. This can be re-arranged to $P_o = (\mathrm{CO})R = (\mathrm{SV})(\mathrm{HR})R$ by inputting the equation for cardiac output. This expression allows appreciation that the mean aortic pressure is directly related to both the cardiac output and the peripheral resistance. Inertia, which is related to the mass of the blood column, opposes acceleration of blood flow and is dependent upon the heart rate. Compliance is a property of the vascular walls, with highly compliant vessels being more distensible. Elastance is the reciprocal of compliance. Compliance is also heart rate dependent; the rate dependence of both inertia and compliance leads to phase shifts between instantaneous pressure and flow within the pulsatile arterial system [1]. The arterial pulse waveform begins with the upstroke imposed by ventricular systole, with a rapid increase in aortic pressure in early systole. The peak proximal aortic flow velocity slightly precedes the peak pressure. The aorta and large arteries expand during systole to accommodate some of the pressure fluctuation. This intermittent input into the proximal system is translated to an almost constant flow into the distal capillary bed, fulfilling the cushion function of the Hales model. This is achieved by absorption of stroke volume by the large elastic vessels, with conversion of the energy of systole into stretch of the arterial walls. The walls recoil as pressure within the vessel falls, and the stored energy is returned during diastole to maintain the blood pressure and distal blood flow during this period of the cardiac cycle. This is termed the Windkessel effect and is dependent both upon the capacitance of the aorta and large arteries, and the resistance to flow in the smaller vessels that do not show systolic expansion. However, this now considered an overly simplistic model and contemporary modeling incorporates elements of wave propagation and reflection.

Reflected Pressure Waves

An additional potential contributor to the afterload, not accounted for in the Hales model, is the phenomenon of retrogradely reflected pressure waves traveling from the periphery back toward the ventricle. The speed of propagation, known as the pulse wave velocity, is high enough for the reflected wave to arrive in the proximal aorta within the same cardiac cycle and so the reflection overlays the incident wave with both contributing to the arterial waveform. A reflected wave occurring during systole will increase the afterload; a reflected wave arriving in the proximal aorta during diastole is more advantageous as it will augment coronary blood flow. Major sites of reflection are arterial branch points, particularly the renal artery branches off the abdominal aorta, and the iliac bifurcation. The degree of wave reflection can change the pressure and flow waveforms seen in older subjects and in hypertensive individuals. Aging in industrialized societies is accompanied by increased systolic pressure and decreased arterial compliance; diastolic pressures tend to fall slightly. Intima-media thickening occurs, which causes progressive stiffening of the aging larger elastic arteries, resulting in elevation of aortic systolic and pulse pressures due to a combination of a rise in the forward incident wave and early return of the reflected wave [5] (Fig. 2.2).

A Framingham substudy documented the increases in arterial stiffness (elastance, the inverse of compliance) with advancing age [6]. The result is increased velocity of both the incident and retrograde reflection waves, with an

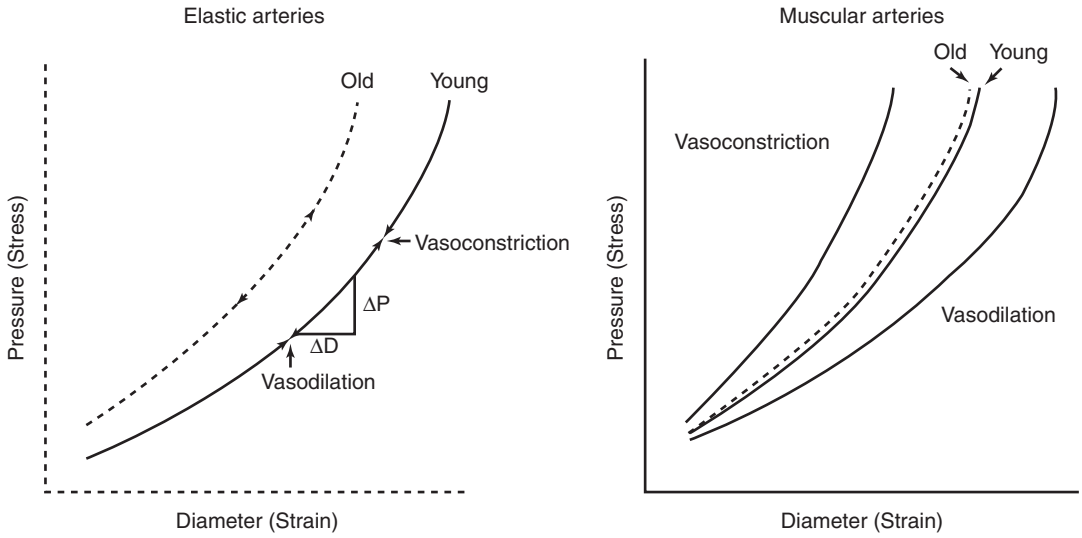

Fig. 2.2 Pressure-diameter relations for elastic and muscular arteries. (From Nichols and Edwards [5])

increase in systolic and pulse pressures. The enhanced incident wave raises myocardial oxygen demand, which can induce ventricular hypertrophy over time. In addition, the early return of reflected pressure waves adds to the afterload by augmenting late systolic pressure and removes the diastolic support of coronary blood flow; hence, the favorable ventriculo-arterial coupling is progressively lost [7]. It is the large central arteries, rather than the peripheral vasculature, that undergo the greatest capacitance changes with age. These changes in reflected waves contribute toward diastolic dysfunction, decreased exercise capacity, and an increased long-term risk of heart failure onset, especially heart failure with preserved ejection fraction (HFpEF) [8]. Large artery stiffness, as measured by carotid-femoral pulse wave velocity, predicts cardiovascular events and mortality, even after accounting for other established cardiovascular risk factors [9].

Decreased compliance in the large arteries may also induce macrovascular damage in organs such as the kidneys and the brain once the cushion effect that absorbs systolic pulsations is lost, causing the microvasculature to be subjected to pulsatile flow. The microvasculature is generally considered to include the small arteries of less than 400 μm diameter, arterioles of less than 100 μm diameter, and the capillaries with their single layer of endothelial cells. It is hypothesized that a more pulsatile microvasculature flow induced by age-related decline in the Windkessel effect is a contributor to end-organ damage [10].

Input Impedance and Characteristic Impedance

Parallels have been suggested between the flow of blood in the arterial system and the flow of current within an alternating current (AC) electrical circuit [11]. An analogous electrical circuit would contain capacitors and resistors, with the alternating storage and discharge of the capacitor separating peak pressure and flow. Impedance is a vector consisting of two components: the magnitude (modulus) and the phase angle, representing the number of degrees by which the sinusoidal pressure is separated from the sinusoidal flow. Electrical impedance occurs as current and voltage fluctuate with AC cycles and can be conceptionally translated into arterial impedance (Z_{in}). However, it should be remembered that blood does not behave sinusoidally, and so biological pressure and flow values must be converted into a fundamental sine wave and a series of harmonic waves using Fourier analysis. A value for impedance is derived from each pair of sine waves of pressure and flow (i.e., harmonics) at their specific phase angle. To validly apply Ohm's law in

this setting, the system should be in the steady state (vasomotor tone should be constant), time invariant (free of beat-to-beat changes in resistance), and linear. The nonlinearity of the ventricle during contraction does somewhat limit this technique, with the variations in elastance of the chamber during contraction being unaccounted for. Therefore, it would not be accurate to derive input impedance from invasive values for the left ventricular pressure and aortic flow, because the intervening aortic valve adds significant nonlinearity. However, when considering the arterial tree, the variations in pressure and flow are minor enough to enable systemic and pulmonary arterial input impendence to be considered valid mathematical descriptions of the systemic and pulmonary arterial trees, respectively.

When using the impedance concept in a compliant vascular system, the flow will be advanced with respect to the pressure sine wave. This is depicted as −90 ° in the phase angle. With inertance the flow is delayed, giving a +90 ° phase angle. The modulus of impedance will decrease with increasing frequency. In a large elastic artery, the compliance and inertia effects interact to keep pressure and flow sine waves in phase. This gives a pulsatile, or characteristic, impedance with a phase angle of 0. In this setting, the modulus will be constant and independent of changes in frequency. If the system were without reflection waves, the input impendence would equal the characteristic impedance. However, the reflected waves moving retrogradely toward the proximal aorta result in a significant difference between arterial input impedance and the characteristic impedance, which incorporates the reflected waves. This difference is more apparent at lower frequencies, where reflected waves return out of phase. Conversely, at high frequencies, the wavelengths are less than the arterial system length and so reflected waves are out of phase and cancel each other out. Therefore, at high frequencies, input impedance is almost equal to characteristic impendence [12]. The aortic input impedance spectrum gives information in the frequency domain about the arterial elastance, pulse wave reflectance, and the peripheral resistance. The clinical relevance is that increases in the pulsatile components – the elastance and reflectance – will lead to ventriculo-arterial mismatch and are, therefore, detrimental to cardiac efficiency (Fig. 2.3).

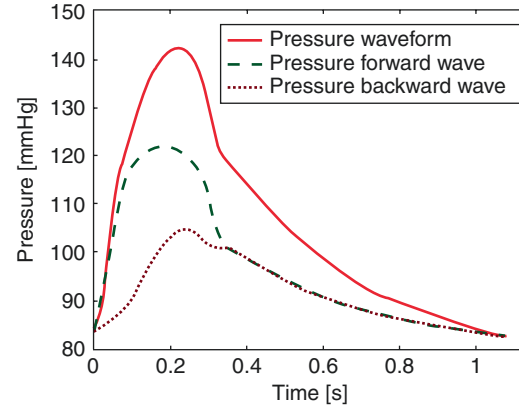

Fig. 2.3 The effects of wave reflection on the systolic pressure profile. (From Chirinos and Sweitzer [32]). Wave separation analysis showing the contributions of the forward (green dashed line) and backward (red dotted line) pressure waves to the systolic pressure profile

Assessing Afterload from Invasive Hemodynamics

Efforts to apply the impedance concept as a clinically measurable tool have been hampered by the complexity of the many advanced analytic functions required to derive values, and hence, the much simpler mean aortic pressure or mean systolic pressure remains the more commonly used surrogate of afterload. Clinically, the invasive measurement of cardiac afterload is usually achieved with a pressure tracing from a fluid-filled catheter with its tip lying just above the aortic valve in the ascending aorta. One phenomenon that the clinician must bear in mind in this setting is the possibility of pressure recovery. This describes the increase in pressure downstream from a stenosis caused by reconversion of kinetic energy to potential energy and can be a source of discrepancy between catheter and Doppler valvular pressure gradients. Bernoulli's theorem, from which Doppler evaluations of flow across a stenosis can be derived, requires that the sum of the pressure head, potential energy, and kinetic energy must be equivalent throughout all parts of the flow system. Therefore, in the setting of aortic

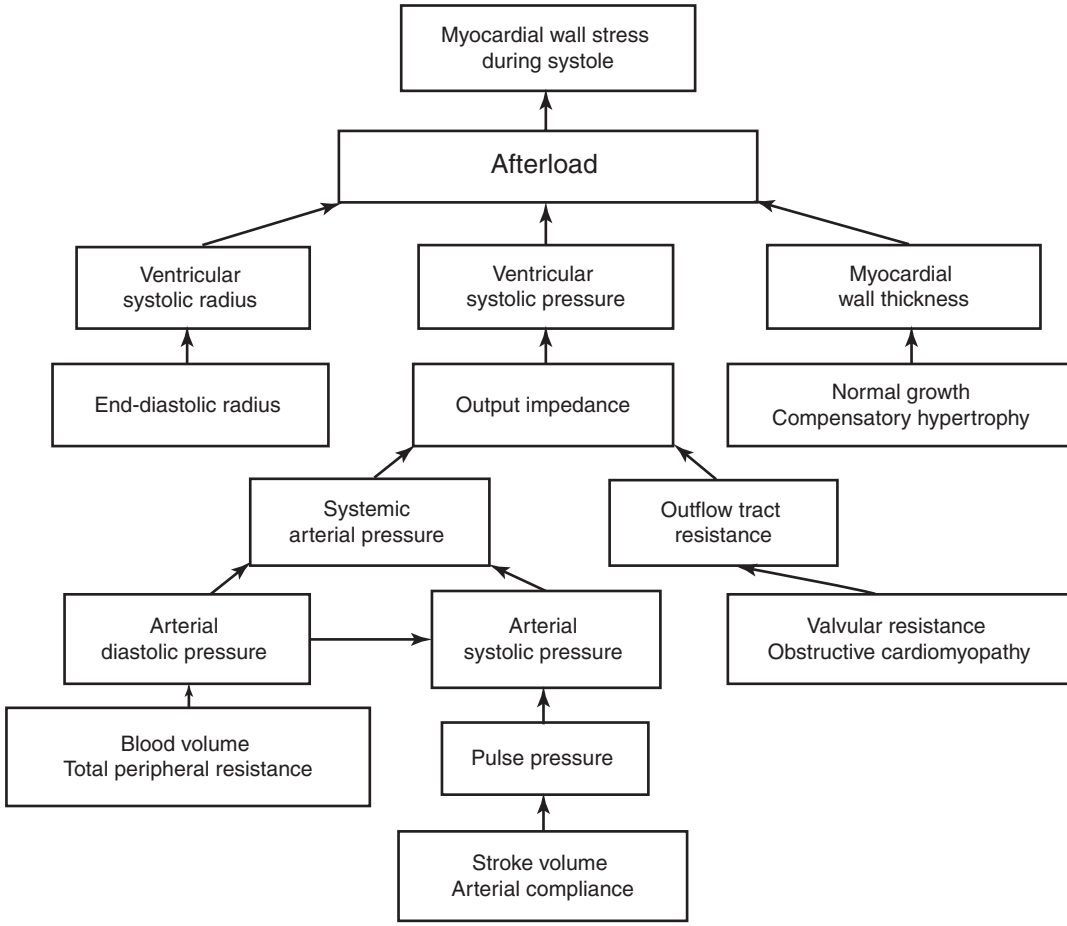

Fig. 2.4 Factors determining afterload. (From Norton [33])

stenosis, the lowest pressure is found where the velocity is highest and hence where the valve orifice is the smallest. Beyond the stenosis, velocity decreases and so pressure will increase, with the total amount of pressure increase (pressure recovery) being dependent upon the dissipation of kinetic energy due to flow separation and vortex formation across the valve. The consequence is that when Doppler gradients are measured at the point of minimal diameter of the stream of blood flow (the vena contracta), they will be higher than the invasive catheter measurements obtained in the proximal aorta, where pressure has been recovered. It has been noted that in milder aortic stenosis, the cusps of the valve form a funnel-shaped orifice and cause greater pressure recovery than in a more severely stenosed valve [13]. The extent of the phenomena is also dependent on the relationship between the dimensions of the valve orifice and the ascending aorta. A smaller aorta will lead to a lesser pressure loss and hence increased pressure recovery, compared to a larger aorta with the same degree of aortic stenosis.

The complexity of the relationship between the contracting ventricle, the arterial system, and its blood flow is such that finding a single parameter to fully encompass the cardiac afterload is probably impossible (Fig. 2.4).

Ventricular Wall Stress Versus Arterial Input Impedance

As previously introduced, aortic input impedance is only one of two biophysical concepts available to define afterload; the other is ventricular wall

stress, defined by LaPlace as $PR/2w$. Wall stress also carries with it some clinical limitations, as the values for pressures and dimensions are instantaneous and cannot account for rapidly changing loads encountered during the cardiac cycle. The calculations are also highly dependent upon ventricular geometric assumptions. The two differing afterload approaches of input impedance and wall stress have been compared in their validity as indicators of ventricular performance. Ross et al. constructed an animal model protocol to elucidate the relative importance of wall stress and impedance in negatively impacting ventricular stroke volume. These early experiments concluded that the dominant factor in regulating ventricular performance, as demonstrated by reduced fractional shortening, was the level of wall stress, rather than input resistance or pulsatile impendence [14].

Afterload Mismatch

Allied to this observation is the recognition that when pulsatile impedance is greater, changes in mean resistance produce greater changes in wall stress. This is presumably the result of the large increase in ventricular volume when pulsatile resistance rises, again emphasizing the impact of ventricular geometry on the outcome of these maneuvers. This appreciation led to the concept of afterload mismatch in 1976, a framework for assessing the matching between the afterload and the inotropic state in the whole heart. Under normal physiologic circumstances, an increase in afterload is usually accompanied by increased venous return (due to movement of blood from the arterial to venous systems) and hence increased end-diastolic volume. This helps to maintain stroke volume in the face of an increased afterload. A mismatch can be induced acutely in a normal heart if end-diastolic volume is not allowed to compensate for the increase in afterload [15]. The result will be a fall in stroke volume, ejection fraction, and ventricular circumference. An example of mismatch creation could be a scenario with sudden infusion of vasopressor into a volume depleted vascular system. An afterload mismatch can also be induced in a normal left ventricle in the opposite hemodynamic situation of volume overload, when the limit of preload reserve has already been reached and the average sarcomere length exceeds 2.2 μm. Additional afterload applied to the ventricle already working at a maximal end-diastolic volume will cause a sharp drop in stroke volume, unless contractility is also enhanced by an inotrope. Thus, an applied afterload stress can serve as an indicator that a heart is operating near either the upper or lower limits of preload [16]. The concept that afterload mismatch can exist even in the basal state explains why therapeutic afterload reduction in conditions such as severe left ventricular dysfunction or mitral regurgitation can significantly improve cardiac output, so long as preload is maintained and the ventricle can achieve an increased end-diastolic volume.

In addition to the acute afterload response studies on the intact heart in unanesthetized large animal subjects, the longer term effects of a sustained increase in afterload have also been extensively studied in animal models. Ross et al. instrumented 12 dogs with ultrasound transducers placed across the left ventricle for measuring the extent and velocity of wall shortening and a micromanometer measuring left ventricular cavity pressure. Transaortic constriction was performed using an inflatable rubber cuff around the proximal aorta to maintain an average systolic blood pressure of 210 mmHg. Ventricular pressures and dimensions were recorded prior to constriction, immediately after constriction, at an early phase after constriction (average 9 days), and a later phase (average 2.5 weeks). Calculations of wall forces relied on a spherical model. Immediately after constriction, there was a decrease in ventricular wall thickness and a 55% increase in calculated peak wall stress above control. Percentage shortening fell by 24% acutely and mean circumferential shortening velocity (V_{CF}) decreased by 39% from control. In the acute phase (mean 9 days), the ventricles were seen to dilate with a 4% increase in end-systolic diameter and peak wall stress fell to 37% above control despite a constant peak systolic left ventricular pressure averaging 210 mmHg. Percentage shortening and

mean V_{CF} remained below control levels at −12% and −20%, respectively. By the later phase at mean 2.5 weeks, the left ventricular walls had significantly hypertrophied with a 15% increase in ventricular wall cross-sectional area above control, with the increased wall thickness successfully reducing peak wall stress to 22% above control. End-diastolic diameter and percent shortening returned to normal [16]. The ventricle was considered to have successfully compensated at this time point by resuming its baseline fractional shortening in the face of a marked sustained elevation in afterload. This study reinforces the concept that the initial afterload mismatch, which causes an acute reduction in stroke volume, can be overcome by the development of physiological hypertrophy with thickened walls once again generating baseline stroke volumes. However, the limited duration in this early proof of concept study does not permit observation of the rapidly hypertrophied heart as it continues to maintain the higher degree of pressure generation against an increased afterload over time. The technique of transaortic banding has been applied to many species of experimental animal models, most commonly mice, enabling investigators to study the development of physiological hypertrophy and subsequent progression to heart failure, so elucidating the myocardial signaling pathways that govern the hypertrophic response [17].

Ventriculo-Arterial Coupling and Pressure–Volume Loops

The relationship between the ventricle and its afterload is key to the concept of ventriculo-arterial coupling and can be illustrated by pressure–volume loops. The effective arterial elastance (E_a) describes the ability of the vessel to accommodate pulsatile flow. E_a can be calculated by dividing the end-systolic pressure by the stroke volume and is, therefore, the slope of the stress/strain or pressure/diameter graphs ($\Delta P/\Delta D$), also known as the end-diastolic pressure–volume relationship. Elastance is the reciprocal of compliance, compliance being the ease of distension. At lower levels of arterial pressure, the arterial wall is supported by compliant elastin fibers, whereas the stiffer collagen fibers predominate at higher pressures. Therefore, the slope of the curve will be greater at higher levels of arterial pressure. Collagen in the human aorta is at least 500 times stiffer than elastin, and the aortic wall collagen content more than doubles from age 20 to 70 years (Fig. 2.5).

During the left ventricular ejection phase of the cardiac cycle, as ventricular volume decreases, the potential for the ventricle to develop pressure also drops. The smallest volume reached is the end-systolic volume, which marks the point of full stroke volume ejection. The aortic valve subsequently closes and the diastolic phase begins. The end-systolic volume at a certain degree of contractility and preload will, therefore, be determined by the afterload. A rise in aortic pressure, all else being equal, will correlate with a decreased stroke volume and a lower aortic pressure with an increased stroke volume. For example, in an individual with aortic stenosis, the pressure–volume loop may show a higher peak pressure, a lesser stroke volume, and an increased end-systolic volume, so shifting the curve into a taller and narrower configuration. Over time, compensatory hypertrophy will mitigate the high wall stress and improve the ventricle's ability to overcome the high afterload and increase the stroke volume, thus causing the loop to increase in width. With a sudden increase in afterload, the stroke volume will be diminished, which causes the end-systolic volume to rise. Over the following few beats, the increase in end-systolic volume predominates over the increased end-diastolic volume (which usually augments ventricular function), with the net change being a decrease in stroke volume and hence a decrease in the width of the pressure–volume loop. With a reduced afterload, the left ventricle ejects blood with greater ease, so augmenting the stroke volume and decreasing end-systolic volume. With less blood remaining in the ventricle after the ejection phase, the ventricle will fill to a lesser end-diastolic volume compared to prior the afterload reduction. Despite this mild reduction in preload, stroke volume shows a net increase because the reduction in end-diastolic volume is less than the reduction in end-systolic volume.

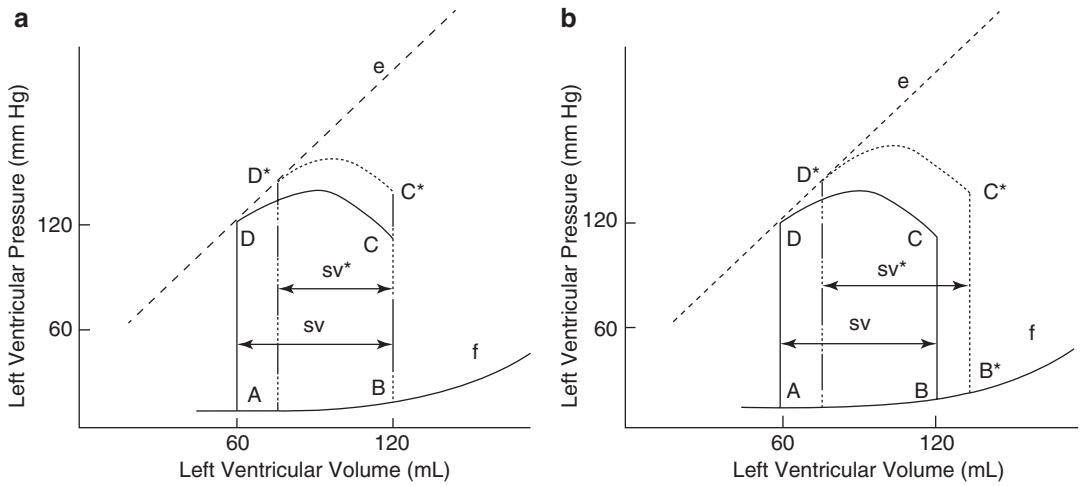

Fig. 2.5 Effects of acutely increasing afterload on the pressure–volume loop. . *A* mitral valve opens, *B* mitral valve closure, *C* aortic valve opens, *D* aortic valve closure, *e* end-systolic pressure–volume relationship, *f* end-diastolic pressure–volume relationship (or ventricular elastance). The dotted loop represents the effect of increasing afterload. Panel b demonstrates the impact of afterload plus (dotted loop) increased preload, increased end-diastolic volume, and therefore preservation of stroke volume. (From Iaizzo [19])

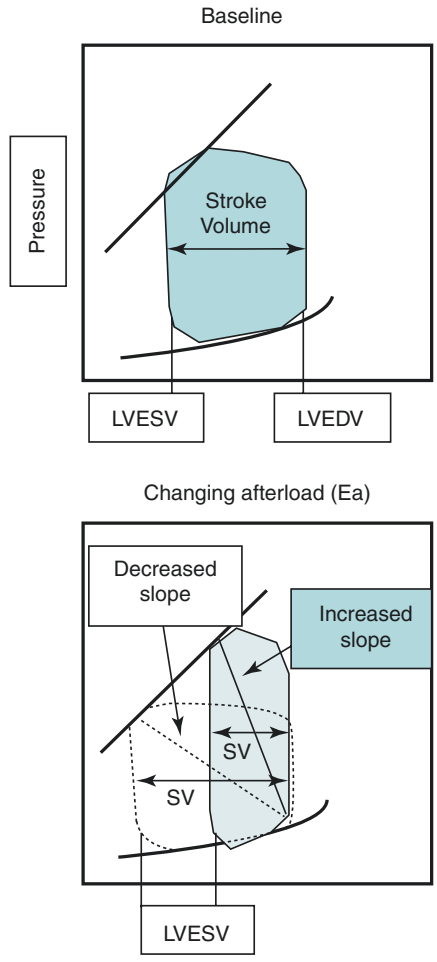
The ratio of the effective arterial elastance to the E_{es} (the slope of the ventricular end-systolic pressure–volume relationship) represents a measure of pump efficiency in expelling blood into the vasculature. This value can be used as a reflection of the ventriculo-arterial coupling and helps conceptualize the relationship between the pump and the vasculature. As E_a increases initially, the arteries accommodate greater blood flow, permitting a greater stroke work. If E_a were to continue to increase, the stroke work would reach a maximal plateau value where arterial and ventricular properties are equal, meaning that $E_a = E_{es}$. The E_a also increases with improvements in ventricular efficiency, which is defined by external stroke work/MVO_2/beat. Ventricular efficiency is maximal at $E_a = E_{es}/2$, meaning that the most favorable ventriculo-arterial coupling occurs when the E_a/E_{es} ratio lies in the range 0.5–1.0 [18] (Fig. 2.6).

Afterload and Cardiac Efficiency

The heart requires significant energy generation to perform its functions. Cardiac metabolism is predominantly aerobic, and hence, the work performed by the heart is typically gauged in terms of myocardial oxygen consumption (MVO_2). Myocytes are densely packed with mitochondria to generate sufficient ATP, predominantly from fatty acid breakdown, to fulfill the required cellular mechanics to sustain the cardiac cycle. The energy required for development and maintenance of systolic wall tension is a key factor in determining myocardial energy expenditure. One hallmark of the failing heart is its disordered and inefficient myocardial metabolism. The degree of afterload is also highly relevant in the ischemic heart, where reducing afterload and reducing heart rate are the major strategies in reducing myocardial oxygen consumption. A systolic pressure increase of only 20–30 mmHg can have a dramatic negative impact on function in a failing or ischemic left ventricle, both by inducing a lower stroke volume and by raising myocardial oxygen demands. Oxygen extraction in the capillary bed is near-maximal, and hence, the capacity to meet the oxygen demands of the myocardium may not be possible in the setting of a high afterload, especially if coronary blood flow can no longer be increased due to flow-limiting stenoses. The other determinants of myocardial oxygen demand are the heart rate, preload, and contractility. The MVO_2 in the rest-



$$EF = \frac{SV}{LVEDV} = \frac{\text{Width of PV Loop}}{LVEDV}$$

Fig. 2.6 The pressure–volume relationship and elastance. Increased elastance, as illustrated by the steeper diagonal slope, leads to smaller stroke volume. (From Bashore [35])

ing heart is approximately 8 mL O_2/min per 100 g [19]. The instantaneous cardiac oxygen consumption can be measured in a human heart by employing the Fick principle; however, this does require catheterization of the coronary sinus to directly measure the venous oxygen saturation and coronary blood flow. Therefore, indirect assessments of the MVO_2 are necessary. Relative changes can be estimated by calculating the pressure-rate product. A simple method, described as early as 1912 using isolated cat and rabbit myocardium, is multiplication of the heart rate with the systolic blood pressure [20]. This noninvasive hemodynamic determinant of oxygen consumption has been validated by other investigators using the isolated dog heart, with the aortic pressure being shown to be the dominant influence in determining myocardial oxygen requirement. A 175% increase in work with afterload elevation was matched with a 178% increase in oxygen consumption as calculated by the product of coronary flow and coronary arteriovenous oxygen difference [21]. These investigators also established the use of the time-tension index/beat in mmHg seconds, derived from the area under the systolic portion of the aortic pressure curve, as an alternate metric of oxygen consumption. They also point out, by the Law of LaPlace, that the generation of the same intraventricular time-tension index will require greater myocardial fiber tension in a large radius heart compared to a smaller one. This fact highlights the inherent mechanical inefficiency of the dilated failing heart. Also of note is a study using healthy humans that demonstrated a corre-

lation of 0.88 between MVO_2 and heart rate alone and 0.90 using the rate–pressure product [22] although some authors have emphasized the limitations of these indirect indices of MVO_2 which do not capture all potentially important changes in myocardial contractility and ventricular dimensions, particularly in less healthy subjects [23].

The Law of LaPlace can also be used to explain why the pressure-overloaded left ventricle (such as that associated with aortic stenosis) will incur a higher myocardial oxygen demand than the volume-overloaded ventricle (as in aortic regurgitation). LaPlace stated that wall tension is proportional to $PR/2$, where P is chamber pressure and R is chamber radius. The pressure-overloaded ventricle shows a large increase in the pressure variable, which will equate to much higher wall tension, and hence MVO_2. Conversely, in the volume-overloaded ventricle, the radius will increase, but not as dramatically as the pressure in the pressure-overload model. Hence, the rise in wall stress in the volume-overload setting will be less substantial, and the corresponding MVO_2 less dramatically elevated.

Afterload in Clinical Practice

Afterload in the Pulmonary Vasculature

Afterload is most frequently discussed in reference to the left ventricle, but can also be applied to the right ventricle and the pulmonary vasculature into which this chamber pumps. It should be noted that significant differences exist in the manners in which the right and left ventricle handle increases in their afterloads. Normally, the resistance to flow in the pulmonary vascular system is much lower at about one-tenth of the resistance met by the left ventricle for the same stroke volume. The thicker walled left ventricle is able to generate much greater pressures and usually successfully generates unchanged stroke volumes in the face of afterload increases. The right ventricle operates much nearer to its full contractility capacity, because it has only a sixth of the muscle mass of the left ventricle and yet performs a quarter of the work. It succeeds in pumping the same cardiac output as the left ventricle due to the much lower resistance in the pulmonary vasculature than the systemic circulation. Operating within this closely matched ventriculo-arterial framework, the right ventricle is extremely sensitive to elevations in its afterload. Even a structurally normal right ventricle may decrease its stroke volume to small elevations in pulmonary vascular resistance. However, the right ventricle can also remodel and adapt to higher pulmonary pressures with time, with the maximal mean artery pressure normally accommodated without right ventricular failure being in the order of 40 mmHg. Severe right ventricular dilatation and dysfunction usually result from its attempts to compensate and maintain stroke volume as the pulmonary pressures rise beyond this [24].

- The pulmonary arterioles also serve as the site of major resistance to flow; however, the pulmonary arterioles receive a more pulsatile input of blood flow than their systemic counterparts. Within this much smaller vascular system, the roles of cushion, conduit, and resistance are not as clearly ascribed to certain generations of vessels as in the systemic circulation. Pulmonary hypertension is currently defined as a mean pulmonary artery pressure of greater than 25 mmHg, with a pulmonary capillary wedge pressure less than 15 mmHg indicating that the hypertension is not secondary to left-sided heart disease [25]. The various etiologies of pulmonary hypertension all tend to show common histopathology features, namely, initial fibrosis, medial thickening, and pulmonary arteriolar occlusion [26]. Right ventricular afterload reduction with pulmonary vasodilators is key to the management of pulmonary hypertension and right ventricular failure. Inhaled nitric oxide has a role during the invasive assessment of pulmonary vascular pressures to help determine the potential for pulmonary vasodilatation, and the use of continuous oxygen therapy can help reduce the degree of hypoxic vasoconstriction. Pulmonary hypertension therapeutics include calcium channel antagonists (nifedipine, amlodipine), prostacyclin analogs (epo-

prostenol, treprostinil, iloprost), endothelin receptor antagonists (bosentan, ambrisentan, macitentan), phosphdiesterase-5 inhibitors (sildenafil, tadalafil), and soluble guanylate cyclase simulators (riociguat) [27].

Afterload and the Respiratory Cycle

The potential for mechanical ventilation to affect invasive assessments of preload (such as the right atrial and pulmonary capillary wedge pressures) and possibly reduce preload by decreasing the pressure gradient into the thorax was discussed in Chap. 1. Positive pulmonary pressures during mechanical ventilation also affect afterload. The degree of pulmonary vascular resistance, and hence RV afterload, is proportional to the degree of airway pressure elevation. With significant RV afterload elevations, the right ventricle will dilate and induce intraventricular dependence, with shifting of the septum into the left ventricle, which reduces left ventricular filling and stroke volume. Conversely, the direct effect of positive airway pressure on the left ventricle is to increase stroke volume by increasing the intrathoracic aortic pressures relative to peripheral arterial pressure. Also worth mentioning in the consideration of valvular lesions and afterload is the effect of mitral regurgitation on the degree of cardiac afterload. Mitral regurgitation will decrease afterload because, during ventricular systole, a fraction of the left ventricular end-diastolic volume will take a retrograde route and flow back into the left atrium through the incompetent valve. Hence, the left ventricle will be working against a reduced afterload, as some blood ejection is into the lower-pressure atrium rather than the usual anterograde flow into the higher-pressure aorta.

Total Peripheral Resistance

The term "total peripheral resistance" (TPR) encompasses the sum of all regional resistances in the systemic circulation. It is sometimes used to infer the total afterload faced by the heart, although as we have already seen the resistance to flow, largely imposed by the arterioles, is actually only one component of the complete cardiac afterload. TPR can be approximated from Ohm's law. In the patient with Swan-Ganz calculations of cardiac output, values for systemic vascular resistance (SVR) and pulmonary vascular resistance (PVR) are routinely derived in Wood units from:

$$\text{SVR} = 80 \times \left(\text{mean arterial pressure} - \text{mean right atrial pressure}\right) / \text{cardiac output}$$

$$\text{PVR} = 80 \times \left(\text{mean pulmonary artery pressure} - \text{pulmonary capillary wedge pressure}\right) / \text{cardiac output}$$

These equations give values in dyn s cm^{-5}. Other units for measuring vascular resistance are pascal seconds per cubic meter (Pa s/m^3), or for convenience when using pressure in mmHg and cardiac output in l/min, resistance can be expressed in mmHg min/L. This equates to hybrid reference units (HRU), also known as Wood units, favored by pediatric cardiologists. Multiplying by a factor of 8 converts from Wood units to MPa s/m^3 or by a factor of 80 converts from Wood units to the international unit of dyn s cm^{-5}.

The resistances imposed by the arterial system are arranged in both serial and parallel orientations. In a circuit where resistances lie in series, the total resistance will be the sum of the individual resistive components. Conversely, a parallel circuit will have a total resistance equaling the sum of the reciprocals of the individual resistive components, thus creating a much lower overall resistance than in a series circuit. Therefore, most organ arterial supplies are configured in a parallel arrangement, so limiting the pressure generation required by the ventricle to perfuse all organs. A rise in resistance within one organ bed will have minimal impact on the other arterial beds.

The majority of the resistance component of arterial input impedance lies in the arterioles.

These vessels range 10–150 μm in diameter and are under constant vasoactivity regulation from the sympathetic nervous system and local mediators, thus controlling the flow of blood into specific capillary beds. Local vasodilators include platelet-derived substances, such as serotonin, and endothelium-derived mediators, such as nitric oxide.

Therapeutic Afterload Reduction

The concept of therapeutic afterload reduction was initially clinically applied in the form of intra-aortic balloon counterpulsion to support patients with cardiogenic shock post myocardial infarction. This technique was demonstrated to unload the left ventricle, enhance left ventricular ejection fraction, and improve coronary artery perfusion. Pharmacological afterload reduction strategies for unloading the left ventricle, principally the use of a sodium nitroprusside infusion, are useful tools in acute cardiac care. Nitroglycerin, which combines more venodilation with arteriolar vasodilation in comparison to nitroprusside, may also be used for afterload reduction. The angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers, hydralazine, and dihydropyridine calcium channel blockers are additional options, and clevidipine, an intravenous dihydropyridine drug, is increasingly used in critical care settings.

Vasodilating drugs have minimal direct effect on the large elastic arteries, but can markedly reduce reflected wave amplitude from the periphery by decreasing elastance of the smaller muscular arteries. The decreased amplitude and velocity of the reflected wave decreases systolic arterial pressure and increases proximal aortic flow during the deceleration phase. The resulting afterload reduction can help to optimize cardiac output and clinical status in patients with cardiogenic shock, severe mitral or aortic regurgitation, or even aortic stenosis with decompensated left ventricular dysfunction [28], by correcting the afterload mismatch. The afterload tends to be high in decompensated heart failure due to activation of the renin–angiotensin–aldosterone system, as well as a higher effective blood velocity due to slow forward flow. Although the sympathetic activation causing vasoconstriction in heart failure is compensatory to maintain arterial blood pressure despite low output, these adaptations can be counterproductive and impose further afterload on the failing ventricle. Pharmacological afterload reduction can, therefore, achieve marked improvements in cardiac output and symptoms for patients with a dilated left ventricle and sufficient preload reserve (Fig. 2.7).

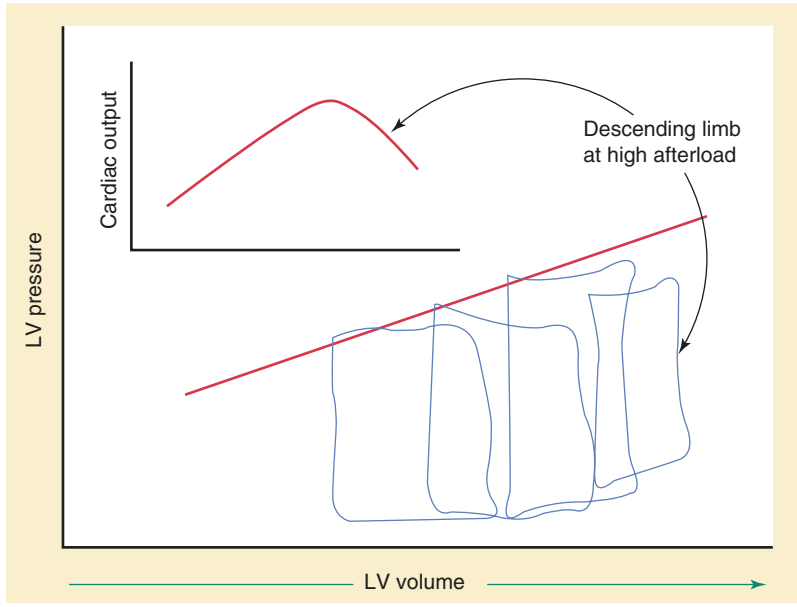


Fig. 2.7 Conditions for afterload mismatch in systolic heart failure. (From Ross [15]). The stroke volume is seen to decrease (decreased width of the pressure–volume loop) as afterload increases

The use of afterload reduction in patients with aortic stenosis may initially seem counterintuitive as the cardiac output across a stenotic aortic valve has traditionally been considered to be fixed with a risk of hypotension without improvements in output if the blood pressure is lowered. However, this scenario underlines the complexity of afterload, because the aortic stenosis in not actually the sole factor determining the force against which the ventricle must pump. Resistances in series are additive, and so the resistive component of aortic input impedance can still be lowered by reducing the most distal resistances in the arterioles despite the proximal resistance across the valve remaining constant. The reduction in total peripheral resistance and hence mean arterial pressure with nitroprusside can, therefore, successfully reduce the afterload mismatch of the dysfunctional ventricle pumping against a high afterload despite the presence of severe and fixed aortic stenosis. Conversely, the administration of nitroprusside to a relatively normal cardiovascular system, or to the heart with aortic stenosis but a preserved ejection fraction, would be expected to lower the cardiac output. This is due to some concurrent venodilation, which will reduce preload and actually induce an afterload mismatch. Another setting where pharmacological afterload reduction can precipitate a worsened clinical status is in the setting of a significant pulmonary shunt. Nitroprusside can inhibit the hypoxic vasoconstriction in a region of pulmonary vasculature, thus supplying blood flow to an area of the lung not receiving good oxygenation (e.g., due to lobar consolidation). This will exaggerate a perfusion–ventilation mismatch and potentially worsen the arterial oxygen saturation. The use of nitroprusside as a lone afterload reducer in the setting of ischemia should also be avoided. Nitroprusside has been shown to decrease myocardial perfusion in the setting of coronary stenoses, whereas nitroglycerin can enhance myocardial perfusion, largely through dilatation of coronary collateral vessels [28, 29].

Bullet Point Summary

- Afterload consists of the forces against which the heart pumps to expel blood into the vasculature.
- Afterload can be defined in terms of wall stress, using the law of LaPlace.
- Alternatively, afterload can be conceptualized as arterial input impedance, drawing parallels from electrical circuits.
- An inverse relationship exists between stroke volume and afterload.
- The aorta and proximal large arteries have a higher ratio of elastic to collagen and are, therefore, highly compliant.
- These elastic arterial walls absorb the systolic pulsations in blood flow, converting stored energy into recoil that maintains the pressure and flow during diastole – the Windkessel effect.
- The arterioles are the site of the majority of arterial resistance, with arteriolar tone being highly dependent on the sympathetic nervous system and local mediators.
- Reflected waves from bifurcations and arterial discontinuities can increase afterload when they return to the proximal aorta during systole.
- With aging, or pathological processes such as hypertension, afterload rises due to increased magnitude of the incident systolic wave and also early return of the reflected wave.
- Afterload mismatch is a scenario in which the ventricular performance is not well coupled to the afterload it encounters, which increases myocardial oxygen consumption and decreases cardiac energy efficiency.
- Over time, an afterload mismatch can induce ventricular hypertrophy.
- Intra-aortic balloon counterpulsion, and drugs such as nitroprusside, hydralazine, and ACE inhibitors, can decrease systemic afterload.
- Pulmonary vasodilators are the cornerstone of pulmonary hypertension management and decrease the afterload faced by the right ventricle.

Review Questions

1. The primary determinant of cardiac output is:
   (a) Preload
   (b) Myocardial contractility
   (c) Heart rate
   (d) Afterload
   Answer is (a).

2. Which one of the following statements regarding the vasculature is *false*?
   (a) With aging, changes in the media of the large elastic arteries cause them to stiffen.
   (b) Vascular compliance is heart rate dependent.
   (c) The small peripheral vessels show a prominent Windkessel effect.
   (d) Retrogradely reflected pressure waves usually arise from arterial branch points such as the iliac bifurcation.
   (e) A reflected wave falling during diastolic is more advantageous to the cardiovascular system,

   Answer is (c). It is the proximal elastic arteries that show the Windkessel effect. The smaller peripheral arteries and arterioles have the capacity to vasoconstrict substantially, but they are not exposed to highly pulsatile blood flow and do not have the elastic properties to permit significant recoil if the pressure within the vessel falls. A reflected wave falling within diastole can help to augment coronary blood flow.
3. Which one of the following statements is true regarding the concept of afterload mismatch?
   (a) Afterload mismatch can occur when the patient is vasodilated.
   (b) An increase in afterload is usually accompanied by a decrease in venous return, due to decreased availability of blood in the venous system.
   (c) Afterload mismatch may occur with sudden infusion of vasopressor in the setting of volume depletion.
   (d) Afterload mismatch can be induced in a normal left ventricle with high preload, when a sudden increase in both afterload and myocardial contractility occurs.
   (e) A chronic afterload mismatch does not result in structural myocardial changes.

   Answer is (c). Under normal physiologic circumstances, an increase in afterload is usually accompanied by increased venous return, due to movement of blood from the arterial to venous systems. A mismatch can be induced acutely in a normal heart if end-diastolic volume is not allowed to compensate for the increase in afterload. Alternatively, additional afterload applied to a ventricle already working at a maximal end-diastolic volume will cause a sharp drop in stroke volume, unless contractility is also enhanced.
4. Which one of the following statements is true regarding potential strategies to reduce afterload clinically?
   (a) The goal of intra-aortic balloon counterpulsion is to lower systolic blood pressure and hence reduce afterload.
   (b) In the setting of some pulmonary conditions, nitroprusside can cause hypoxia.
   (c) Afterload reduction is strictly contraindicated in the setting of a fixed obstructive lesion such as aortic stenosis.
   (d) The sympathetic activation causing vasoconstriction in heart failure is compensatory to maintain blood pressure despite low cardiac output, and hence, afterload reduction should be avoided.
   (e) Sildenafil is a selective pulmonary arterial vasodilator and has no effect on the systemic vasculature.

   The answer is (b). Nitroprusside can inhibit the hypoxic vasoconstriction in a region of pulmonary vasculature, thus supplying blood flow to an area of the lung not receiving good oxygenation (e.g., due to lobar consolidation). This will exaggerate a perfusion–ventilation mismatch and potentially worsen the arterial oxygen saturation. Intra-aortic balloon counterpulsion augments diastolic blood pressure, thus reducing left ventricular wall stress. Afterload reduction with an IABP or nitroprusside may be indicated in acutely ill patients with severe aortic stenosis and a reduced left ventricular ejection fraction. Vasodilation in the setting of decompensated systolic heart failure can correct an afterload mismatch and improve the cardiac output. Sildenafil does have some peripheral vasodilating affects, and hence, dosage may be limited by systemic hypotension.

5. A 70-year-old male with severe aortic stenosis (peak/mean pressures by echocardiography 68/42 mmHg, aortic valve area by continuity equation 0.6 cm^2) presents with worsening dyspnea, lower extremity edema, oliguria, and a 15-lb. weight gain. The blood pressure is 88/74. He is peripherally cool and mildly confused. The left ventricular ejection fraction on his most recent echo was 25%. Are the following statements true or false?
   (a) Due to the severity of the aortic valve stenosis, the only option for reducing afterload is valvuloplasty or valve replacement.
   (b) There is an afterload mismatch.
   (c) Pressure recovery may lead to overestimation of the valve gradient by Doppler measurements and is more likely to occur with smaller ascending aorta diameter.
   (d) The calculated SVR is likely to be elevated; a lower than expected SVR may suggest a septic component to the hypotension.
      (a) False. The total resistance presented by the arterial system is the sum of the many components arranged in series through the vasculature. The significant resistive contribution provided by the arterioles is additive to the resistance imposed by the stenotic valve. Therefore, the afterload can be reduced by vasodilatation of the arterioles.
      (b) True. Although we do not have invasive hemodynamics provided for this patient, the cool peripheries, delayed mentation, and oliguria strongly suggest a low cardiac output state. Therefore, the poor ventricular performance is not well matched to the high afterload imposed by the aortic stenosis plus peripheral vasoconstriction due to the activation of the renin–angiotensin system in cardiogenic shock. Better matching of the low stroke volume may be achieved through peripheral vasodilatation, if this can be tolerated by the low blood pressure. Aortic balloon counterpulsion and/or low doses of intravenous nitroprusside may be successful in improving the cardiac output and stabilizing the decompensated patient ahead of definitive aortic stenosis management.
      (c) True. Pressure recovery is a phenomenon arising from the decrease in velocity and increase in pressure in the proximal aorta, beyond the stenotic aortic valve. This can lead to overestimation of the valve gradient by Doppler measurements and is more likely to occur with smaller ascending aorta diameter.
      (d) True. As described above, the systemic vascular resistance would be expected to be at the higher end, or above, the normal range for SVR. A value in the range of 1200–2500 dyn s/cm^5 would be consistent with the scenario. If the calculated value lies much below this, consideration should be made of an additional distributive shock process, such as sepsis. Of note, a patient with cardiogenic shock and a poor cardiac output can sometimes be seen to have an encouraging rise in their mixed venous saturation, cardiac output, and a fall in the SVR, with the actual etiology being early sepsis causing peripheral vasodilatation.
6. A 55-year-old female with hypertension, diabetes, and chronic kidney disease presents acutely dyspneic. Her blood pressure is 210/110 mmHg, right atrial pressure 15 mmHg, and heart rate is 92 bpm. Her examination is consistent with pulmonary edema. A diagnosis of hypertensive emergency is made. Are the following statements true or false?
   (a) The decrease in arterial compliance associated with hypertension and diabetes is most pronounced in the arterioles.
   (b) Effective arterial elastance is calculated by dividing the stroke volume by end-systolic pressure.
   (c) If the mean arterial pressure is known to be 143 mmHg and the cardiac output

4.0 L/min, the systemic vascular resistance will calculate in the region of 2500 dyn s/cm5.

(d) If this patient receives an arteriovenous fistula in preparation for future hemodialysis, the afterload would be expected to fall and the preload increase.

(a) False. The arteriosclerosis associated with hypertension and diabetes is most prominent in the large elastic arteries. The enhanced incident wave increases afterload, as does the early return of reflected pressure waves.

(b) False. Effective arterial elastance is calculated by dividing the end-systolic pressure by the stroke volume. It is visualized as the slope on the stress/strain graph.

(c) True. MAP = (2 × diastolic pressure + systolic pressure)/3 = 143. SVR = 80 × (MAP − RA pressure)/cardiac output = 80 × (143 – 15)/4 = 2560.

(d) True. Creation of a shunt from the arterial to venous system would be expected to decrease the afterload by directing blood flow away from the high resistance arterioles into the lower resistance venous system, and so enhancing venous return to the heart. The decreased afterload has been shown to slightly reduce myocardial oxygen demand, but also negatively impacts the coronary blood flow [30].

Contractility

3

Jordan S. Thomas and Justin M. Dunn

Introduction

Myocardial contractility—often referred to as inotropy—is the inherent capacity of the myocardium to contract *independent* of loading conditions, that is, preload and afterload (discussed in Chaps. 1 and 2, respectively). Thus, for a given preload and afterload, contractility is a manifestation of all other factors that influence the interactions between contractile proteins. The incorporation of all these factors makes a simple definition of "contractility" difficult, and it is more easily understood through discussions of *changes* in contractility. Clinically, a change in left ventricular contractility can be defined as a change in the work performed per beat at a constant end-diastolic volume and aortic pressure.

Contractility is best understood by assessing the rate of rise of left ventricular pressure or dP/dt (Fig. 3.1). The contours of these left ventricular pressure curves provide a reasonable index of myocardial contractility. The slope of the ascending limb of each curve indicates the maximal rate of force development by the ventricle. The maximal rate of change in pressure over time, also referred to as the maximum dP/dt, is shown by the tangents to the steepest portion of the ascending limb of each curve. This slope is maximal during the isovolumic phase of early systole in the cardiac cycle, from closure of the mitral valve until opening of the aortic valve (Fig. 3.2).

Accurate clinical measurement of contractility is difficult. In the cardiac catheterization lab, the maximum rate of pressure development (dP/dt_{max}) can be measured during isovolumetric contraction by placing catheters directly in the ventricle. This measurement is often used as an index of contractility [3]. Decreases in left ventricular dP/dt_{max} below the normal value of 1200 mmHg/s suggest depressed myocardial contractility.

The ejection fraction (EF), defined as the ratio of stroke volume to end-diastolic volume, is widely used clinically as a noninvasive surrogate index of cardiac contractility [4]. In current practice, EF is most often measured noninvasively with echocardiography, but alternative methods including nuclear imaging and, more recently, cardiac MRI also exist with each having their own relative strengths and weaknesses. Normal ejection fraction reference values vary depending on gender and the imaging modality used. In clinical practice, however, a range of approximately 50–70% can be considered normal by the majority of imaging modalities, while an EF less than 50% suggests at least some degree of depressed myocardial contractility.

(Adapted from Berne and Levy [1], p. 313, Fig. 16.9)

With recent advancements in imaging techniques, 2D speckle tracking echocardiography (STE) with strain imaging has become a key noninvasive tool and is one of the most direct measurements of both global and segmental myocardial tissue deformation and underlying contractility. With its high sensitivity and reproducibility, strain echocardiography has been validated in multiple cardiovascular disease states and holds tremendous promise in both clinical and research settings [5].

Physiology of Contraction

Contraction of cardiac muscle begins when a wave of excitation spreads via gap junctions along the myocardial sarcolemma and into the cells via T tubules. During phase 2 of the action potential, calcium permeability in the sarcolemma increases, and calcium enters the cell via calcium channels in the sarcolemma/T tubules (invaginations in the sarcolemma). This extracellular calcium triggers the release of a much larger store of calcium from the sarcoplasmic reticulum within the cell. This calcium then binds to troponin C forming the calcium–troponin complex, which subsequently interacts with tropomyosin to unblock active sites between the thin actin and thick myosin filaments and allows cross-bridge cycling and thus contraction to occur.

To understand the concept of contractility, it is important to revisit the underlying mechanisms by which contractility changes, beginning at the cellular level. This discussion must begin with the fundamental role of calcium in cardiac contraction and relaxation. With each spontaneous wave of excitation in the myocardium, sodium channels in the sarcolemma are opened by an action potential. Sodium moves into the cytosol depolarizing the membrane. Depolarization opens voltage-gated L-type calcium channels in the sarcolemma/T tubules, allowing an influx of calcium from the extracellular space. Each calcium channel controls a number of calcium release channels which are composed of four ryanodine receptors in the membrane of the sarcoplasmic reticulum. The influx of calcium through the L-type calcium channels triggers a conformational change in the ryanodine receptors, which allows calcium to flow from the sarcoplasmic reticulum into the cytosol via the

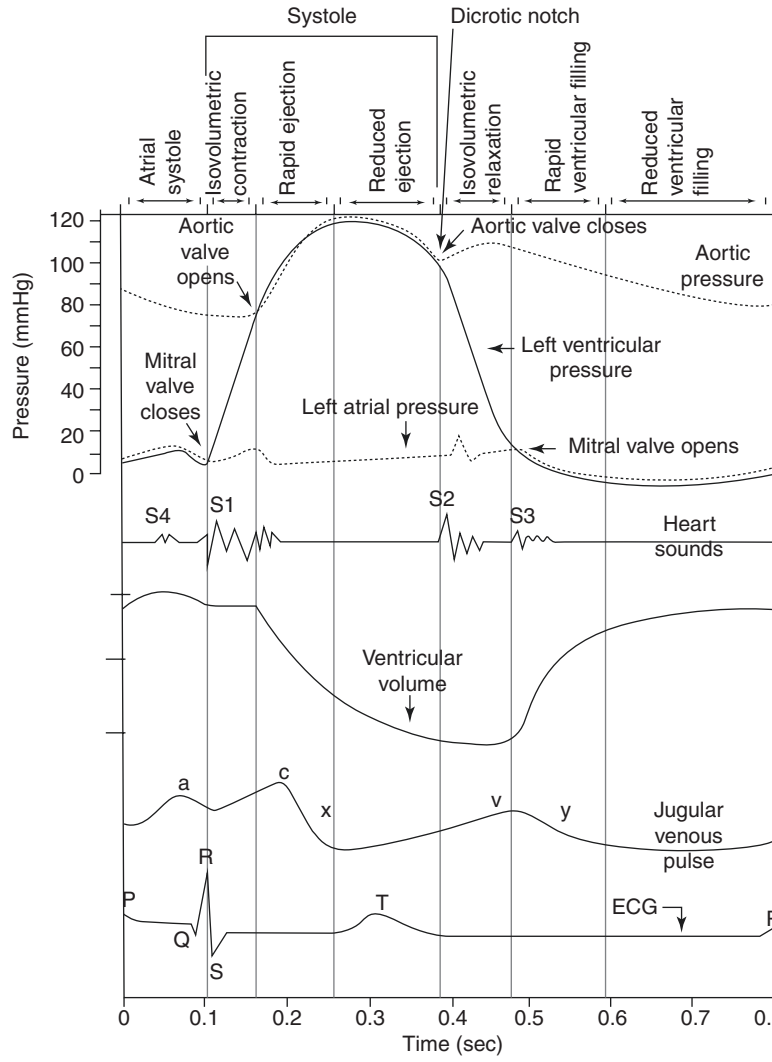

Fig. 3.2 Left atrial, aortic, and left ventricular pressure pulses correlated in time with aortic flow, ventricular volume, heart sounds, venous pulse, and the electrocardiogram for a complete cardiac cycle. (Adapted from Berne and Levy [2], p. 313, Fig. 16.10)

calcium release channels. The amount of calcium released from the sarcoplasmic reticulum is approximately 10 times the amount entering from the extracellular space (Fig. 3.3).

During systole, calcium in the cytosol binds to troponin C, initiating myocardial contraction by relieving the baseline inhibition of the contractile proteins (thin actin filament and thick myosin filament) by troponin I. When cytosolic calcium levels are low, the troponin complex (troponin C/I/T) holds tropomyosin in a position on the thin actin filament that prevents interaction between the cross-bridges on the thick myosin filament and the myosin-binding sites on the thin actin filament. When calcium binds to troponin C, a conformational change occurs, which weakens the bond between troponin I and actin. This conformational change moves the tropomyosin away from the myosin-binding sites and allows the myosin cross-bridges to interact with actin (Fig. 3.4).

At the end of systole, the calcium influx from the extracellular space ceases and the sarcoplasmic reticulum is no longer stimulated to release calcium. The sarcoplasmic reticulum then begins to avidly take up calcium via an ATP-dependent process. A cAMP-dependent protein kinase A (cAMP-PKA) phosphorylates phospholamban, which in turn stimulates the sarcoendoplasmic reticulum calcium ATPase (SERCA) pump in the membrane of the sarcoplasmic reticulum to take up calcium

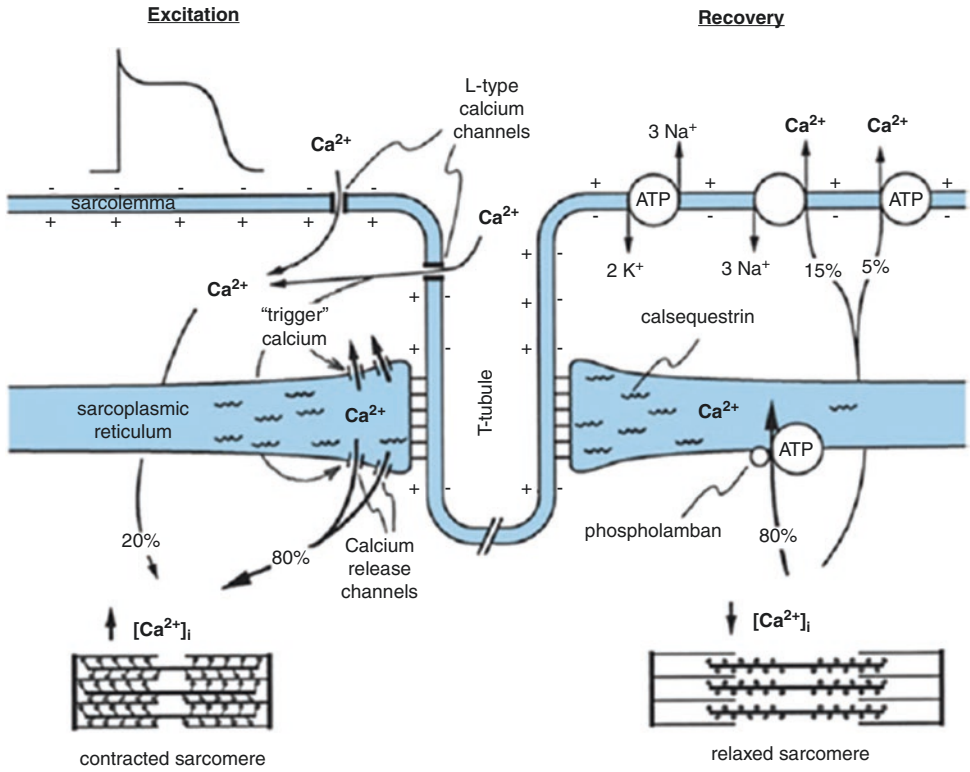

Fig. 3.3 Schematic diagram of the movements of calcium in excitation–contraction coupling in cardiac muscle. The influx of calcium (Ca^{2+}) from the interstitial fluid during excitation triggers the release of Ca^{2+} from the sarcoplasmic reticulum. The free cytosolic Ca^{2+} activates contraction of the myofilaments (systole). Relaxation (diastole) occurs as a result of uptake of Ca^{2+} by the sarcoplasmic reticulum, by extrusion of intracellular Ca^{2+} by Na^+–Ca^{2+} exchange, and to a limited degree by the Ca^{2+} pump. (Adapted from Berne and Levy [2], p. 365)

and facilitate relaxation. Phosphorylation of troponin I by cAMP-PKA also inhibits the calcium binding to troponin C, allowing tropomyosin to return to its resting inhibition of the myosin-binding sites and allowing diastole.

Cardiac contraction and relaxation are both enhanced by catecholamines, a physiologic phenomenon which has important clinical implications. Catecholamines (primarily endogenous norepinephrine, but also endogenous epinephrine) acting at the β receptor in the myocardial sarcolemma lead to the formation of cAMP from ATP and activation of PKA, which in turn increases the influx of extracellular calcium via increased opening of L-type calcium channels in the sarcolemma as discussed above. Catecholamines also enhance myocardial contractile force by increasing the rate of calcium release from the ryanodine receptor in response to calcium entry. The inotropic and lusitropic (relaxation) effects of catecholamine stimulation are mediated by the phosphorylation of phospholamban, accelerating calcium uptake into the sarcoplasmic reticulum by the SERCA receptors. Phosphorylation of phospholamban by cAMP-PKA removes its baseline inhibitory effect on SERCA receptors. While less physiologically significant, catecholamine stimulation of $\alpha 1$ receptors increases the formation of inositol 1,4,5-triphosphate (IP3) in the cytosol, which also stimulates some calcium release from the sarcoplasmic reticulum.

The parasympathetic nervous system has a much smaller effect on contractility as the vagus nerve fibers, mediated via acetylcholine at muscarinic (M2) receptors, are primarily distributed to the atria with very few to the ventricles. This explains the primary effect of parasympathetic stimulation on heart rate rather than contractility. However, under normal circumstances, there is a

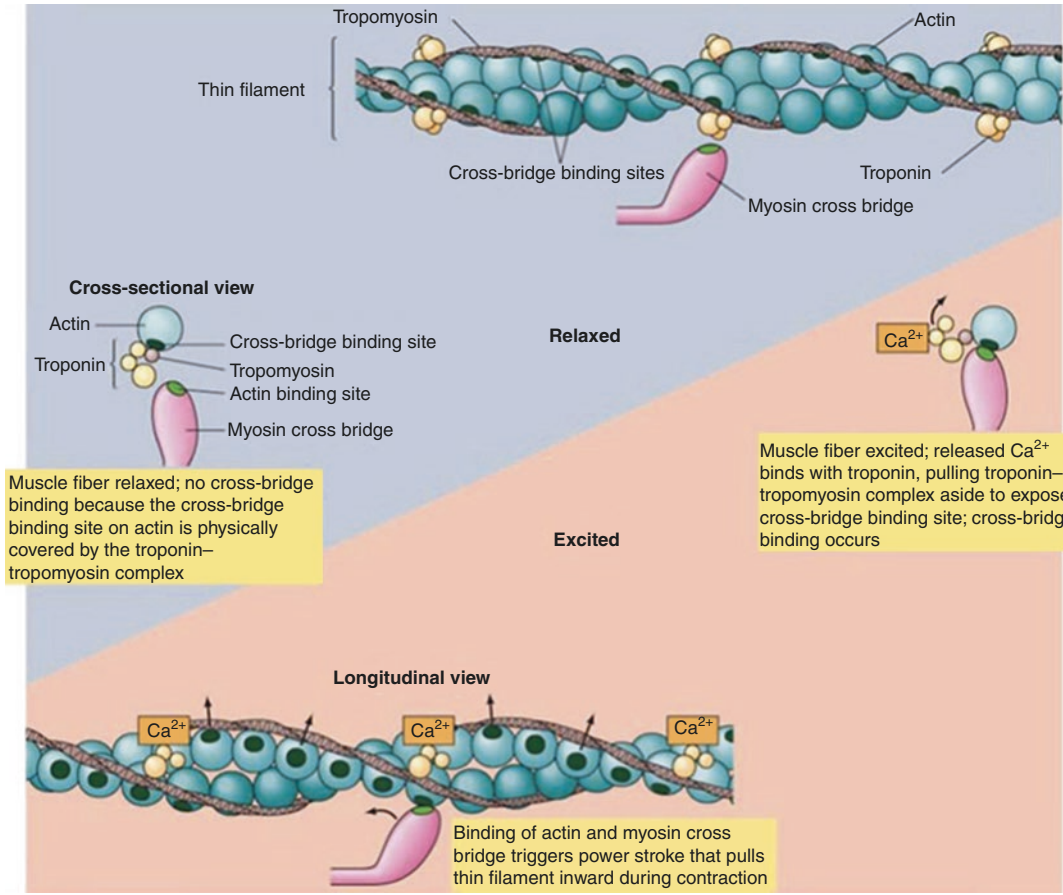

Fig. 3.4 Organization of the thin filament in both the relaxed and excited states. In the relaxed state, the myosin-binding site on actin is covered by the troponin–tropomyosin complex. In the presence of elevated calcium (Ca^{2+}), the troponin–tropomyosin complex is pulled away from the myosin-binding site when Ca^{2+} binds to troponin, allowing the myosin cross-bridge to interact with actin. Hydrolysis of ATP causes a conformational change in the myosin molecule, which pulls the actin filament toward the center of the sarcomere. A new ATP binds to myosin causing the release of the cross-bridge. If Ca^{2+} levels are still elevated, the cycle repeats. If Ca^{2+} are low, relaxation results

complex interplay between the sympathetic and parasympathetic nervous systems such that the sympathetic nerve fibers discharge continuously against tonic vagal inhibition.

There are two factors which affect inotropy that are worth mentioning despite the fact they are poorly understood: the Anrep effect and the Bowditch effect. The Anrep effect is the intrinsic ability of the heart to increase inotropy in response to abrupt increases in afterload [6]. This is seen in denervated hearts, suggesting it is an intrinsic mechanism. The other factor is the Bowditch or treppe effect, also called frequency-dependent activation. This is the ability of the heart to increase contractility slightly in the setting of an increase in heart rate [7]. This phenomenon is likely due to the inability of the Na/K-ATPase to keep up with the sodium influx at high heart rates, leading to an increase in intracellular calcium via the sodium–calcium exchanger.

Contractility in Cardiac Disease

Ischemia

Myocardial ischemia causes a decrease in contractility primarily by reducing ATP production in the mitochondria secondary to inadequate oxygen delivery [8]. This reduction in aerobic

ATP formation results in dysfunctional contractile shortening and reduced sarcoplasmic reticulum calcium pump function. Under these conditions, there is an increase in glycolysis, glucose uptake, and glycogen breakdown resulting in an increase in pyruvate [9]. Pyruvate is not readily oxidized in the mitochondria and is converted to lactate in the cytosol, resulting in a fall in intracellular pH [10]. When the intracellular pH falls, the sarcoplasmic calcium pump requires even more ATP to function properly [11]. In addition, the calcium concentration required for a given amount of myocyte force generation increases as the pH falls [12]. This leads to more ATP use in order to pump calcium back into the sarcoplasmic reticulum, leaving even less ATP to be used for contraction.

Heart Failure

At low inotropic states, the force-generating capabilities of ventricular muscle strips from normal and failing human hearts are similar [13]. As the inotropic demand increases, however, the ability of the failing heart to maintain its contractility reserve (the ability to increase contractility with heart rate or sympathetic stimulation) is severely depressed [14].

One of the major mechanisms of poor contractile reserve in heart failure is blunted adrenergic effects on myocyte contractility compared to normal myocardium [15]. Myocardium from heart failure patients shows significant reduction in beta-adrenergic receptor density, isoproterenol-mediated adenylyl cyclase stimulation, and contractile response to beta-adrenergic agonists [16]. The poor pump performance of the failing heart produces a reflex-mediated, sustained increase in sympathetic activity to maintain blood pressure [17]. It is this sustained sympathetic activity and an increased concentration of norepinephrine at the beta-adrenergic receptors that induce significant changes in beta-adrenergic signaling and downregulation of beta-adrenergic receptors [18]. In dilated cardiomyopathy, the $\beta 1$ receptor density is selectively reduced compared to the $\beta 2$ receptor which maintains its density but appears to be uncoupled from some downstream effector molecules. It is yet unclear whether adrenergic signaling abnormalities are adaptive or maladaptive in heart failure. By reducing LV contractility, desensitization may be detrimental; however, it may also be advantageous by reducing energy expenditure and protecting muscle from the effects of sustained adrenergic stimulation.

A second major mechanism contributing to altered contractility in the failing heart is abnormal calcium regulation within the myocyte. The sarcoplasmic reticulum is altered in heart failure such that the peak systolic cytosolic calcium level is decreased and the uptake of calcium into the sarcoplasmic reticulum is slowed. These abnormalities can explain features of systolic dysfunction including reduced force-generating capacity and slower rates of force decay [19] as well as diastolic dysfunction due to rate-dependent elevations in diastolic calcium levels [20]. There is some evidence to suggest that alterations in SERCA, L-type calcium channels, the ryanodine receptor, Na/K-ATPase, and the Na/Ca exchanger may all play some role in the initiation and progression of heart failure. Research continues in order to further elucidate the mechanisms of heart failure in the hope that targeted therapies may be developed.

Medications and Contractility [21, 22]

Dobutamine ($\beta 1 > \beta 2 > \alpha$)

Dobutamine is a synthetic sympathomimetic amine that approximates the hemodynamic profile of a pure $\beta 1$ agonist. The clinically available formulation is a racemic mixture of enantiomers. Both the (+) and (−) enantiomers stimulate $\beta 1$ receptors and, to a lesser degree, $\beta 2$ receptors. The (+) enantiomer, however, acts as an $\alpha 1$ antagonist, while the (−) enantiomer acts as an $\alpha 1$ agonist. Thus, the enantiomers essentially negate one another in their effect on the $\alpha 1$ receptor. The aggregate effect is that of an agonist at the $\beta 1$ receptor, leading to increased heart rate,

contractility, and diastolic relaxation. Dobutamine does have a modest agonist effect at peripheral β2 receptors causing mild peripheral vasodilation. Due to the increase in stroke volume secondary to its effects on contractility, however, blood pressure often does not change and can even increase despite the peripheral vasodilatory effects. Dobutamine is often used for short-term management of low output heart failure. Usual dosage: 2.5 μg/kg/min is initial dose, titrated to desired effect. Max dose is 20 μg/kg/min, though doses over 10 μg/kg/min are rarely needed. Onset of action is within 1–2 min, with a peak effect in 10 min. Drug effects cease very shortly after the drug infusion is discontinued. Tachycardia and ectopy are seen at higher doses, though these side effects are seen more frequently with dopamine.

Dopamine (D → β → α)

Dopamine is an endogenous sympathomimetic amine that functions as a neurotransmitter. It is a biosynthetic precursor of norepinephrine and epinephrine, and unlike dobutamine, it releases endogenous norepinephrine from stores in the nerve endings in the heart (this is overridden peripherally by prejunctional dopaminergic receptors which inhibit norepinephrine release). At low doses (<3 μg/kg/min), it has a peripheral vasodilatory effect by activating D1 receptors in the renal and mesenteric vascular beds. At intermediate doses (3–10 μg/kg/min), dopamine stimulates β1 and β2 receptors increasing heart rate, contractility, and peripheral vasodilation. At high doses (>10 μg/kg/min), dopamine begins to activate peripheral α1 receptors. This effect leads to a progressive increase in peripheral vasoconstriction with increasing doses. At these higher doses, the actions of dopamine become more like norepinephrine. Higher doses can also cause pulmonary vasoconstriction, and PCWP may be an unreliable estimate of LVEDP in the setting of a high-dose dopamine infusion. Dopamine is typically not recommended for patients with pulmonary edema because its venoconstrictor effects can increase venous return.

Onset of action is within 1–5 min and lasts for approximately 10 min. Tachycardia and ventricular arrhythmias are common at higher doses.

Norepinephrine (β1 > α > β2)

Norepinephrine (noradrenaline) is an endogenous neurotransmitter and is a potent β1 receptor agonist in the heart, with positive inotropic and chronotropic effects. It is also a potent peripheral α1 receptor agonist (more than epinephrine) and causes a dose-dependent increase in systemic vascular resistance. Due to these potent alpha effects, the resultant vasoconstriction limits the inotropic benefit of norepinephrine. It does have a small effect on β receptors. It is synthesized from dopamine and is precursor of epinephrine. Norepinephrine can be used in cardiogenic shock and is considered safer than epinephrine in ischemic disease, though it is still not a first-line choice.

Dosing: Typically start with 8–12 μg/min and titrate or wean to desired effect. Effects are seen within 1–2 min and duration is approximately 1–2 min.

Epinephrine (β1 = β2 > α)

Epinephrine (adrenaline) is an endogenous neurotransmitter synthesized from norepinephrine which is relatively nonselective at all receptors, but it primarily gives mixed β1 and β stimulation with some added α-mediated effects at higher doses. A low physiologic infusion rate (<0.01 μg/kg/min) increases contractility and speeds impulse generation via β activation, but often decreases peripheral resistance and blood pressure via β2 activation. Higher doses (>0.2 μg/kg/min) increase peripheral resistance when α-medicated constriction dominates over β2-mediated vasodilation. The positive inotropy, positive chronotropy, and vasoconstriction act together to raise blood pressure.

Epinephrine should typically be avoided in patients with cardiogenic shock due to myocardial ischemia because of the dramatic increases

in cardiac work and myocardial oxygen consumption. Usual dosing: for ACLS 1 mg IV (10 mL 1:10,000), for anaphylaxis 0.1 mg SQ/IM (0.1 mL 1:1000) or 0.1 mg IV (1 mL 1:10,000) over 5–10 min. The effects are seen within seconds of administration and last for 1–2 min.

Isoproterenol ($\beta 1 > \beta 2$)

Isoproterenol (isoprenaline) is a synthetic epinephrine analog. It is a pure β-agonist with almost no α effect. It has positive inotropic and chronotropic effects in the heart. In the peripheral vessels, $\beta 2$ stimulation leads to a decrease in peripheral resistance and often causes a drop in blood pressure. This drug causes a significant increase in myocardial work and oxygen consumption, so it is rarely used in patients with ischemic heart disease. Its use is typically limited to temporary treatment of bradyarrhythmias, refractory torsades de pointes, refractory bronchospasm, and in cardiac transplant patients to increase heart rate. Dosing: Initially 0.5 μg/min, with most patients responding to 2–20 μg/min. Onset is seen within 30–60 s and lasts anywhere from 8 to 50 min.

Milrinone (PDE-3 Inhibitor)

Milrinone exerts its positive inotropic actions by inhibiting phosphodiesterase in cardiac myocytes. This inhibition reduces the breakdown of intracellular cAMP, ultimately leading to enhanced calcium entry into the cell and increased force of contraction. It also causes some peripheral vasodilation. Milrinone, therefore, has inotropic, vasodilatory, and minimal chronotropic effects. It is used for short-term management of low output heart failure, similar to dobutamine. Dosing: Initial loading dose of 50 μg/kg over 10 min followed by 0.25–0.75 μg/kg/min. The effect is usually seen within 5–15 min. Milrinone is primarily excreted unchanged by the kidney, so dose adjustments may be necessary in patients with significant renal dysfunction.

Digoxin

It is theorized that digoxin (digitalis) improves contractility via inhibition of the sarcolemmal Na^+K^+-ATPase pump, normally responsible for maintaining transmembrane Na^+ and K^+ gradients. Inhibiting this pump causes intracellular Na^+ to rise, which then reduces Ca^{++} extrusion from the cell by the Na^+–Ca^{++} exchanger. This leads to more Ca^{++} being pumped into the sarcoplasmic reticulum with higher amounts of Ca^{++} being released into the myofilaments with each action potential. Increased Ca^{++} release from the sarcoplasmic reticulum enhances the force of contraction. The magnitude of the positive inotropic effect correlates with the degree of Na^+ K^+-ATPase inhibition.

Digoxin is a relatively weak inotropic agent and is used primarily for the treatment of chronic symptomatic systolic dysfunction, especially if accompanied by atrial arrhythmias.

Bullet Point Summary

- Contractility, or inotropy, is the inherent capacity of the myocardium to contract *independent* of preload and afterload.
- Contractility can be evaluated through assessing the rate of rise of left ventricular pressure, or dP/dt. With advancements in echocardiography, 2D speckle tracking with strain imaging now represents an effective method of noninvasive assessment of both global and segmental myocardial contractile function and has been well-validated in multiple cardiovascular disease states.
- In relation to a normal heart, a hypodynamic heart has an elevated end-diastolic pressure, a slowly rising ventricular pressure, and a prolonged ejection phase. A hyperdynamic heart has a reduced end-diastolic pressure, a fast-rising ventricular pressure, and a brief ejection phase.

- Contractility is primarily determined by the way calcium is processed and utilized in the cardiac myocyte.
- Ischemia causes reduced contractility primarily via a decrease in ATP production.
- The failing heart loses its contractile reserve via multiple mechanisms, including blunting of the response to adrenergic stimulus and abnormalities in the handling of calcium within the cardiac myocyte.
- Exogenous inotropic agents work to enhance cardiac contractility via several different mechanisms.

Review Questions

1. An influx of calcium into the cell triggers a conformational change in which receptors to allow calcium release from the sarcoplasmic reticulum?
   A. SERCA
   B. L-type
   C. Calcium release channels
   D. Na/Ca exchanger
   E. Ryanodine

   Answer: E. Depolarization of the myocyte membrane causes calcium inflow via voltage-gated L-type calcium channels. This calcium inflow then triggers a conformational change in ryanodine receptors in the sarcoplasmic reticulum membrane, which allows calcium to flow out into the cytosol via the calcium release channels.
2. The ability of the heart to increase inotropy in response to abrupt increases in afterload is known as the:
   A. Bowditch effect
   B. Lusitropic effect
   C. Anrep effect
   D. Chronotropic effect
   E. Treppe effect

   Answer: C. The Anrep effect is the intrinsic ability of the heart to increase contractility in response to an acute increase in afterload. This is even seen in denervated hearts. The Bowditch or treppe effect is the ability of the heart to increase contractility in the setting of an increasing heart rate.

Special thanks to Frederick Heupler Jr., MD, for his contributions to the previous version of this chapter.

Cardiac Output

4

Daniel H. Katz, Frederick Heupler Jr.,
and Marwa A. Sabe

Definition and Determinants of Cardiac Output

Cardiac output is defined as the volume of blood ejected from the heart every minute. At rest the normal adult cardiac output is approximately 5–6 L/min [1] and the normal cardiac output indexed to body surface area is 2.6–3.2 L/min/m^2. Cardiac output is the product of stroke volume and heart rate [2]. The three major determinants of stroke volume, and thus cardiac output, are preload, afterload, and contractility, which are discussed in depth in the three preceding chapters. Preload and contractility are directly correlated to stroke volume, while afterload is inversely correlated [2]. Cardiac output can also be affected by structural abnormalities of the heart such as valvular regurgitation and intracardiac shunts, which reduce the volume of forward flow. These will be discussed in later chapters.

Preload contributes to cardiac output by its effects on stroke volume and heart rate (see Chap. 1). Preload is most directly associated with the ventricular end-diastolic pressure or simply the "filling pressure." The effect of preload on stroke volume is described by the Frank-Starling mechanism [3] (Fig. 4.1). As more volume fills the left ventricle, the pressure at end-diastole increases, and there is greater stretch of the left ventricular walls. The walls behave like a spring, so the greater the stretch of the walls, the more forceful their recoil, and thus the greater the amount of ejected blood [3]. However, as seen in isolated heart preparations, if the stretch on the myocardium exceeds a certain point, the opposite occurs, and stroke volume as well as cardiac output can decrease. Preload also affects heart rate. Although the common conception is that volume depletion leads to tachycardia due to a reduction in baroreceptor firing, an increase in the effective circulating volume may also lead to an increase in heart rate. With increased stretching in the right atrium, the heart pumps at a faster rate due to stretch of the sinus node. The stretching of the right atrium also causes the Bainbridge reflex, a sympathetic nervous system-mediated reflex that increases heart rate in response to this stretching [4].

Afterload is a force that opposes myocardial contraction (see Chap. 2). It is equal to the tension across the ventricular wall during systole.

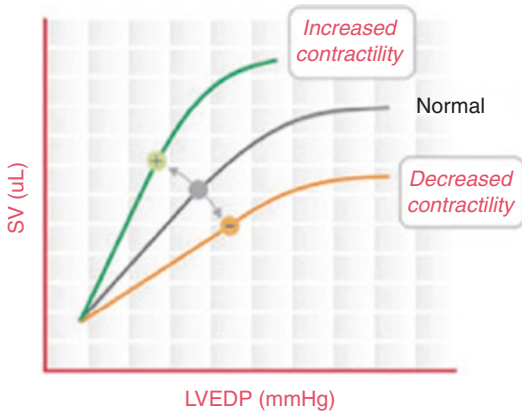

Fig. 4.1 Relationship between cardiac output, preload, and contractility. (*SV* stroke volume, *LVEDP* left ventricular end-diastolic pressure, a measure of preload). (Adapted from http://scisense.com/education/cv-application.html)

The Law of Laplace describes the relationship between the determinants of ventricular wall tension, or afterload, by the equation: $\sigma = (P \times r)/(2w)$, where σ is wall stress, P is chamber pressure, r is the radius of the chamber, and w is the wall thickness. In other words, wall stress (afterload) is directly proportional to ventricular pressure and size (radius) and indirectly related to wall thickness. Ventricular dilation increases afterload, and left ventricular hypertrophy (LVH) is a compensatory mechanism that attempts to decrease afterload [4]. A major component of afterload is captured by forces exerted on the ventricle by the vasculature, which is well estimated by vascular resistance.

Please refer to Chap. 3 for an in-depth discussion of the relationship between contractility and cardiac output. Increases in contractility increase the cardiac output for any given preload or afterload.

Circulatory Hemodynamics

The heart is at the center of two interrelated cardiovascular systems: the systemic, or peripheral, cardiovascular system and the pulmonary cardiovascular system. The flow through each of these systems is fundamentally described with the same equation that describes flow through any tube, wherein the pressure gradient across the tube is equal to the flow across the tube multiplied by the resistance of that tube.

$$\Delta P = Q \times R$$

The abovementioned equation is applied to the circulatory system by defining Q as the cardiac output, R as either the systemic vascular resistance (SVR) or the pulmonary vascular resistance (PVR), and ΔP as the change in pressure across either of the two circuits. In general terms, it is the difference between the average blood pressure before the circuit and the average blood pressure after the circuit. Specifically, the change in pressure across the pulmonary circulation is estimated as the mean pulmonary artery pressure minus the pulmonary capillary wedge pressure (mPAP – PCWP) while the change in pressure across the systemic circulation is estimated as the mean arterial pressure minus the right atrial pressure (MAP – RAP). Right atrial pressure is also referred to as the central venous pressure (CVP). Thus, systemic cardiac output is equal to (MAP – RAP)/SVR. As discussed previously, the noted pressures can easily be determined from a combination of a Swan-Ganz catheter and either invasive or noninvasive blood pressure monitoring [3].

Physiologically, it is useful to see Ohm's law expressed as written above because it reminds us that the pressure gradient across a vascular circuit is the *result* of flow and resistance. Clinically, this means that blood pressure depends both on cardiac output and vascular resistance. Perturbations in blood pressure, either from illness or medications, are the result of changes to one or both of these two factors. It also highlights that a normal blood pressure can occur in the setting of a low cardiac output with a compensatory increase in vascular resistance. Normal blood pressure does not mean that there is normal tissue perfusion!

Despite the fact that the pressure change is the result of changes in cardiac output and resistance, resistance is not measured directly. Instead, we measured the pressures and cardiac output using a variety of tools which will be discussed in detail in this chapter (but most commonly a Swan-Ganz catheter), and calculated the resistance from

Table 4.1 Hemodynamic parameters

Hemodynamic parameter	Formula	Normal range
CO	HR × SV	4–6 L/min
CI	CO/BSA	2.6–4.3 L/min/m^2
SVR	(MAP-CVP)/CO × 80	800–1400 dyn s/cm^5
SVRI	(MAP-CVP)/CI × 80	1500–2300 dyn s/cm^5/m^2
PVR	(PAP-PCWP)/CO × 80	140–250 dyn s/cm^5
PVRI	(PAP-PCWP)/CI × 80	240–450 dyn s/cm^5/m^2

CO cardiac output, *CI* cardiac index, *BSA* body surface area, *SVR* systemic vascular resistance, *SVRI* SVR index, *PVR* peripheral vascular resistance, *PVRI* PVR index

Ohm's law. Normal values for cardiac output, filling pressures, and vascular resistances are listed in Table 4.1.

Hemodynamic Disturbances: The Failing Heart and Shock

Heart failure is defined as either: (1) inadequate cardiac output to support normal organ function, or (2) maintenance of adequate cardiac output at elevated filling pressures. The majority of encountered clinical heart failure falls into the latter category. These patients often present with signs and symptoms of volume overload which are the result of such elevated filling pressures (see Chap. 10). The volume overloaded state can be managed with fluid removal either by diuresis or dialysis. However, a variety of insults can push a heart which functions adequately (either with normal or elevated filling pressures) into a state in which cardiac output is inadequate, assuming the body's demand is held constant. These insults must affect one or more of the four factors of cardiac output (Table 4.2).

Table 4.2 Selected hemodynamic insults to cardiac output

	Examples of insults that predominantly affect listed factor
Preload	Hemorrhage, cardiac tamponade, pulmonary embolism
Afterload	Increase in sympathetic tone, vasopressors
Contractility	Ischemia, systemic acidemia, negative inotropes (calcium channel blockers, beta-blockers)
Heart rate	Heart block, sinus, or AV nodal blocking agents

AV atrioventricular

Inadequate tissue perfusion is a clinical state known as circulatory shock. Human tissues require a constant supply of oxygen to maintain aerobic metabolism. When this supply is impaired, the body tissues slowly revert to anaerobic metabolism, producing toxic metabolic breakdown products, such as lactic acid. By this mechanism, shock leads to end organ dysfunction and eventual failure. Shock resulting from low cardiac output, as described above, is one possible cause of inadequate tissue perfusion. From a hemodynamic standpoint, the three major types of circulatory shock are cardiogenic, hypovolemic, and vasogenic (also known as distributive). Cardiogenic shock and hypovolemic shock are low cardiac output states, whereas vasogenic shock is a high output type of shock [5].

Differentiating these states can be achieved by determining the hemodynamic parameters already discussed. Cardiogenic shock and hypovolemic shock are both associated with low cardiac output and high SVR, but may be differentiated by PCWP, which is elevated in cardiogenic shock but decreased in the hypovolemic shock. Vasogenic shock is a low SVR state due to vasodilation, and with causes including sepsis, thyrotoxicosis, anemia, anaphylaxis, and AV fistulas [6]. Vasogenic shock is typically accompanied by a high cardiac output. Management of heart failure and shock will be discussed more extensively in Chaps. 19 and 21, respectively.

Methods of Determining Cardiac Output

In critically ill patients, differentiating the shock states described above is essential to management, especially when inadequate cardiac output may be related to increased morbidity and mortality [7]; therefore, it is essential to have reliable methods to measure cardiac output.

There are multiple bedside indicators that help estimate the adequacy of cardiac output and/or tissue perfusion. Mental status, specifically, patients falling asleep during their interviews, and decreased urine output are early indicators of inadequate perfusion of the brain and kidneys. Cool forearms and legs also signal low cardiac output as vascular resistance increases and blood is shunted away from the extremities in favor of internal organs [8]. The proportional pulse pressure is another useful bedside marker, and can be calculated as the difference between the systolic and diastolic blood pressures divided by the systolic blood pressure ((SBP-DBP)/SBP). A ratio of less than 25% suggests a cardiac index of less than 2.2 L/min/m^2 [9].

There are also several methods of actually measuring cardiac output. These include invasive methods such as thermodilution and Fick methods, which require the use of a Swan-Ganz pulmonary artery catheter, and noninvasive methods such as transpulmonary thermodilution [10]. Noninvasive clinical measures may help determine whether a patient is in a low output state; however, invasive methods of measuring cardiac output in the intensive care unit are mainstays for precise monitoring to guide therapeutic management.

Thermodilution

With the use of a pulmonary artery catheter, cardiac output may be measured directly by the thermodilution method (introduced in 1953 by Fegler) or indirectly by means of the Fick principle [1]. The thermodilution method of measuring cardiac output involves injection of cold fluid into the Swan-Ganz catheter positioned in the pulmonary artery. This injectate flows through the catheter and exits into the right ventricle where it mixes with blood, which is warmer than the injected fluid. This mixture of blood and indicator fluid then moves into the pulmonary artery, where a thermistor at the catheter tip senses temperature changes [6]. With each beat, the blood temperature rises as the cold fluid is washed out of the right side of the heart [1]. A time-temperature curve is electronically obtained, and the cardiac output is calculated using the Stewart-Hamilton Formula. The key components of this formula are cardiac output, amount of indicator, and the integral of the amount of indicator concentration over time. The cardiac output is inversely related to the area under the thermodilution curve as measured by the integral of the amount of indicator concentration over time [3, 6]. When cardiac output is low, it takes longer for the cold fluid to wash out of the right ventricle and thus for the temperature of the blood to return to baseline, producing a low amplitude, prolonged curve with a large area underneath it. On the other hand, the blood temperature returns to baseline quicker when the injection fluid moves at a faster rate through the heart, as it does with higher cardiac output [3]. This produces a higher amplitude, shorter curve with a smaller area Fig. 4.2. The advantage of this method is the use of computer calculations to give quick measurements as well as less need for blood draws. However, this method becomes less useful in patients with cardiac output less than 2.5 L/min as it tends to overestimate the cardiac output in these cases [3]. It also miscalculates cardiac output in patients with tricuspid regurgitation because the indicator fluid is recycled, thus producing a curve that is similar to the low cardiac output curve and thus underestimates cardiac output [5]. On the other hand, left-to-right shunts tend to overestimate the cardiac output as a portion of the injectate crosses through the shunt and thus the temperature change that is detected downstream occurs quickly as would occur in a true high cardiac output state [5].

Another thermal method of measuring cardiac output is the continuous cardiac output method. This method uses a warm indicator rather than a cold one in the standard thermal dilution [11]. A thermal filament on the right ventricular portion of the pulmonary artery catheter releases small amounts of heat, which is measured by the thermistor at the tip of the pulmonary artery catheter.

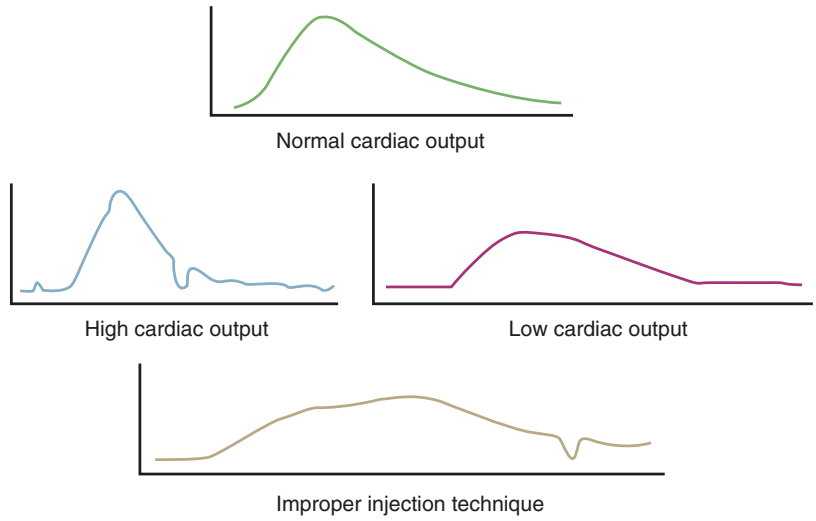

Fig. 4.2 Thermodilution cardiac output curves. (Adapted from Braunwald et al. [3])

The cardiac output is automatically calculated and updated every 30–60 s, giving an average cardiac output over 3–6 min. The major disadvantage of this method is that it does not respond quickly in unstable hemodynamic conditions, such as fluid resuscitation or hemorrhage [12].

The Fick Cardiac Output

The Fick principle is employed to provide an indirect measurement of cardiac output that is based on the oxygen saturation of blood samples obtained through a Swan-Ganz catheter. This method was developed by Eugene Fick in 1870, and is based on the principle that the rate of oxygen consumption by the peripheral tissues is equal to the cardiac output multiplied by the change in oxygen concentration between the arterial and venous system [1]. In other words, when blood volume arrives to tissues at a lower rate, tissues must extract a greater percentage of the available oxygen in each mL of blood to meet their rate of oxygen consumption. This principle is expressed:

$$\text{oxygen consumption} = \text{cardiac output} \times \text{arteriovenous oxygen difference}$$

To calculate the *exact* concentration of oxygen in either the arterial or venous blood, one must calculate the amount of oxygen carried by the red blood cells and the very small amount dissolved in the blood. The following equation is used:

$$\text{Oxygen content} = \text{Hgb}\left(\text{g/dl}\right) \times 1.34\left(\text{mL O}_2\text{/g of Hgb}\right) \times \text{SO}_2\left(\%\right) + 0.0032 \times \text{PO}_2$$

where Hgb is the hemoglobin concentration, SO_2 is the oxygen saturation, and PO_2 is the partial pressure of oxygen not bound to hemoglobin and freely dissolved in the blood. The freely dissolved oxygen is extremely small compared to oxygen bound to hemoglobin and is frequently ignored. Therefore, the arteriovenous oxygen difference can be expressed as:

$$\text{Arteriovenous oxygen difference} = \left(\text{SaO}_2 - \text{SvO}_2\right) \times 1.34 \times \text{Hgb}$$

where SaO_2 and SvO_2 are the arterial and venous oxygen saturations respectively. SaO_2 is measured from either an arterial line or a pulse oximeter with a reliable tracing. SvO_2 is measured as the oxygen saturation in the main pulmonary artery, and is also referred to as the mixed venous oxygen saturation. Together, the entire Fick equation can then be rewritten as:

$$\text{Cardiac output}\left(\text{L}/\text{min}\right) = \frac{\text{VO}_2\left(\text{mL}/\text{min}\right)}{\left(\text{SaO}_2 - \text{SvO}_2\right)\times 1.34 \times \text{Hgb}} \times 10$$

where VO_2 is oxygen consumption. Cardiac output is usually corrected for body size using this equation: cardiac index (CI) = CO/BSA where CI is the cardiac index and BSA is the body surface area. CI is commonly used in the ICU setting to monitor a patient's hemodynamic status and guide therapy. The normal CI is 2.6–4.3 L/min/m^2 [13], and it is normally lower in elderly persons. In healthy adults, the normal value for VO_2 is 200–300 mL/min, or 110–160 mL/min/m^2 when adjusting for body size [5].

The Fick method is more accurate when VO_2 is measured using a calorimeter rather than estimated, as is the usual practice, especially in hyperdynamic states such as sepsis [10]. However, in general practice, even if the calculated CI is not exactly precise, the trend in the estimated CI indicates clinical changes from therapies or insults. The disadvantages of the Fick method are similar to other invasive methods including risk of infection or pulmonary hemorrhage.

Other Methods of Assessing Cardiac Output

An alternate, but still invasive, method of measuring cardiac output is ventriculography [1]. This method requires placement of a catheter in the left ventricle and subsequent injection of contrast dye. The cardiac cycle is recorded in a cine loop, and the stroke volume is calculated by subtracting the end systolic volume from the end-diastolic volume. This method is particularly useful in the setting of valve stenosis or regurgitation. However, the CO may be miscalculated in patients with enlarged ventricles [1]. It is more invasive, requiring arterial access, and catheter placement in the left ventricle with associated risks of structural damage and arrhythmia.

A less invasive method of measuring CO is called the transpulmonary thermodilution technique, which is used by the PICCO monitor. There is no need for catheter placement into the heart using this method [10]. Instead, a central venous catheter is placed along with an arterial catheter with a thermistor at the tip. Indicator fluid is injected into the central line, and the arterial catheter thermistor senses the blood as it passes through the thorax, producing a similar thermodilution curve as the standard thermodilution method. The advantage of this method is that it is less invasive and less influenced by the respiratory cycle than the thermodilution technique, which employs a pulmonary artery catheter [14]. However, it may be inaccurate in patients with aortic stenosis, aortic aneurysm, and intracardiac shunts.

Other noninvasive or minimally invasive methods (See Chap. 13) of measuring CO include esophageal Doppler analysis of aortic blood flow, the indirect Fick method which uses partial carbon dioxide rebreathing, thoracic electrical bioimpedance, and pulse contour analysis of the arterial pressure waveform [6]. Each of these methods has disadvantages that make them less practical in the clinical setting. Esophageal Doppler analysis requires sufficient training to obtain accurate measurements. The indirect Fick method, which is applicable to intubated patients, is less accurate in severe lung injury or when there is variability in tidal volume (as is seen with spontaneous breathing) [6]. Thoracic electrical bioimpedance is less accurate in patients with peripheral edema or pleural effusions, and pulse contour analysis requires that another method of measuring CO be used in order to calibrate the pulse contour device [6].

Summary

- Cardiac output is defined as stroke volume multiplied by heart rate, and the determinants of stroke volume are afterload, preload, and contractility.
- Cardiogenic shock is a low cardiac output, high wedge pressure state that is often associated with hypotension. In cases of impending cardiogenic shock, blood pressure may be preserved. It is important to measure cardiac output in patients who are extremely hemodynamically unstable in order to guide therapy.
- Cardiac output is most commonly measured with a Swan-Ganz catheter using either the thermodilution or the Fick method.
- The Fick principle states that cardiac output is inversely proportional to the arteriovenous oxygen difference and directly proportional to oxygen consumption.

Equations

$$CO = SV \times HR$$

$$CI = CO / BSA$$

$$\text{Fick Principle}: CO = VO_2 / 1.34 \times 10 \times Hgb\left(SaO_2 - SvO_2\right)$$

$$CO = \left(MAP - CVP\right) / SVR$$

Review Questions

1. A 65-year-old male with a history of coronary artery disease status post CABG 5 years prior and known ischemic cardiomyopathy with an ejection fraction of 35% on his last echocardiogram, presents to the ER with palpitations and shortness of breath. His vital signs are blood pressure 120/95, heart rate 130 in sinus rhythm, and oxygen saturation 88% on room air. During his medical interview, he falls asleep between questions. On physical examination, his JVP is estimated to be 14 cm, he has an audible S3, bilateral crackles, and his extremities are cool to the touch. A Swan-Ganz catheter is placed. What is his most likely hemodynamic profile?
   (a) CI = 3.5, PCWP = 24, SVR = 400
   (b) CI = 1.8, PCWP = 30, SVR = 2500
   (c) CI = 2.5, PCWP = 10, SVR = 1800
   (d) CI = 2.0, PCWP = 10, SVR = 800
   - *Answer*: (b) This patient is cold and wet on physical exam and is in severe, decompensated HF.
2. Nitroprusside, a potent vasodilator, is administered to the abovementioned patient. What is the expected effect on blood pressure when it is given?
   (a) The blood pressure will increase
   (b) The blood pressure will decrease
   (c) The blood pressure will stay exactly the same
   (d) The change in blood pressure is uncertain
   - *Answer:* (d) While vascular resistance will drop, the reduction in afterload will increase cardiac output. The percent change in each of these factors will determine the direction and magnitude of blood pressure change, but this cannot be predicted beforehand. Administering a vasodilator to a patient in acute decompensated heart failure can make the blood pressure increase!
3. A 40-year-old female presents with shortness of breath 6 weeks after giving birth. A Swan-Ganz catheter is placed to calculate her cardiac output. Her SvO_2 is 40%, Hgb is 11, and SaO_2 is 98%. What is her cardiac output in L/min output using the Fick equation? Assume a VO_2 of 250 ml/min.
   (a) CO = 2.9 L/min
   (b) CO = 4.2 L/min
   (c) CO = 3.9 L/min
   (d) CO = 6.2 L/min
   - *Answer:* (a) *The Fick cardiac output is calculated as follows*:

$$CO = \left(VO_2\left(\text{assumed}\right) / 1.34 \times Hgb \times \left(SaO_2 - SvO_2\right)\right) \times 10.$$

4. In which of the following situations would the thermodilution method overestimate the cardiac output?
   (a) A 55-year-old woman with carcinoid syndrome associated with severe tricuspid regurgitation.
   (b) A 48-year-old male who presents with an acute inferior myocardial infarction associated with right ventricular failure.
   (c) A 40-year-old male who had an acute ST elevation myocardial infarction 1 week ago who now presents with acute cardiogenic shock due to ventricular septal rupture (VSR).
   (d) A 66-year-old female who presents with a type A dissection associated with severe aortic insufficiency.
   - *Answer:* (c) Shunts tend to overestimate CO when the thermodilution technique is used as a portion of the injectate crosses through the VSR and thus the temperature change that is sensed downstream occurs at a rate similar to a high CO state. Severe TR (choice a) tends to underestimate the cardiac output when using their modulation.
5. In which of the following situations is the estimated oxygen consumption (VO_2) (rather than a direct measurement) most likely to be inaccurate?
   (a) A 60-year-old female with right ventricular infarction.
   (b) An 80-year-old male with sepsis due to *Clostridium difficile* colitis.
   (c) A 48-year-old male with acute ischemic mitral regurgitation.
   (d) A 90-year-old male with severe aortic stenosis.
   - *Answer*: (b) The estimated VO_2 is inaccurate in hyperdynamic states such as sepsis.

Effects of Selected Interventions on CV Hemodynamics

5 Renin–Angiotensin–Aldosterone Axis Modulators and Other Vasodilators

Chirag Bavishi, Roberto Ramirez, and Franz H. Messerli

Introduction

The renin–angiotensin–aldosterone system (RAAS) is a complex system that plays an important role in maintaining hemodynamic stability in the human body through regulation of arterial blood pressure, water and electrolyte balance, as well as cardiovascular hemodynamics. Both over- and under activation of the RAAS can result in loss of vital cardiac and vascular functions leading to pathological consequences. Blockade of the RAAS has been shown to be beneficial in patients with hypertension, acute myocardial infarction, and chronic systolic heart failure.

Mechanism of Raas Inhibitors

The renin–angiotensin–aldosterone system (RAAS) plays an integral role in the homeostatic regulation of arterial pressure, tissue perfusion, and extracellular volume. This pathway is initiated by the secretion of renin synthesized by the juxtaglomerular cells in the afferent arteriole of the renal glomerulus. Renin secretion is modulated through interplay of pathways such as renal baroreceptor mechanism, changes in sodium and chloride delivery in distal tubule, sympathetic stimulation through beta-1 adrenergic receptors, and negative feedback by direct action of angiotensin II. Once activated, renin cleaves angiotensinogen to angiotensin-I, which is then hydrolyzed by the circulating and local angiotensin-converting enzyme (ACE) to the active angiotensin II. Angiotensin-converting enzyme also inactivates bradykinin with its nitric oxide and prostacyclin stimulating and vasodilatory activity. Angiotensin II acts mainly via angiotensin type 1 (AT-1) and angiotensin type 2 (AT-2) receptors. Angiotensin II also stimulates the release of aldosterone from the adrenal cortex. Aldosterone enhances the reabsorption of sodium and water in the distal tubules and collecting ducts and promotes potassium excretion. Like Angiotensin II, aldosterone is an effector hormone of the RAAS, principally involved in volume and blood pressure regulation. It also facilitates cardiovascular and renal inflammation, fibrosis, and remodeling.

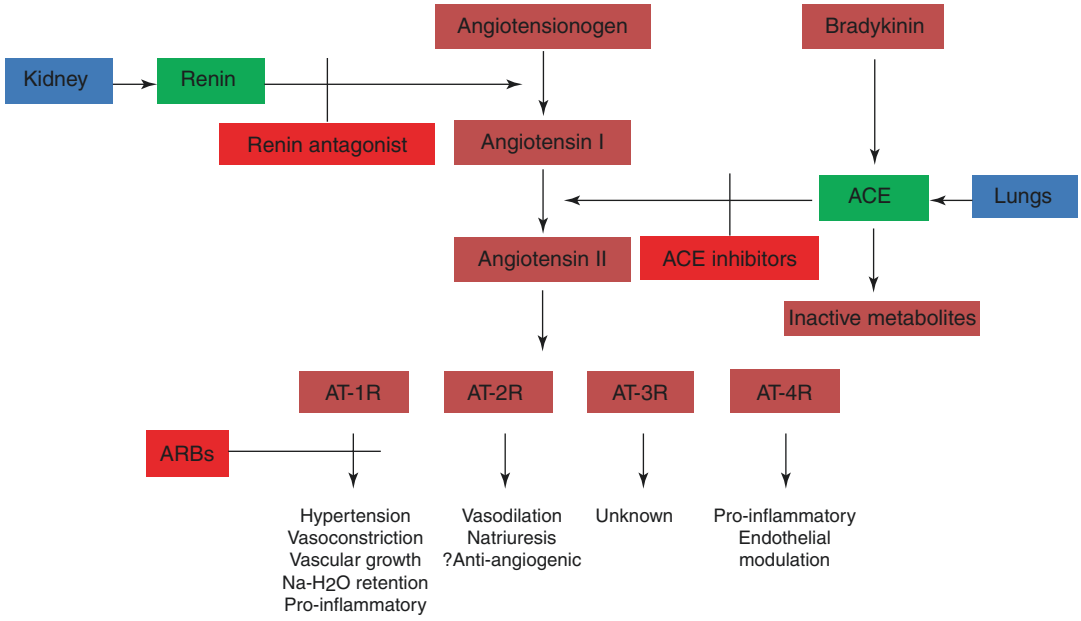

Fig. 5.1 The renin–angiotensin–aldosterone system. Mechanism of action of ACEIs, ARBs, and DRIs

ACE inhibitors (ACEIs) competitively inhibit the enzyme ACE, thereby preventing the conversion of angiotensin I into angiotensin II (Fig. 5.1) and blocking downstream activity of angiotensin II via both AT-1 and AT-2 receptors. They also reduce aldosterone, vasopressin, and plasminogen activator inhibitor-1. ACEIs increase the concentration of bradykinin which contributes to their vasodilatory action; however, this mechanism is also implicated in the occurrence of side effects such as cough and angioedema. Moreover, chronic ACEI use triggers ACE escape pathways; hence, angiotensin II is produced despite blockage of ACE. Angiotensin receptor blockers (ARBs) prevent the binding of angiotensin II to AT-1 receptors, leading to inhibition of all the deleterious effects modulated by angiotensin II, yet preserving the potential beneficial effect of angiotensin II via the AT-2 receptor pathway. Like ACEIs, ARBs reduce BP by decreasing systemic vascular resistance through selective AT-1 receptor blockade. Due to direct receptor blockade, ARBs do not demonstrate angiotensin II escape phenomenon and bradykinin-associated effects.

Table 5.1 Mechanistic differences between ARBs and ACEIs

Principle mechanism of action	ARBs	ACEIs
Plasma angiotensin II	↑	↓
Plasma renin activity	↑	↑
Bradykinin	–	↑
Prostaglandin E_2 and prostacyclin	–	↑
Nitric oxide release	–	↑
Uric acid levels	↓[a]	–
Cough	Not observed	Class specific

[a]Losartan potassium only. Table adapted from Messerli et al. Angiotensin II receptor inhibition. A new therapeutic principle. *Arch Intern Med*. 1996

However, stimulation of the AT2 receptor may result in some bradykinin release. Direct renin inhibitors, DRI (aliskiren), bind to renin with high affinity and prevent the conversion of angiotensinogen to angiotensin I, thereby blocking the synthesis of all angiotensin peptides downstream. These different modes of RAAS inhibition may explain some of the clinical differences between these agents (Table 5.1).

Cardiovascular Hemodynamics

Angiotensin-Converting Enzyme Inhibitors

The cardiovascular effects of ACEIs are evident immediately after the first dose. Single oral dose causes decrease in pulmonary capillary wedge pressure, mean arterial blood pressure, total systemic vascular resistance and increase in cardiac output [1]. Chronic oral dosing produces sustained beneficial hemodynamic effects translating into considerable improvement in LV function and symptoms in patients with systolic heart failure. In patients with systolic heart failure, ACEIs cause dose-dependent reduction in cardiac preload and afterload preventing progressive left ventricular dilatation and systolic dysfunction. These effects probably result from a combination of altered remodeling and sustained reduction in preload and afterload [1], causing leftward shift of the pressure-volume loop (Fig. 5.2). ACEIs also decrease renal vascular resistance, increase renal blood flow, and promote sodium and water excretion mainly though cellular effects in the kidney and alteration in glomerular hemodynamics. All these mechanisms underline the beneficial effects of these agents in heart failure.

ACEIs decrease Ang II and aldosterone formation and potentiate the vasodilatory effects of the kallikrein-kinin system, causing reduction in total peripheral vascular resistance without significant change in heart rate [2]. Moreover, improvement in stroke volume and cardiac output, seen in systolic heart failure patients, is also seen in patients with essential hypertension [3]. The hemodynamic effect of ACEIs in hypertension extends to the regional circulation. During acute or prolonged ACE inhibition, renal and coronary blood flow is increased in patients with heightened RAAS activity [4, 5]. Thus, ACEIs may augment myocardial perfusion both by preventing the vasoconstrictor effect of angiotensin II and by reducing coronary vasoconstriction induced by cardiac sympathetic activation. ACEI also affects arterial compliance and wave reflections in patients with hypertension [6] (Fig. 5.3). ACEIs reduce pulse wave velocity and augmentation index which are markers of arterial stiffness, and this effect is at least partly independent of changes in blood pressure [7]. ACEIs also cause regression of left ventricular hypertrophy, independent of their effects on blood pressure reduction [8]. Inhibitors of the RAAS permit regression of pathologic LVH more effectively than other antihypertensive agents. Table 5.2 summarizes key landmark trials of ACEI in patients with heart failure, hypertension, and myocardial infarction.

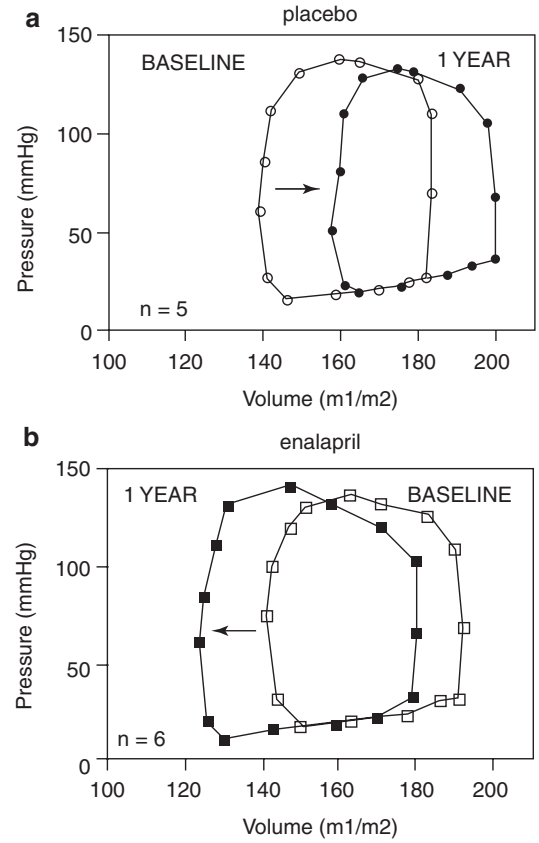

Fig. 5.2 Mean left ventricular pressure-volume loops at baseline and 1 year in patients randomized to placebo (panel A) and to enalapril (panel B) in SOLVD trial. At 1 year, there was a rightward shift in placebo group and leftward shift in enalapril group. (Reprinted from Konstam et al. with permission of the publisher)

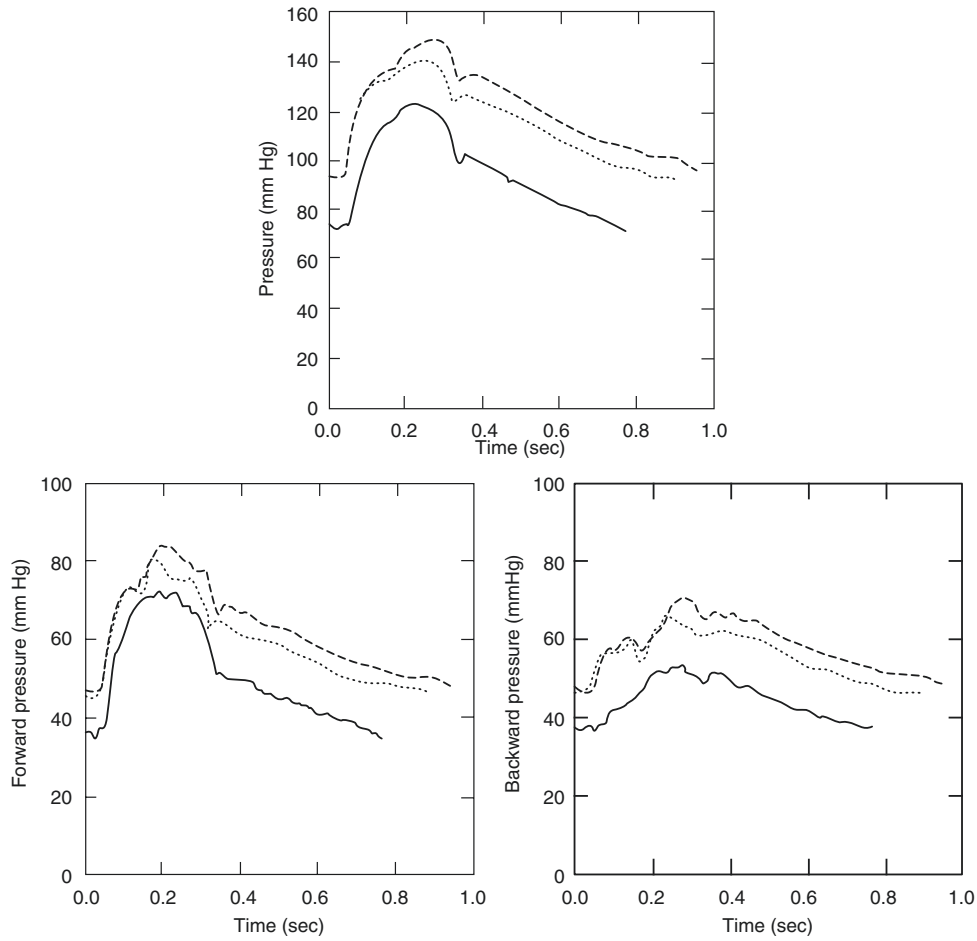

Fig. 5.3 Plots showing ascending aorta pressure waveforms (top) along with their forward (bottom left) and backward (bottom right) components in a representative normotensive (solid line) and hypertensive patient (dashed line). After captopril infusion (dotted line), attenuation of the higher backward wave and prominent late systolic peak in hypertensive patient was seen. (Reprinted from Ting et al. with permission of the publisher)

Angiotensin Receptor Blockers

The cardiovascular hemodynamic effects of ARBs are similar to ACEIs due to similarity in their mechanism of action. However, unlike ACE inhibitors, ARBs do not directly modulate the formation of bradykinin. Due to more downstream inhibition by ARBs and lack of angiotensin II escape phenomenon, they may exert more potent antihypertensive effects compared to ACEIs. Table 5.3 summarizes key landmark trials of ARBs in patients with heart failure, hypertension, and myocardial infarction. Although head-to-head trials comparing ACEIs and ARBs have shown equivocal results, ARB trials had lower rates of events in the placebo arm due to better use of contemporary medications (statins). Moreover, due to fewer adverse events with ARBs, the risk-to-benefit analysis should favor use of ARBs, particularly in patients with hypertension [9].

Aldosterone Antagonists

The pathophysiological effects of hyperaldosteronism on the cardiovascular hemodynamics extend beyond increased intravascular fluid reten-

Table 5.2 Key clinical outcome trials of ACEI in cardiovascular diseases

Trial and year	Active arm (N)	Comparator (N)	Patients	Primary outcome	Follow-up	Major findings
ALLHAT, 2002	Lisinopril (9054)	Chlortalidone (15,255), Amlodipine (9048)	Hypertension	Combined fatal coronary heart disease or nonfatal MI	4.9 years	No difference in primary outcomes
ANBP-2, 2003	Enalapril (3044)	HCTZ (3039)	Hypertension	All CV events or all-cause mortality	4.1 years	Enalapril showed 11% reduction in all CV events or mortality
Pilot HYVET, 2003	ACEI (usually Lisinopril) (431)	Diuretic (usually Bendroflumen-thiazide) (426), Placebo (426)	Hypertension	Stroke, all-cause mortality	1.12 years	No difference in all-cause mortality. Diuretic showed 69% reduction in stroke compared to placebo
SOLVD, 1991	Enalapril (1285)	Placebo (1284)	Chronic heart failure	All-cause mortality	3.5 years	Enalapril showed 16% reduction in all-cause mortality
CONSENSUS, 1987	Enalapril (127)	Placebo (126)	Chronic heart failure	All-cause mortality	6 months	Enalapril showed 40% reduction in mortality
CONSENSUS II, 1992	Enalapril (3044)	Placebo (3046)	MI	All-cause mortality	6 months	No difference in all-cause mortality
SAVE, 1992	Captopril (1115)	Placebo (1116)	MI and left ventricular dysfunction	All-cause mortality	1.8 years	Captopril decreased all-cause mortality by 19%
EUROPA, 2003	Perindopril (6110)	Placebo (6108)	Stable coronary artery disease	Composite of CV mortality, nonfatal MI, and cardiac arrest	4.2 years	Perindopril reduced composite primary end point by 20%
HOPE trial, 2000	Ramipril ($n = 4645$)	Placebo ($n = 4652$)	Multiple CV risk factors	Composite of MI, stroke, or CV death	5 years	Ramipril showed 22% reduction in primary end point

ACEI angiotensin-converting enzyme inhibitor, *CV* cardiovascular, *MI* myocardial infarction

tion and volume overload. Hyperaldosteronism alters fibrinolysis by increasing plasminogen activator inhibitor-1 expression and promotes tissue fibrosis and inflammation [10]. Increased aldosterone activity leads to endothelial dysfunction and arterial stiffness [11]. Moreover, aldosterone is intriguingly involved in sympathetic nervous system activation, decreased baroreceptor sensitivity, increased electrolyte excretion, and cardiomyocyte apoptosis. These effects exerted by aldosterone, one of the final mediators of the RAAS pathway, are only partially inhibited by ACEIs/ARBs. Thus, in addition to modulating volume status, some of the clinical benefits of aldosterone antagonists come from abrogating these adverse effects to limit target organ dysfunction.

Aldosterone antagonists improve LV structural remodeling and performance by increasing LV ejection fraction and decreasing LV end-diastolic and end-systolic volumes, particularly in patients with systolic heart failure and myocardial infarction. Experimental studies have shown that early use of aldosterone antagonist after myocardial infarction could improve myocardial healing as well as both electrical and structural remodeling [12, 13]. Table 5.4 summarizes key

Table 5.3 Key clinical outcome trials of ARBs in cardiovascular diseases

Trial and year	Active arm (N)	Comparator (N)	Patients	Primary outcome	Follow-up	Major findings
LIFE, 2002	Losartan (4605)	Atenolol (4588)	Hypertension	Death, MI, or stroke	4.8 years	Losartan caused 13% reduction in primary end point compared to atenolol
SCOPE, 2003	Candesartan (2477)	Placebo (2460)	Hypertension	CV death, nonfatal stroke, and nonfatal MI	3.7 years	No difference in primary end point, candesartan cause 28% reduction in nonfatal stroke
Val-HeFT, 2001	Valsartan ($n = 2511$)	Placebo ($n = 2499$)	Chronic heart failure	All-cause mortality; combined end point of all-cause mortality, cardiac arrest with resuscitation, heart failure hospitalization, IV inotropic or vasodilator drugs	1.9 years	No difference in all-cause mortality, valsartan showed 23% reduction of combined end point
VALIANT, 2003	Valsartan ($n = 4909$)	Valsartan + captopril ($n = 4885$); captopril ($n = 4909$)	MI	All-cause mortality	2.1 years	No difference in all-cause mortality among the three groups
OPTIMAAL, 2002	Losartan ($n = 2744$)	Captopril ($n = 2733$)	MI	All-cause mortality	2.7 years	No difference in all-cause mortality between the two groups

Table 5.4 Key clinical outcome trials of aldosterone antagonists in cardiovascular diseases

Trial and year	Active arm (N)	Comparator (N)	Patients	Primary outcome	Follow-up	Major findings
RALES, 1999	Spironolactone (822)	Placebo (841)	Chronic systolic heart failure	All-cause mortality	2 years	Spironolactone showed 30% reduction in all-cause mortality
EMPHASIS-HF, 2011	Eplerenone (1364)	Placebo (1373)	Chronic systolic heart failure	CV mortality or heart failure hospitalization	1.8 years	Eplerenone showed 37% reduction in primary end point
TOPCAT, 2014	Spironolactone (1722)	Placebo (1723)	Chronic heart failure and ejection fraction ≥45%	CV mortality, aborted cardiac arrest or heart failure hospitalization	3.3 years	No difference in primary composite end point between the two groups
EPHESUS, 2003	Eplerenone (3313)	Placebo (3319)	MI	All-cause mortality and CV mortality or hospitalization or events	1.3 years	Eplerenone reduced all-cause mortality by 15% and CV mortality or hospitalization or CV events by 13%

CV cardiovascular, *MI* myocardial infarction

landmark trials of aldosterone antagonists in patients with heart failure and myocardial infarction.

Direct Renin Inhibitors

Direct renin inhibitor, Aliskiren, is a potent competitive renin inhibitor that binds strongly to renin, resulting in very low circulating levels of angiotensin II and other peptides, thereby rendering the RAAS quiescent. Aliskiren has been as effective as other RAAS inhibitors in reducing blood pressure and left ventricular remodeling [14, 15]. In patients with systolic heart failure, Aliskiren has a potent vasodilatory effect on the efferent arteriole in the glomerulus, leading to marked reduction in renal blood flow and a drop-in filtration fraction [16]. Overall, the lack of incremental benefit in reducing cardiovascular outcomes over ACEI/ARBs, coupled with the noteworthy incidence of adverse effects (diarrhea, hypotension, hyperkalemia, and renal dysfunction), has placed this drug out of favor.

Dual RAAS Blockade

In theory, combination of an ACEI and ARB should result in enhanced RAAS blockade. Conceivably, combination therapy has been shown to be more effective in reducing BP compared with monotherapy alone [17]. In spite of this, dual therapy of ACEI and ARBs were not found superior compared to individual therapy. Multiple studies have also documented increased risk of adverse events such as worsening renal function, hyperkalemia, symptomatic hypotension, and increased medication discontinuation due to adverse effects with combination therapy of ACEIs and ARBs. Based upon the clear evidence of possible harm, ACEIs should not be combined with ARBs. With the advent of the Aliskiren, dual RAAS blockade could now be achieved by combining an ACEI or an ARB with Aliskiren. However, such dual RAAS blockade also has not proven safe, and should be avoided. Table 5.5 summarizes key landmark trials of dual RAAS blocking agents in patients with heart failure and myocardial infarction.

Table 5.5 Key clinical outcome trials of dual RAAS blockade in cardiovascular diseases

Trial and year	Active arm (N)	Comparator (N)	Patients	Primary outcome	Follow-up	Major findings
ALOFT, 2008	Aliskiren + ACEI/ARB (156)	Placebo (146)	Chronic heart failure	Between treatment difference in N-terminal pro-BNP	3 months	Aliskiren added to ACEI/ARB decreased NT-proBNP by 25%
ATMOSPHERE, 2016	Enalapril +Aliskiren (2340)	Aliskiren (2340), Enalapril (2336)	Chronic heart failure	Composite end point of CV death or heart failure hospitalization	3.1 years	No difference in primary end point
CHARM-Added, 2003	Candesartan + ACEI (1276)	Placebo (1272)	Chronic heart failure	CV mortality or heart failure hospitalization	3.4 years	Candesartan added to ACEI showed 15% reduction in primary end point
ONTARGET, 2008	Ramipril + Telmisartan (8502)	Ramipril (8576), Telmisartan (8542)	CV disease	Composite end point of CV death, MI, stroke, or heart failure hospitalization	4.6 years	No difference in primary outcomes among the three groups
VALIANT, 2003	Valsartan + Captopril (4885)	Valsartan (4909), Captopril (4909)	MI	All-cause mortality	2.1 years	No difference in all-cause mortality among the three groups

ACEI angiotensin-converting enzyme inhibitor, *ARB* angiotensin receptor blocker, *BNP* brain natriuretic peptide, *CV* cardiovascular, *MI* myocardial infarction

Other Vasodilators

Several physiological studies demonstrated the dependence of cardiac function on vascular resistance, so vasodilator therapies that reduce systemic vascular resistance should improve cardiovascular hemodynamics. Vasodilators are broadly subclassified into venodilators (e.g., nitrates), which reduce left ventricular filling pressure and relieve pulmonary congestion; arteriolar dilators (e.g., hydralazine), which enhance cardiac output; and balanced vasodilators (e.g., nitroprusside, nitroglycerine), which dilate both resistance and capacitance vessels. Seminal work conducted by Franciosa et al. in the early 1970s showed that intravenous infusion of sodium nitroprusside produced a marked reduction in the elevated left ventricular filling pressure and systemic arterial pressure, resulting in a modest increase in cardiac output [18]. A subsequent study in patients with refractory heart failure revealed even more striking improvements in systemic vascular resistance and cardiac output, with reduced left ventricular filling pressure [19]. Similar effects of nitroprusside were seen in patients with myocardial infarction and depressed left ventricular ejection fraction [20]. Despite being a potent vasodilator, sodium nitroprusside is seldom used these days as prolonged infusion has been associated with thiocyanate toxicity, particularly in those with severe renal dysfunction and systemic hypotension. Currently, intravenous nitroglycerine is the preferred vasodilator in acute conditions. It has comparable hemodynamic effects compared to nitroprusside and likely has more beneficial effects on intercoronary collateral blood flow in the setting of regional ischemia [21]. Although vasodilators are effective in relieving congestion and improving symptoms in patients with acute heart failure, their role in improving cardiac indices has not been demonstrated consistently. The increase in stroke volume and cardiac output with intravenous vasodilators is modulated by several factors such arterial elastance, ventricular function, preload dependence, presence of mitral regurgitation etc. In patients with severely impaired ventricular function, isolated reduction in preload may not translate into higher stroke volume due to markedly reduced cardiac contractility [22] (Fig. 5.4). Combination therapy of dobutamine and nitroglycerin can result in greater overall hemodynamic improvement than either drug alone in such cases.

The hemodynamic benefits of intravenous vasodilators led to the evolution of various oral agents with vasodilatory properties. Combination

therapy of hydralazine and isosorbide dinitrate (H-ISDN) is one of the common agents used widely in management of chronic systolic heart failure. There is simultaneous reduction of preload with isosorbide dinitrate and afterload with hydralazine (Fig. 5.5). H-ISDN reduce left ventricular filling pressure and pulmonary capillary wedge pressure, increase cardiac index, and

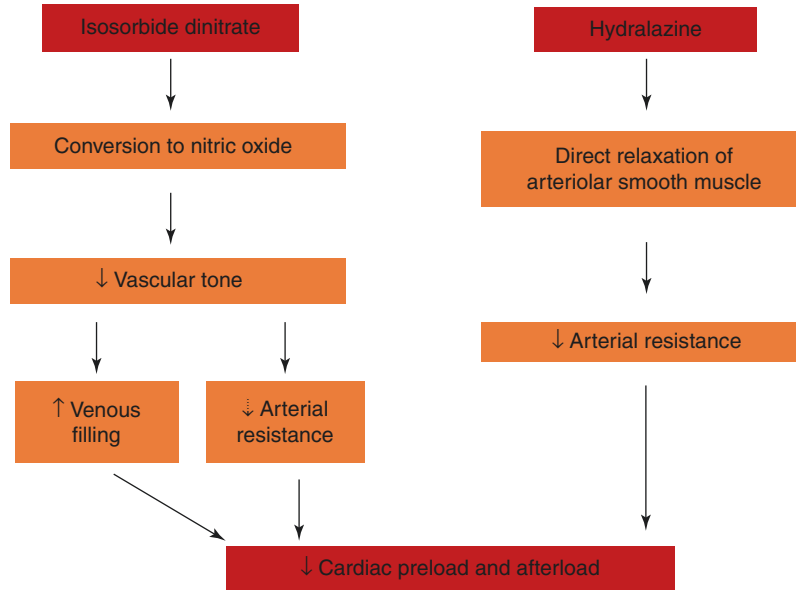

Fig. 5.5 Schematic diagram of mechanism of action of hydralazine and Isosorbide dinitrate

Table 5.6 Key clinical outcome trials of vasodilators in cardiovascular diseases

Trial and year	Active arm (N)	Comparator (N)	Patients	Primary outcome	Follow-up	Major findings
V-HeFT I, 1986	Hydralazine-Isosorbide dinitrate	Placebo	Chronic heart failure	All-cause mortality	2.3 years	Hydralazine-Isosorbide showed 36% reduction in all-cause mortality
A-HeFT, 2004	Hydralazine-Isosorbide dinitrate	Placebo	Chronic heart failure	Composite all-cause mortality, heart failure hospitalizations, and change in quality of life	10 months	Hydralazine-Isosorbide showed 43% reduction in all-cause mortality
WMAC, 2002	IV nesiritide (204), IV nitroglycerin (143)	Placebo (142)	Acute decompensated heart failure	Change in PCWP or dyspnea	3 h, 24 h	Nesiritide improved PCWP at 3 and 24 h than IV nitroglycerin or placebo. Nesiritide resulted in improvement in dyspnea compared with placebo but not IV nitroglycerin
ROSE, 2013	IV dopamine (122), IV nesiritide (119)	Placebo (119)	Acute decompensated heart failure	72-h cumulative urine volume, change in serum cystatin C	72 h	Low-dose dopamine or low-dose nesiritide showed no benefit when added to diuretic therapy

IV intravenous, *PCWP* pulmonary capillary wedge pressure

reduce systemic vascular resistance [23]. These properties make H-ISDN an effective therapy in patients with systolic heart failure. When compared to enalapril, H-ISDN resulted in greater improvements in ejection fraction, peak exercise oxygen consumption, and exercise tolerance [24]. Nesiritide, a synthetic natriuretic peptide, is an intravenous vasodilator with diuretic properties. In patients with heart failure, nesiritide produces dose-dependent balanced arterial and venous vasodilatation leading to reduction in pulmonary capillary wedge pressure, with minimal effect on cardiac contractility or output. Nesiritide also possesses anti-fibrotic, anti-hypertrophic, anti-inflammatory, and aldosterone-inhibiting properties, and may prevent adverse left ventricular remodeling. In a small study, low-dose nesiritide showed reduction of cardiac dilatation and improvement in ejection fraction in patients with acute myocardial infarction. The role of intravenous vasodilators is predominantly limited to management of acute decompensated heart failure. For oral agents, H-ISDN is a part of guideline-directed medical therapy for patients with chronic systolic heart failure. Hydralazine and long-acting nitrates are occasionally used in management of resistant hypertension. Table 5.6 summarizes key landmark trials of vasodilators in management of patients with acute and chronic systolic heart failure.

Review Questions

Question 1: Angiotensin-converting enzyme inhibitors:

A. Decrease preload
B. Decrease afterload
C. May cause hyperkalemia
D. Improve long-term outcome for patients with HFrEF
E. All of the above are correct

Answer 1: E. ACEIs are associated with all of the listed choices.

Question 2: 4. An elderly, nonverbal male is admitted to your facility after initial treatment for a heart attack. You notice that over the past 3 days, he has become lethargic. His appetite has decreased. His urine output has decreased. His blood pressure has been 190/100. His weight has increased 2 pounds. He has rales on his lung examination. His lower extremities are cold with trivial swelling.

Given the above scenario what would be the best way to improve his current state?

A. Decrease his afterload with an ACE inhibitor
B. Decrease his afterload with a beta-blocker
C. Decrease his afterload with a pure vasodilator
D. Decrease his preload with a diuretic
E. Both A and B
F. Both A and D

Answer 2: C. This patient is already exhibiting a decreased CO (cold extremities) and evidence of congestion at rest (rales on examination). A pure afterload-reducing agent would be optimal at this point. Any agent that may decrease this patient's preload will make an already low cardiac output worse. ACEI decrease preload and afterload. Beta-blockers do not decrease afterload but negatively impact contractility and heartrate. Giving a diuretic alone to this person will decrease an already low CO further through a decrease in preload.

Question 3: The mechanism(s) by which ACEIs decrease preload is:

A. Venodilation
B. Inhibition of bradykinin breakdown
C. A direct effect on sodium reabsorption
D. Both A and B
E. Both A and C

Answer 3: D. ACEI decreases both preload and afterload. The mechanism(s) by which these agents decrease preload are thought to be the following: Decrease breakdown of bradykinin and through its effect on decreasing angiotensin II levels. Bradykinin is a potent venodilator and the increase in bradykinin with ACEI use is a major contributor to the reduction in preload seen with these agents.

Question 4: A 68-year-old male presents with an acute anterior MI. After a successful PCI of the proximal LAD, he is started on statin, dual antiplatelet therapy, an ACEI, and beta-blocker. What would be an indication to initiate an aldosterone antagonist?

A. He is a nondiabetic with depressed ejection fraction and no heart failure

B. He is a diabetic with depressed ejection fraction and no heart failure
C. He is a nondiabetic with depressed ejection fraction, heart failure and a serum creatinine of 2.8
D. He is a diabetic with a depressed ejection fraction, heart failure and a serum potassium of 5.1 mmol/liter

Answer 4. B. In the Ephesus trial, patients with an acute MI and the presence of a reduced EF (≤40%) and heart failure (rales, pulmonary venous congestion, or an S3) were randomized to eplerenone or placebo. Diabetic patients could be randomized without any evidence of heart failure. Exclusion criteria included a potassium >5 mmol/liter and a serum creatinine >2.5 mg/dl.

Question 5: ARBs and ACEIs:

A. Both decrease angiotensin II levels
B. Both decrease plasma renin activity
C. Both increase levels of bradykinin
D. Both increase plasma renin activity

Answer: D. Both ACEI and ARB increase plasma renin activity. ACEI decrease angiotensin II levels while ARBs are associated with increased levels. ACEI block the breakdown of bradykinin while ARBs do not.

6 Beta Blockers and Calcium Channel Blockers

Alexandra-Maria Neagoe, Emrush Rexhaj, Ehud Grossman, and Franz H. Messerli

Introduction

In this chapter, we present pharmacological characteristics and hemodynamic effects of beta blockers (BBs) and calcium channel blockers (CCBs) as well as their main therapeutic indications. These classes of medications are two of the most frequently used for the treatment of cardiovascular diseases such as arterial hypertension, arrhythmia, and heart failure. The main clinical studies will be summarized.

Beta Blockers

Introduction

Propranolol was the first BB discovered in 1964 by Sir James Black while he was working on the effects of adrenalin on heart in patients with angina pectoris [1]. Ever since, BBs have been the most prescribed drug class in cardiovascular disorders, especially in patients after myocardial infarction. The term "cardioprotection" was extensively used to describe their benefits. As their name indicates, BBs block the action of adrenaline and noradrenaline at β-adrenergic receptors. Table 6.1 summarizes the distribution and the main responses of activation of β-adrenergic receptors. Depending on the selectivity of their actions, they are divided in two groups: cardioselective and non-cardioselective. The stimulation of β1-receptors increases heart rate (chronotropy) and myocardial contractility (inotropy) and speeds up atrioventricular node conduction (dromotropy), while the stimulation of β2-receptors induces vasodilation and bronchodilation and stimulates glycogenolysis in the liver. Thus, inhibition of β1-receptors by BBs results in decreased chronotropy, inotropy, and dromotropy and increased relaxation (lusitropy). At low doses β1-selective BBs act more selectively at a cardiac level, with insignificant effects on vascular and bronchial β-receptors,

https://doi.org/10.1007/978-3-030-19131-3_6

reducing in that way the risk of vasoconstriction and bronchospasm. These cardioselective effects are dose dependent and may disappear with high doses.

Table 6.1 Distribution of α- and β-receptors and mediated effects

Receptor subtype	Organ system	Effect
α	Blood vessel	↑ Constriction
	Uterus	↑ Contraction
	Pancreas	↓Insulin secretion
β1	Heart	↑ Heart rate
	Kidneys	↑ Contractility
	Adipose tissue	↑ Conduction
	Parathyroid glands	↑ Excitation
		↑ Automaticity
		↑ Renin secretion
		↑ Lipolysis
		↑ Secretion
β2	Heart	↑ Heart rate
	Blood vessels	↑ Contractility
	Skeletal muscle	↑ Conduction
	Liver	↑ Excitation
	Lungs	↑ Automaticity
	Pancreas	↑ Vasodilation
	Uterus	↑ Glycogenolysis
	Urinary bladder	↑ Contractility
	Gastrointestinal	↑ Potassium uptake
	Gall bladder and ducts	↑ Bronchodilation
	Nerve terminals	↑ Insulin and glucagon secretion
	Thyroid	↑ Relaxation
	Parathyroid glands	↑ Adrenaline release
		↑ T4-T3 conversion
		↑ Secretion

Pharmacological Characteristics of Beta Blockers

Some specific *pharmacological* properties of BBs distinguish one agent from another (Table 6.2): (1) cardioselectivity and relative affinity for the β1- and/or β2-receptors; (2) intrinsic sympathomimetic activity (slow heart rate less than other BBs by partially acting as β-agonist); (3) lipid solubility; (4) half-life elimination and the way of elimination; (5) additional effects of the drug such as vasodilation.

As Poirier et al. have pointed out in an excellent review [2], the following are of clinical significance:

1. Cardioselectivity

By definition, cardioselectivity represents the property of an agent to block β1-receptors, predominantly present in the heart and renal juxtaglomerular apparatus. Nebivolol and bisoprolol are the agents with the highest β1-selectivity. The β2-inhibition is also dose related, so agents with β1-inhibition can also inhibit β2-receptors at higher doses. Bronchial reactivity in asthma appears to be less enhanced with more cardioselective BBs and is a concern with nonselective agents.

2. Vasodilation

Some agents such as nebivolol and carvedilol exert their effects through vasodilatory properties. Nebivolol administration in healthy subjects

Table 6.2 Pharmacological properties of selected beta blockers

β-Blocker	β-Receptor activity	Membrane stabilizing activity	Intrinsic sympathomimetic activity	Vasodilatation	Elimination half-life (hours)	Route of elimination	Lipid solubility
Propranolol	No	Yes	No	No	3.5–6	Hepatic	High
Atenolol	β1	No	No	No	6–7	Renal	Low
Bisoprolol	β1	No	No	No	9–12	Renal	Low
Carvedilol	No	No	No	Yes	7–10	Hepatic	Moderate
Metoprolol	β1	At high levels	No	No	Tartrate 3–4 Succinate 3–7	Hepatic	Moderate
Nebivolol	β1	No	No	Yes	12	Hepatic	Low
Sotalol	No		No	No	12	Renal	Low

decreased systolic and diastolic blood pressure, and heart rate at rest and during submaximal and maximal exercise [3]. BBs with vasodilation effect (carvedilol via α1 blockade and nebivolol via stimulation of NO release) significantly decrease central blood pressure and wave reflection (augmentation index) as compared to atenolol [4]. Carvedilol and nebivolol have been shown to improve left ventricular systolic function in patients with nonischemic heart failure [5].

3. Lipophilicity/Hydrophilicity

Lipophilic agents such as propranolol, metoprolol, and nebivolol have the ability to cross the blood-brain barrier and have a shorter half-life. They are mainly eliminated through hepatic metabolism and are more susceptible to drug interaction. Due to crossing of blood-brain barrier, one of the most common side effects is vivid dreams and nightmares. Hydrophilic agents are eliminated mainly through renal metabolism, and their dosage needs to be adjusted in renal failure. Special attention needs to be given to sotalol in patients with renal failure since its accumulation might lead to torsade de pointes.

Hemodynamic Effects of Beta Blockers

Due to different properties, there is a difference in the cardiovascular hemodynamics of different BBs.

Intravenous administration of propranolol in anesthetized dogs decreased heart rate, myocardial contractile force, and cardiac output, whereas it increased LV end-diastolic pressure, left atrial pressure, and total and pulmonary peripheral resistances [6]. As shown by Nakano and Kusakari, acute administration of cumulative doses of propranolol results in a shift to the right of the left ventricular function curves, resulting in a reduction of cardiovascular performances. In a small study published in 1967 [7], it was showed the administration of propranolol to healthy subjects while exercising was associated with a reduction of cardiac output, mean arterial pressure, left ventricular minute work, and maximal O_2-uptake and increased the calculated arteriovenous O_2 difference and the central venous pressure. The administration of the same medication in patients with heart disease showed the same effect, although the cardiac outputs achieved during exercise were usually lower than in normal subjects. The cardiac output in patients under propranolol decreased 18%. At the same time, in all patients the heart rate as well as the pulmonary arterial O_2 saturation decreased. The reduction of cardiac output by only 18% with beta blockade suggests there are also other mechanisms through which the cardiac output is increasing during exercise, not only sympathetic stimulation.

The decrease of cardiac output with BBs was noted in another study [8]. Carvedilol, propranolol, bopindolol, and celiprol have each showed a decrease in cardiac output. The maximum decrease was induced by administrating propranolol, whereas the minimum through administrating celiprol. At the same time, in comparison to propranolol, improved coronary flow through coronary vasodilatation as well as reduced peripheral resistance has been demonstrated with carvedilol.

Nebivolol on the other hand has been proven to maintain the cardiac output while concomitantly reducing the arterial stiffness, vascular resistance, blood pressure, and heart rate and increasing the systolic function and stroke volume. Peripheral vasodilatation is caused by nitric oxide release [9].

To conclude, the non-vasodilating beta blockers increase the afterload through increase of the peripheral resistance, while the beta blockers with vasodilating properties cause a decrease of afterload through reducing the peripheral resistance and therefore reducing the blood pressure. At the same time all beta blockers cause bradycardia which consequently decreases the myocardial oxygen consumption and increases the duration of diastole, thereby increasing preload.

Effect on Central Pressure

Studies have shown the carotid and aortic blood pressure (BP) curves are a result of the summation of two different waves: a forward wave coming from the heart during ventricular ejection and a backward wave that has been reflected at the periphery back toward the heart. Normally, when there is physiological ventricular-vascular coupling, the reflected pulse wave returns to the left ventricle in diastole and serves to increase coronary perfusion. When resting heart rate (RHR) is slowed down by a negative chronotropic drug, the reflected pulse wave may return during ventricular systole. The resulting ventricular-vascular mismatch will augment central systolic pressure. To maintain cardiac output when RHR is low, the stroke volume has to increase in parallel with the fall in RHR. An elevated stroke volume will increase pulse pressure, which, in turn, is prone to increase systolic and decrease diastolic BP, particularly when aortic Windkessel function is impaired. For obvious reasons not all BBs are created equal; the vasodilating agents have little if any effect on central pressure [10].

The Therapeutic Indications of Beta Blockers

Hypertension

The mechanism of lowering BP is not clear; no single mechanism can explain the effect for all agents in this class of medication. One possibility is that lowering the cardiac output results in lower blood pressure and increased peripheral resistance [6]. Continuous therapy results in a decrease in peripheral resistance, but still above pretreatment levels and in consequence cannot be the only mechanism responsible for blood pressure lowering [11]. The second possibility is the decrease in sympathetic activity in the central nervous system results in a reduced sympathetic activity in the periphery. This is however only true for agents that cross the blood/brain barrier. Hydrophilic agents like practolol and sotalol do not decrease peripheral sympathetic activity while lowering blood pressure [12]. The reduction of renin secretion, and the consequent reduction of angiotensin II in plasma, is another possible mechanism [13–15]. The BBs with ISA such as pindolol have been shown to increase plasma renin levels while simultaneously reducing the blood pressure [11]. Blocking the β2-receptors diminishes the release of norepinephrine which consequently reduces the BP. This is obvious with nonselective agents such as propranolol, whereas β1 selective agents such as atenolol seemingly are good blood pressure lowering agents [16] However, as already described before, there is a pseudo-antihypertensive effect due to elevation (or lesser decrease) of the central aortic pressure. The slower the heart rate, the greater the pseudo-antihypertensive effect, and the less the reduction in morbidity and mortality [17].

The American, British, and most other formal hypertension guidelines no longer recommend the use of BBs as first-line therapy, except in some patients with ischemic heart disease or heart failure. In older patients, BBs have never been shown to reduce the risk of heart attack, stroke, and/or death [18].

The European guidelines for hypertension still consider the use of BBs as a class I indication for monotherapy or combined therapy. The preferred combination consists of thiazide diuretics, calcium antagonist, and ACE inhibitors/angiotensin receptor blockers with addition of BB in specific situations. Thus we should consider BBs in certain clinical conditions (e.g., aortic dilatation or patients who are symptomatic in case of excessive sympathetic activity). In the young, both atenolol and non-atenolol BBs have been proven to reduce the cardiovascular endpoints for hypertension without other indication. Atenolol is associated with an increased risk for stroke in the elderly, but whether this extends to other non-atenolol BBs is uncertain [19]. The availability of vasodilating BBs with both alpha and beta effect influences positively the cardiac output, heart rate, blood pressure, and systemic vascular resistance. Carvedilol may be superior to traditional BBs in several regards, it has a lower rate of new-

onset diabetes, it has a beneficial effect on lipid profile, and it increases plasma flow to the kidneys [20]. Due to well-documented adverse effects as well as different responses in different patient population, the use of BBs should be used selectively if at all in hypertension.

Arrhythmia

BBs have not only an antihypertensive effect but also an antiarrhythmic effect. They are considered to be class II agents in the Vaughan Williams classification. They act by blocking the effects of catecholamines at the site of β1-receptor, thereby decreasing the sympathetic activity in the heart.

The European guidelines for the management of patients with ventricular arrhythmias and the prevention of sudden cardiac death recommend BBs as a first-line therapy in the management of ventricular ectopic beats and ventricular tachycardia and the prevention of sudden cardiac death in patients with or without heart failure. Furthermore, the same guidelines recommend the use of BBs in patients with long QT-syndrome.

BBs are also used as rate control therapy in patients who have atrial fibrillation (AF). Importantly, a mortality benefit in patients with atrial fibrillation receiving BBs in comparison with placebo in patients with heart failure with reduced ejection fraction (HFrEF) has not been shown [21]. In general, BBs do not reduce the risk of AF or recurrent AF after ablation. However, in patients with HFrEF in sinus rhythm pretreated with ACE inhibitors/ARBs, BBs were shown to reduce the incidence of AF [21].

Sotalol is the only BB used as a rhythm control therapy in patients with atrial fibrillation and normal ventricular systolic function. However, there is a risk of torsades de pointes so the benefits and risks have to be taken into consideration when administrating sotalol.

Heart Failure

BBs are part of the standard therapy for HFrEF along with ACE inhibitors and diuretics since it has been proven to reduce the mortality and morbidity in such patients [22–28]. BBs should be started in stable patients and gradually up-titrated to the maximum tolerated dose. In patients admitted due to acute heart failure, BBs should be initiated under medical surveillance once the patient is stable.

Coronary Artery Disease

BBs have been shown to reduce the cardiovascular mortality after a myocardial infarction [29–31]. The reduction in mortality was shown to be smaller in Afro-Americans, patients 80 years old or older, and those with an ejection fraction below 20% or patients with renal insufficiency or diabetes. After a myocardial infarction, even in patients with relative contraindications such as pulmonary disease, BBs have shown a benefit [32]. The necessity as well as the duration of BBs after a non ST-elevation myocardial infarction in patients where the ejection fraction is normal or close to normal still needs to be assessed [33, 34].

Beta blockers are also used in stable coronary artery disease to treat patients with stable angina. The antianginal effect is explained through a reduction in myocardial oxygen demand.

Conclusion

After five decades of clinical experience, heart failure with reduced EF remains the only iron-clad indication for BBs in cardiovascular disease – the very indication that decades ago was considered to be the only contraindication for BB therapy. Many of so-called cardioprotective effects of BBs were mostly based on old studies and on hearsay and have never been documented in contemporary prospective randomized trials [35, 36].

Calcium Channel Blockers (CCBs)

Introduction

The observation made by Fleckenstein in 1967 that a reduction of calcium movement into cardiac myocytes determined a negative inotropic effect facilitated the development of calcium antagonist drugs, currently called calcium channel blockers (CCBs). CCBs were introduced for the treatment of hypertension in the 1980s. Their

use was subsequently expanded to disorders such as angina pectoris, paroxysmal supraventricular tachycardia, hypertrophic cardiomyopathy, coronary spasm, Raynaud phenomenon, pulmonary hypertension, esophageal spasms, migraine, and cerebral vasospasm. In this chapter, the main hemodynamic and cardiovascular effects of CCBs will be summarized.

Mechanism of Action

The mechanism of action is reducing the cytosolic free calcium concentration by blocking calcium entry into cells, acting on the L (long-lasting) subtype. There is a difference in selectivity for L-Type and T-Type channels, although all calcium blockers act on both subtypes. Mibefradil has showed the highest selectivity on the T-Type channels, whereas lacidipine was showed to have the highest selectivity on the L-Type channels [37].

Classification

According to their chemical structure, CCBs can be subdivided into dihydropyridines (nifedipine, amlodipine, nitrendipine) and non-dihydropyridines. The non-dihydropyridines are divided into two major groups: (1) phenylalkylamines (verapamil) and (2) benzothiazepines (diltiazem) (Table 6.3). CCBs act on different receptor sites on Ca channels due to their different molecular structure. Since their discovery, there has been an evolvement of different CCB generations. The first generation is characterized by a rapid onset of action and very short half-life, whereas the second and third generations provide a longer duration of action or extended-release mechanisms, poor activation of the sympathetic nervous system, and fewer side effects [38–40] (Fig. 6.1).

Cardiovascular Hemodynamics

CCBs vary in their effects on cardiovascular hemodynamics. Dihydropyridines such as amlodipine and nifedipine are potent arterial vasodilators, whereas non-dihydropyridines work primarily on the heart; phenylalkylamines (verapamil) have a negative chronotropic, dromotropic, and inotropic effect with a positive lusitropic effect, while benzothiazepines (diltiazem) have intermediate chronotropic, dromotropic, and inotropic effects (Table 6.4 and Fig. 6.2).

All CCBs lower arterial pressure when given over the short term and with prolonged administration [41–46]. Head-to-head comparisons of five different calcium antagonists reveal little, if any, difference in blood pressure lowering potency among the various agents, provided that adequate doses are given.

Table 6.3 CCB classification, recommended uses, and adverse effects

Calcium channel blockers	Amlodipine, clevidipine, nicardipine, nifedipine, nimodipine (dihydropyridines, act on vascular smooth muscle); diltiazem, verapamil (non-dihydropyridines, act on heart)
Mechanism	Block voltage-dependent L-type calcium channels of cardiac and smooth muscle → ↓ muscle contractility
	Vascular smooth muscle – amlodipine = nifedipine > diltiazem > verapamil
	Heart – verapamil > diltiazem > amlodipine = nifedipine (verapamil = ventricle)
Clinical use	Dihydropyridines (except nimodipine): hypertension, angina (including Prinzmetal), Raynaud phenomenon
	Nimodipine: subarachnoid hemorrhage (prevents cerebral vasospasm)
	Nicardipine, clevidipine: hypertensive urgency or emergency
	Non-dihydropyridines: hypertension, angina, atrial fibrillation/flutter
Adverse effects	Non-dihydropyridine: cardiac depression, AV block, hyperprolactinemia, constipation
	Dihydropyridine: peripheral edema, flushing, dizziness, gingival hyperplasia

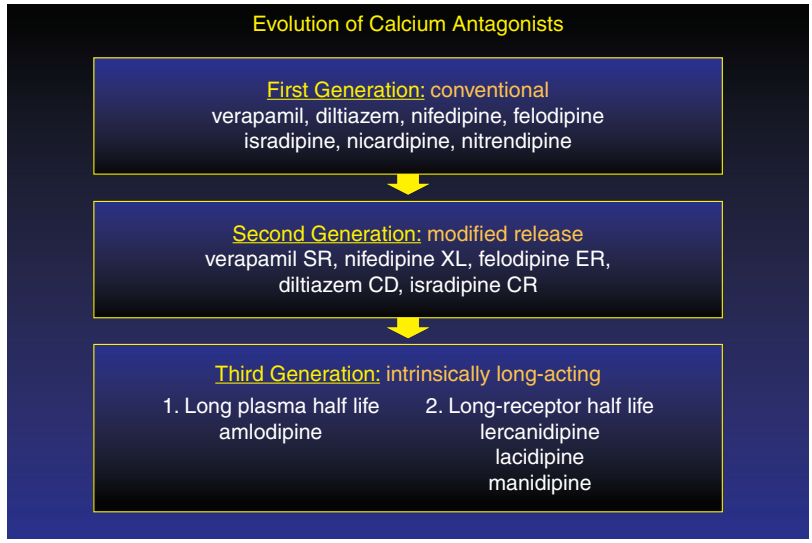

Fig. 6.1 Evolution of CCBs

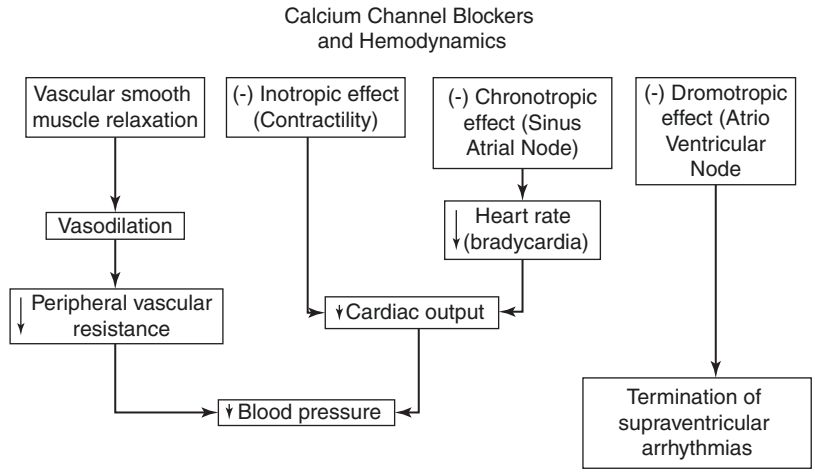
Table 6.4 Effect of calcium channel blockers

	Dihydropyridines	Non-dihydropyridines	
		Benzothiazepines	Phenylalkylamines
	Amlodipine	Diltiazem	Verapamil
(−) Chronotropic effect	–	↓	↓
(−) Dromotropic effect	–	↓	↓
(−) Inotropic effect	↓/–	↓↓	↓↓
(+) Lusitropic effect	↑	↑↑	↑↑
Peripheral dilatation	↑↑	↑	↑
Coronary dilatation	↑	↑	↑
Cardiac output	–	↓	↓
Blood pressure	↓	↓	↓

(−) negative effect, ↑ increase, ↓ decrease, – no difference

Fig. 6.2 Effect of CCBs on hemodynamics



Left Ventricular Hypertrophy

Most CCBs tend to reduce left ventricular mass (LVM) when given for a sustained period [41–43, 45, 47–85]. In a meta-analysis of 80 randomized, double-blind trials, calcium antagonists decreased LVM by 11% compared with a 10% decrease by ACE inhibitors, 8% decrease by diuretics, 6% decrease by β-blockers, and 13% decrease by angiotensin receptor blockers [85]. The decrease in LVM documented with CCBs is associated with improved ventricular filling, diminished ventricular ectopy, and preserved LV contractility. Evidence from experimental studies indicates that nifedipine, nisoldipine, and amlodipine additionally lead to regression of interstitial and perivascular myocardial fibrosis, which may contribute to the improvement of diastolic function (see below) and coronary reserve.

Effects on Cardiac Contractility

By and large, CCBs are negative inotropic agents and, therefore, are likely to impair cardiac pump function to some extent [86–98]. The most profound negative inotropic effect is seen with verapamil and diltiazem. To some extent this effect is overridden by afterload reduction and reflexive sympathetic activity elicited predominantly by the dihydropyridine derivatives. Favorable hemodynamic responses such as a decrease in pulmonary wedge pressure and end-diastolic ventricular pressure were documented when isradipine, felodipine, and amlodipine were given over the short term. However, improvement of hemodynamics in patients with heart failure did not translate into an increased survival rate. In the Prospective Randomized Amlodipine Survival Evaluation (PRAISE I) [99] study, retrospective subgroup analysis suggested that amlodipine prolonged survival only in patients with nonischemic dilated cardiomyopathy; there was no beneficial effect on cardiovascular morbidity or mortality in patients with ischemic cardiomyopathy. A follow-up trial, PRAISE-2 was specifically crafted to test the hypothesis observed in the prespecified subgroup analysis of a secondary outcome in the original PRAISE study; that is, that amlodipine would reduce the rates of death from all causes in patients with heart failure. The results of PRAISE-2 did not validate the favorable association of amlodipine with improved survival for patients with nonischemic heart failure observed in the initial PRAISE-1 trial. Combined analysis of both trials suggests that amlodipine has no appreciable harmful or beneficial effect on mortality in patients with severe chronic heart failure. Similarly, in the Vasodilator-Heart Failure Trial (V-HeFT) III study, felodipine was safe but not clearly efficacious in patients with heart failure [100].

Left Ventricular Filling

In simplistic terms, left ventricular filling consists of an early diastolic active relaxation phase and a late diastolic passive distensibility phase. CCBs have been documented to have a favorable effect on both. This effect may be heart rate – dependent and appears to be most pronounced with verapamil, less pronounced with diltiazem, and even less so with the dihydropyridine CCBs. However, with prolonged administration of most CCBs, late diastolic passive distensibility is improved as well. The clinical significance of decreased left ventricular filling in patients with hypertension and of its improvement by CCBs is unclear. Certain patients with long-standing hypertension have been documented to have latent or overt heart failure, primarily as a result of impaired filling. In such patients, CCBs that lower heart rate may be helpful because they not only lower arterial pressure but also improve ventricular filling.

Endothelial and Anti-atheromatous Effects

Various experimental studies have documented that CCBs exert anti-atheromatous effects in certain animal models, such as cholesterol-fed rab-

bits. CCBs, particularly of the dihydropyridine class, can reverse endothelial dysfunction in various vascular beds, including subcutaneous, epicardial, and peripheral arteries and forearm circulation. In the Comparison of Amlodipine vs Enalapril to Limit Occurrences of Thrombosis (CAMELOT) trial [101], the slowest rate of progression of coronary atherosclerosis was observed in those patients whose BP fell within the "normal" JNC-7 category (i.e., systolic BP <120 mm Hg and diastolic BP <80 mm Hg). Administration of amlodipine (but not of enalapril) to patients with CAD and normal blood pressure resulted in reduced adverse cardiovascular events. Intravascular ultrasound imaging noted evidence of slowing of atherosclerosis progression in the amlodipine cohort.

Outcome Data

In a meta-analysis of 15 studies evaluating 47,694 patients with coronary heart disease, Bangalore et al. [102] showed that long-acting CCBs (either dihydropyridines or non-dihydropyridines) were associated with a reduction in the risk of stroke, angina pectoris, and heart failure, with similar outcomes for other cardiovascular events as the comparison group. When compared with placebo, CCBs resulted in a 28% reduction in the risk of heart failure (95% CI, 0.73–0.92). Similarly, in a recent Cochrane meta-analysis on first-line therapy in hypertension, first-line ACE inhibitors and CCBs were similarly effective as low-dose thiazides to reduce all morbidity and mortality outcomes in adult patients [103]. Of note, the Avoiding Cardiovascular events through Combination therapy in Patients Living with Systolic Hypertension (ACCOMPLISH) study showed that in combination therapy with benazepril, amlodipine was superior to hydrochlorothiazide in reducing morbidity and mortality [104]. Even in diabetes which was for years a primary indication for blockers of the renin-angiotensin system, a meta-analysis of 19 randomized controlled trials that enrolled 25,414 participants revealed no superiority of ACE inhibitors or ARBs compared to other drug classes such as CCBs in reducing the risk of hard cardiovascular and renal endpoints [105]. Finally, Wang et al. [106] looking at amlodipine specifically in head-to-head studies concluded that compared with other drug regimens, amlodipine-based antihypertensive regimen, as evidenced by the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) [107] and Anglo Scandinavian Cardiac Outcomes Trial (ASCOT) [108], the two largest-ever trials in hypertension, might confer more outcome benefit, possibly by better lowering central systolic pressure or ambulatory pressure over 24 hours (Fig. 6.3).

Dihydropyridine CCBs

The most commonly used dihydropyridine CCBs are amlodipine and nifedipine. These drugs induce a selectively transmembrane influx of Ca++ into vascular smooth muscle and cardiac cells, thus causing vasodilation and decreasing the peripheral vascular resistance of coronary arteries and peripheral vasculature (Fig. 6.2). As a result of this effect, blood pressure will be reduced, while coronary blood flow and myocardial oxygen delivery will be increased [109]. The slow-onset, long-acting formulations such as amlodipine, lacidipine, and lercanidipine exert their hemodynamic effects over days and induce long-acting smooth and graded changes of blood pressure.

One of the primary indications for dihydropyridines is blood pressure reduction; many clinical trials have shown that this class of CCBs offers an equivalent reduction in blood pressure when compared to other antihypertensives, which translates into comparable cardiovascular events reduction. These studies include Syst Eur [110], Syst China, ASCOT, ALLHAT, Valsartan Antihypertensive Long-term Use Evaluation (VALUE), and ACCOMPLISH.

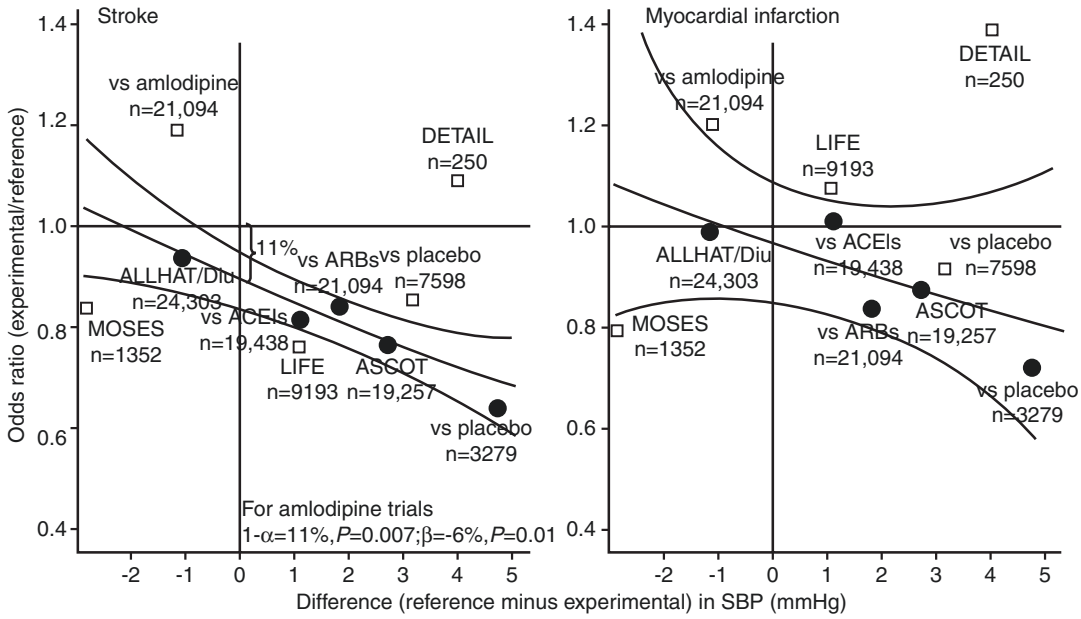


Fig. 6.3 Odds ratios for fatal and nonfatal stroke (left) and fatal and nonfatal myocardial infarction (right) in relation to corresponding differences in systolic blood pressure. Odds ratios were calculated for the amlodipine group vs placebo or other classes of antihypertensive drugs including ARBs (dots) or for the angiotensin receptor group vs placebo or other classes of antihypertensive drugs including amlodipine (squares). Blood pressure differences were obtained by subtracting the mean change in the amlodipine or ARB group from the corresponding mean change in the reference group. When a group of trials was pooled, the blood pressure difference was calculated by averaging the between-group blood pressure difference within each trial with the number of randomly assigned patients as weighting factor. Positive values indicate tighter blood pressure control in the experimental group. The regression line was drawn for trials involving an amlodipine group and weighted by the inverse of the variance of the individual odds ratios [105]

Non-dihydropyridine CCBs

1. *Phenylalkylamines*

The most commonly prescribed CCB in this subclass is verapamil; less commonly used are gallopamil and tiapamil. The systemic vasodilation is moderate and less strong in comparison to dihydropyridines. However, the negative inotropic and negative chronotropic effects induced by verapamil depress sinoatrial (SA) node and atrioventricular (AV) node conduction. As a result, there is commonly a decrease in heart rate. The cardiac output remains stable however due to the increase in stroke volume [111].

Verapamil is most commonly used for decreasing blood pressure and attenuation of angina pectoris. Moreover, verapamil offers similar efficacy as adenosine in reversing supraventricular tachycardia [112–115]. The effects of dihydropyridines and verapamil on atheromatous plaque have been studied in the Verapamil in Hypertension and Atherosclerosis Study (VHAS) trial [116]; in brief, no significant differences between verapamil and chlorthalidone on progression/regression of the atheromatous plaque were appreciated [117]. Studies such as the Controlled Onset Verapamil Investigation of Cardiovascular Endpoints (CONVINCE) [118] and the International Verapamil SR/Trandolapril Study (INVEST) ([119]) showed the reduction in cardiovascular events was not significantly different compared with drugs such as beta blockers or diuretics. Verapamil should be used with caution in combination with any beta blocker due to the additive negative inotropic and chronotropic effects [120].

2. *Benzothiazepines*

Diltiazem causes vasodilatation, especially in the coronary arteries [121, 122]. Overall, diltiazem has similar hemodynamic properties as verapamil. In atrial fibrillation or flutter without heart failure, diltiazem is preferred over digoxin for control of the heart rate [123]. Due to its moderate negative inotropic and chronotropic effect, the use of diltiazem is contraindicated in patients who have heart failure with reduced ejection fraction [124], sick sinus syndrome [125], and second-degree or third-degree atrioventricular block [126]. For the same reason, combination therapy with beta blockers is also relatively contraindicated.

In the Nordic Diltiazem (NORDIL) trial, the arm treated with diltiazem lowered the risk for stroke compared to the diuretics and β-blocker arm, despite the fact that the systolic pressure was higher in the group treated with diltiazem [127].

Questions

Question 1: A person presents with an anterior MI. Current vital signs are blood pressure 100/60 mmHg, heart rate of 120 beats per minute, rales are noted bilaterally. Extremities are cool with 1+ bilateral lower extremity edema.

Which of the following class of medications should not be initiated acutely?

A. ACEI
B. ARB
C. Beta blocker
D. Diuretic

Answer 1. C. Of all the agents listed, beta blockers would have the most acute deleterious effects. Given CO = HR ∗ SV. The HR in this person is what is maintaining the cardiac output.

Question 2: The optimal time to initiate beta blockers in the above person would be:

A. Immediately
B. Upon initiation of discharge planning
C. Once the person is stable
D. At the same time dobutamine (if required) is being administered
E. Not during this admission

Answer 2: C. Beta blockers should be initiated in patients once they are in a stable state.

Question 3: Beta blockers:

A. Increase contractility, increase heart rate, and decrease dromotropy
B. Increase contractility, decrease heart rate, and decrease dromotropy
C. Decrease contractility, increase heart rate, and increase dromotropy
D. Decrease contractility, decrease heart rate, and decrease dromotropy

Answer 3: D. Beta blockers affect hemodynamics in many ways including negative inotropy, negative chronotropy, and negative dromotropy. The result is decreased contractility, decreased heart rate, and decreased dromotropy.

Question 4: The Prospective Randomized Amlodipine Survival Evaluation (PRAISE 2) trial revealed the following about amlodipine in patients with chronic, severe heart failure:

A. A beneficial effect of amlodipine on mortality in ischemic cardiomyopathy patients
B. A reduction in mortality in nonischemic cardiomyopathy patients
C. No appreciable harmful or beneficial effect in patients with chronic severe heart failure
D. Both A and B

Answer 4: C. Analysis of trials suggests that amlodipine has no appreciable harmful or beneficial effect on mortality in patients with severe chronic heart failure.

Question 5: Arrange the following CCBs in order of their negative inotropic effects:

A. Diltiazem, verapamil, amlodipine
B. Amlodipine, verapamil, diltiazem
C. Verapamil, diltiazem, amlodipine
D. Amlodipine, diltiazem, verapamil

Answer 5: C

Parts of this chapter are modified and updated from Grossman E and Messerli F, Calcium Antagonists, Progress in Cardiovascular Diseases [40].

7 Pressor Agents, Pure Inotropes, Mixed Function Agents

Paul Anaya and Tracy E. Macaulay

Introduction

In critically ill patients presenting with shock, hemodynamic stability can be achieved using mechanical support with intra-aortic balloon pumps, ventricular assist devices, or extracorporeal membrane oxygenation (ECMO); however, an initial pharmacologic approach is typically undertaken and often preferred. The primary objective of using vasoactive medications is to maintain adequate tissue perfusion and optimize oxygen delivery by improving mean arterial pressure and cardiac output [1, 2]. When considering the use of vasodilators, inotropes, and vasopressors, it is important to be mindful of the balance sought in providing adequate oxygen delivery by maintaining the minimal effective perfusion pressure while simultaneously limiting myocardial oxygen demand and preventing tissue ischemia.

A working knowledge of the hemodynamic effects of these vasoactive agents is the key to guide therapeutic decision-making regarding the choice of vasoactive agent for any given clinical setting. A detailed discussion of basic hemodynamic principles is provided in Part I of this book. To briefly review, cardiac performance is dependent on the physiologic elements of preload and afterload. According to the Frank-Starling principle, stroke volume (or cardiac output) will increase with an increase in preload (Fig. 7.1).

Left ventricular (LV) preload can be estimated by measures of left atrial pressure, pulmonary capillary wedge pressure, or left ventricular end-diastolic pressure. Right ventricular (RV) preload can be estimated by measuring right atrial pressure, central venous pressure, or right ventricular

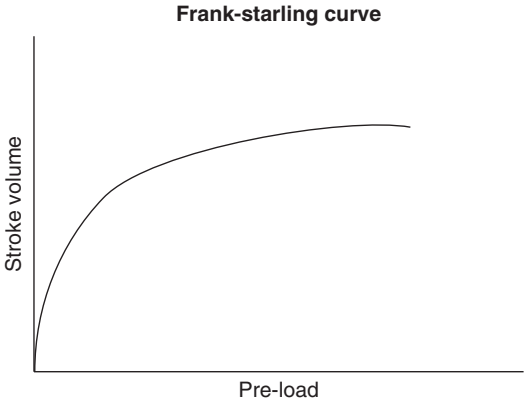

Fig. 7.1 The Frank-Starling curve as it applies in cardiac hemodynamics depicts the relationship between preload and stroke volume or cardiac output

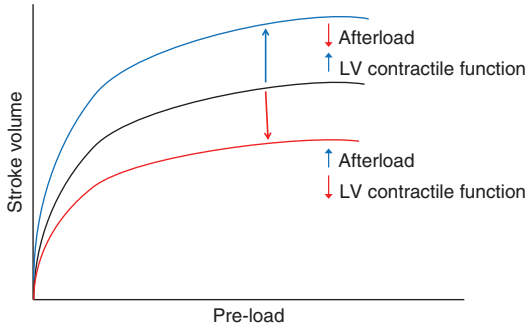

Fig. 7.2 The effects of afterload and intrinsic LV contractility on the Frank-Starling relationship

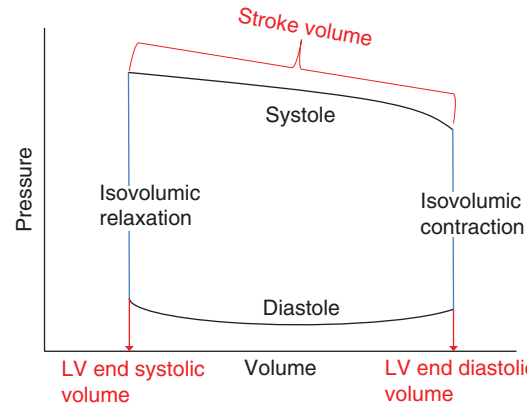

Fig. 7.3 The pressure-volume relation depicts the volumetric and pressure changes that occur through a single cardiac cycle. As is illustrated, the phases of the cardiac cycle include diastole (or filling phase) which begins at the time of mitral valve opening, isovolumetric contraction defined as the time from mitral valve closure until aortic valve opening, systole (or ejection phase) which begins at the time of aortic valve opening, and isovolumetric relaxation defined by the time between aortic valve closure until mitral valve opening heralds the next diastolic phase. Stroke volume is defined as the difference between the volume contained within the ventricle at end diastole and the volume contained at the end of ejection

end-diastolic pressure. In simple terms, preload can be viewed as the distending capacity of the ventricle, and is often referred to as the ventricular filling pressure. An important concept to understand is that in an intact heart surrounded by pericardium, there is a physical limit imposed on the degree of ventricular distention achieved with progressive increases in preload. Furthermore, the distending pressure of the LV is counteracted by, and therefore, determined in part by the surrounding pericardial (or RV) pressure [3]. In mathematical terms, the distending pressure is equal to the ventricular filling pressure minus the pericardial pressure. Under normal physiologic circumstances, the pericardial pressure is negligible and can be ignored such that the distending pressure is equal to the filling pressure. In the setting of acute decompensated heart failure associated with volume overload, the pericardial pressure rises and can no longer be ignored. Thus, while measures of left atrial pressure (or PCWP) may be elevated, the actual distending pressure (i.e., preload) is lower, thereby shifting the relationship of stroke volume to preload leftward along the Frank-Starling curve, resulting in a lower stroke volume. Additionally, as illustrated in Fig. 7.2, regardless from where a patient lies on their specific Frank-Starling curve, a shift of the curve downward for any given preload would imply either an increase in afterload forces or a decrease in the intrinsic contractility of the ventricle. Conversely, a shift of the curve upward for any given preload state would imply either a decrease in afterload or an increase in the intrinsic contractility of the ventricle. Afterload influences cardiac performance in a reciprocal manner such that increases in afterload result in lower cardiac output whereas reduced afterload generally results in improved cardiac output. Left ventricular pressure-volume relations contain information regarding cardiac performance, intrinsic contractile function, preload, and afterload (Fig. 7.3). Historically, these have been generated in the cardiac catheterization laboratory using intracardiac pressure sensors and altering intracardiac volume by pharmacologic or mechanical means. Such alterations in volume produce a series of pressure-volume loops whereby the end-systolic pressure-volume points align (Fig. 7.4). This linear relation is known as the left ventricular end-systolic elastance and defines the intrinsic contractile function of the left ventricle. Additionally, a line drawn from the end-systolic pressure-volume point to the end-diastolic pressure-volume point is known as the arterial elastance and defines the ventricular afterload.

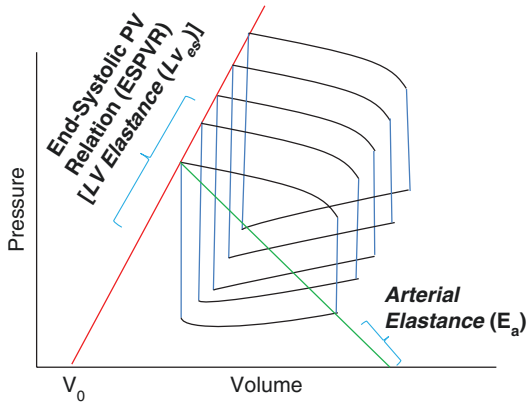

Fig. 7.4 By altering preload, a series of pressure-volume loops can be generated. These can be used to define ventricular end-systolic elastance (LV E_{es}). This end-systolic pressure-volume linear relation is generally accepted as a measure of LV contractility with steeper slopes indicating greater contractility and less steep slopes indicating reduced contractility. Similarly, a linear relationship between the end-systolic pressure-volume point and the end-diastolic pressure–volume point defines arterial elastance (Ea) from which the LV afterload is derived. Black = diastolic and systolic phases of the cardiac cycle; blue = isovolumetric phases; red = LV elastance (LV contractility); green = arterial elastance (afterload)

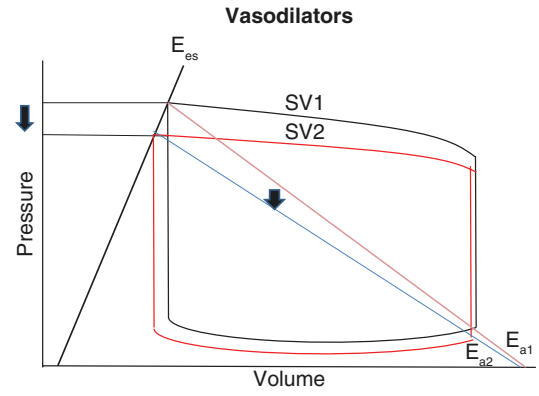

Fig. 7.5 Hemodynamic effects of vasodilators. A reduction in afterload is depicted as a downward shift in the arterial elastance ($E_{a1} \rightarrow E_{a2}$) and a decrease in the end-systolic pressure. This results in an increase in the stroke volume (SV2 > SV1). Vasodilators do not affect the LV contractility. Black = baseline hemodynamic profile; red = hemodynamic profile after intervention

Pharmacologic Fundamentals and Hemodynamic Effects

Vasodilators

Vasodilator therapy is most frequently used in the treatment of hypertension. It is also useful in patients with left ventricular systolic dysfunction (LVSD) with or without pulmonary edema, and has demonstrated a mortality reduction in both acute and chronic management [4, 5]. The primary site of action for vasodilators is the peripheral vasculature where they facilitate the effects of nitric oxide (NO), or act as direct NO donors, to potentiate vasodilatation. Vasodilators used in acute decompensated heart failure or cardiogenic shock include nitroprusside and nitroglycerin. While ace inhibitors, angiotensin receptor blockers, beta-blockers, calcium channel blockers, hydralazine, and long-acting oral nitrates can also achieve vasodilatation, these are more typically used in the management of chronic heart failure or hypertensive crisis [6–8]. Since the primary effect of vasodilators is to reduce the systemic vascular resistance, the expected pressure-volume relation would yield a tracing in which stroke volume is augmented simply by decreasing the LV afterload (Fig. 7.5). These agents also have variable effects on venodilation and therefore may also cause a slight reduction in preload. No change to LV contractility occurs, so the end-systolic pressure-volume relation remains constant.

Nitroglycerin

Nitroglycerin (NTG) is a direct NO donor, providing an exogenous source of NO which increases vascular cGMP resulting in smooth muscle relaxation (Table 7.1). Nitroglycerin acts as a preferential venodilator, thereby reducing cardiac preload. It also is an effective coronary artery vasodilator, making it an ideal choice for the patient with myocardial ischemia, hypertension, and/or elevated pulmonary capillary wedge pressure. Contraindications include right ventricular failure, hypertrophic cardiomyopathy, pericardial disease, or pericardial tamponade. Despite favorable hemodynamic effects, no mortality reduction from the use of intravenous nitrates has been demonstrated in large clinical trials [6, 7].

Table 7.1 Vasodilators

Generic (brand)	Starting dose	Maintenance and titration	Adverse drug Rxn	Precautions and contraindications	Uses
Nitroglycerin (Nitrostat IV)	5 mcg/min	Increase every 3 min to max 200 mcg/min	Headache, tachyphylaxis	RV failure, pericardial dz, restrictive cardiomyopathy	Used to treat symptoms of ischemia (low doses), hypertension (high doses), and pulmonary edema
Nitroprusside (Nipride)	0.5 mcg/kg/min	Increase every 5 min to max 5–10 mcg/kg/min; ideally 48 h	Cyanide toxicity and methemoglobinemia with prolonged use and/or high dose	Severe renal, liver impairment	Acute decompensated heart failure due to high afterload, cardiogenic pulmonary edema
Diltiazem (Cardizem)	Arrhythmias – 10 mg IVP (0.25 mg/kg)	5–20 mg/h infusion	AV nodal blockade	Congestive heart failure, bradycardia, sick sinus syndrome, WPW	Atrial fib/flutter, PSVT
Verapamil (Isoptin)	Arrhythmias – 2.5–5 mg IVP	N/A	AV nodal blockade	Congestive heart failure, bradycardia, sick sinus syndrome, WPW	Atrial fib/flutter, PSVT
Nicardipine (Cardene)	No bolus	3–15 mg/h	Low BP, tachycardia, edema	Aortic stenosis	Hypertensive crisis
Nesiritide (Natrecor)	2 mcg/kg IV	0.01 mcg/kg/min; max 0.03 mcg/kg/min; titrate by 0.005 mcg/kg/min q3 h	Low BP, renal failure	Valvular heart dz, pericardial dz, hypotension, restrictive cardiomyopathy	Acute decompensated heart failure with volume overload

Tachyphylaxis can develop within 24 h of continuous therapy, but can generally be overcome by increasing the dose or providing a nitrate-free interval if possible [8].

Sodium Nitroprusside

Sodium nitroprusside is an endothelium-independent vasodilator like nitroglycerin, serving as a direct NO donor within the vasculature. Unlike nitroglycerin, nitroprusside is associated with preferential arterial vasodilating properties [9]. Therefore, while capable of reducing cardiac preload much like nitroglycerin, it has a more potent afterload reducing capability. Unlike other vasodilators, nitroprusside causes only mild increases in heart rate and an overall decrease in myocardial oxygen demand. The molecular composition of sodium nitroprusside includes five cyanide ions which can accumulate as either cyanide or thiocyanate in patients with liver or renal failure, respectively, thereby limiting its applicability. Patients receiving high doses (10 mcg/kg/min) for a prolonged time (>2 days) are particularly at risk of toxicity. Despite this, nitroprusside is considered to be the gold standard intravenous antihypertensive for its remarkable effectiveness and rapid onset of action (Table 7.2).

Other Vasodilators

Intravenous calcium channel blockers, specifically diltiazem, have several important roles in the management of various clinical conditions. Blockade of calcium entry into coronary and peripheral arterial smooth muscle cells results in vasodilation and has a negative chronotropic and negative inotropic effect on the myocardium. The negative chronotropic effects are useful for the management of rapid ventricular heart rates, particularly in patients with supraventricular tachycardia. It is important to note that the significant negative inotropy means diltiazem is only recommended in patients with normal ejection fraction and absence of clinical heart failure. Diltiazem may also play a role in the management of hypertensive urgency and emergency; however, its long biological half-life of 3–4.5 h, makes it less useful than medications with a more rapid onset and easier titration. Also, due to the delayed onset of action, an intravenous bolus of IV diltiazem would typically precede initiation of a continuous infusion.

Esmolol is a β-1 selective adrenergic receptor blocker that has a very rapid onset and short duration of action, making it easily titratable. Unlike labetolol and carvedilol, esmolol exhibits very weak vasodilator effects and therefore is *not* clinically useful as a vasodilator. Rather, its negative chronotropic effect predominates, hence its utility in the treatment of tachyarrhythmias. A resurgent interest in use of esmolol in the treatment of septic shock, mainly due to his negative chronotropic effects, has recently emerged and is a topic of current investigations [10].

Nesiritide is a recombinant B-type natriuretic peptide. Early studies demonstrated that the main clinical effect of nesiritide is peripheral vasodilatation [11]. Nesiritide also induces a

Table 7.2 Comparison of intravenous vasodilators

	NTG	Nitroprusside	Diltiazem	Verapamil	Nicardipine

Table 7.3 Inotrope overview

Generic name	Brand name	Starting dose	Maintenance and titration	Pharmacokinetic properties	Adverse effects
Dobutamine	Dobutrex	1 mcg/kg/min	20 mcg/kg/min	Metabolized by methylation and conjugation, inactive metabolites are renally excreted, *t*1/2 ¼ 2 min	Angina, hypertension, tachyarrhythmia, headache
Isoproterenol	Isuprel	0.01 mcg/kg/min	Increase every 5 min to maximum 0.3 mcg/kg/min	Hepatic metabolism, *t*1/2 ¼ 3–7 h	Syncope, tachyarrhythmia, confusion, tremor
Milrinone	Primacor	0.25 mcg/kg/min	0.75 mcg/kg/min	Renally excreted (83% unchanged), *t*1/2 ¼ 2.3 h (prolonged in renal failure)	Ventricular arrhythmias, hypotension, headache
Levosimendan	Simdax	6–12 mcg/kg IVP	0.05–0.2 mcg/kg/min	Hepatic metabolism with over 10 min active metabolite; $t_{1/2}$ 70 h (prolonged in renal failure)	Hypotension

natriuresis and enhances diuresis, which is associated with a reduction in the PCWP. The combined effects would be expected to improve cardiac performance and increase ventricular stroke volume through a reduction in ventricular afterload and preload. Although initially touted for its clinical effect at reducing dyspnea, subsequent randomized clinical trials failed to demonstrate any meaningful clinical outcomes in terms of renal function or rates of death or rehospitalization [11–13].

Inotropes

Intravenous inotropic therapy is indicated for the treatment of low-output heart failure and cardiogenic shock [14]. In cardiogenic shock, the decrease in cardiac output results in inadequate tissue perfusion, thereby increasing adrenergic drive. Although the release of endogenous catecholamines is temporarily effective acutely, chronic adrenergic stimulation ultimately leads to down-regulation of β_1-receptors and reduced contractile function. The use of inotropic agents such as dobutamine, milrinone, or levosimendan through the direct stimulation of existing β_1-receptors, inhibition of phosphodiesterase III, or calcium sensitization, respectively to augment cardiac output and achieve adequate tissue perfusion may be necessary. Adverse effects of inotropic agents include both supraventricular and ventricular tachyarrhythmias. Therefore, these agents should only be used in acutely ill patients and only for the shortest duration necessary. Additionally, despite their beneficial hemodynamic effects, these agents have not been shown to provide a mortality benefit [15, 16].

The net physiologic effect of inotropic support is an increase in myocardial contractile function and an increased heart rate, resulting in an increased cardiac output. While these effects improve cardiac performance, this occurs at the expense of an increased myocardial oxygen demand (Table 7.3). Pressure-volume relation plots would result in a leftward shift of the LV end-systolic elastance (pressure-volume linear relation) (Fig. 7.6). This leads to an increase in the stroke volume and hence the cardiac output. Despite an increased cardiac output, the blood pressure changes minimally, and any expected increase in the pulsatile pressure is offset by the afterload reduction derived from the peripheral effects of these agents, particularly milrinone.

Dobutamine

Dobutamine is a synthetic catecholamine that acts as a pure inotrope. It binds with high affinity to the β_1- and β_2-receptors in a 3:1 ratio and with lesser affinity to alpha-receptors (B1 > B2 > alpha) [8, 14, 15]. The overarching effect of dobutamine is to augment myocardial contractile function through direct binding of the Gs-protein-coupled β_1-receptor which activates

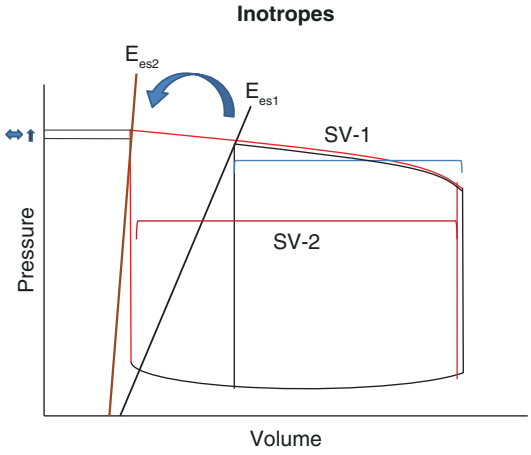

Fig. 7.6 The hemodynamic effect of inotropes. The net effect is a leftward shift in the end-systolic pressure-volume relation (LV end-systolic elastance ($E_{es1} \rightarrow E_{es2}$)) indicating augmented contractility, which results in improved cardiac performance as indicated by the increased stroke volume (SV2 > SV1). Black = baseline hemodynamic profile; red = hemodynamic profile after intervention

adenylate cyclase to produce cyclic AMP (cAMP). The generation of cAMP in turn stimulates calcium influx into the cytoplasm, facilitating actin-myosin interactions with the troponin complex to increase inotropy. In the setting of left ventricular heart failure, dobutamine doses as low as 1 mcg/kg/min and up to 20 mcg/kg/min have been used. At infusion rates of dobutamine above 5 mcg/kg/minute, peripheral vascular effects are seen. Binding of dobutamine to β_2-receptors in the smooth muscle cells of the vasculature also leads to the generation of cAMP. In contrast to its actions on the heart, cAMP activates cAMP-dependent protein kinase (CAMK) within the smooth muscle cells of the vasculature, which causes intracellular reuptake of cytoplasmic calcium by the sarcoplasmic reticulum, thereby leading to vessel relaxation [15]. This effect is counteracted to some extent by the stimulation of alpha-receptors within the vessel wall, which causes peripheral vasoconstriction. The overall effect of dobutamine, however, favors increased myocardial contractility and mild vasodilatation. Advantages of dobutamine include its short half-life (2 minutes) and minimal peripheral effects, which allows infusion through a peripheral vein. It is metabolized by the liver without known active metabolites and is safe to use in patients with renal dysfunction.

Isoproterenol

Isoproterenol is a non-selective beta-receptor agonist which acts as a potent chronotropic and inotropic agent. It is most often used in the setting of cardiogenic shock due to bradycardia in post cardiac transplantation patients. It is also effective in suppressing some ventricular tachycardia arrhythmias [17]. While isoproterenol can augment cardiac output, it has peripheral vasodilatory effects, so no significant change in blood pressure is noted. Therefore, it is not indicated as monotherapy for cardiogenic shock. Like dobutamine, isoproterenol possesses minimal alpha-receptor activity and may therefore be administered through a peripheral vein.

Milrinone

Milrinone is a selective phosphodiesterase (PDE) III inhibitor that prevents the degradation of cAMP and therefore increases intracellular cAMP in cardiac tissue [14, 18]. Hence, this agent operates downstream of the ß-receptor pathway but through its effects results in an increase in intracellular calcium, which augments myocardial contractile function. Compared to dobutamine, milrinone has slightly more potent vasodilatory effects in the periphery through the inhibition of PDE III actions within the pulmonary and peripheral vasculature. Thus, in addition to its positive inotropic effects on the heart, milrinone also reduces afterload and left atrial pressure and enhances LV diastolic relaxation effects. Like dobutamine, milrinone is indicated for severe left ventricular dysfunction. Milrinone may be more beneficial than dobutamine in patients already receiving chronic beta-blockade therapy [19]. In patients with resolving cardiogenic shock, milrinone allows the addition of beta-blocker oral therapy when patients are clinically better compensated, thereby ensuring a more optimal transition to oral heart failure medical management [20]. However, short-term use of milrinone for mild-to-moderate heart failure

exacerbations has not been shown to decrease hospital length of stay and has been associated with an increase in arrhythmias [14]. Compared to dobutamine, no difference in clinical outcomes or arrhythmogenicity has been demonstrated [19]. One disadvantage of milrinone is that it is eliminated by the kidneys, so it should be avoided or administered at a reduced dose in patients with severe renal dysfunction.

Levosimendan

Levosimendan is a calcium-sensitizing agent indicated for the short-term treatment of severe acute decompensated heart failure. It is associated with increased calcium sensitivity of the troponin protein complex, thereby improving myocardial contractility [21, 22]. This is achieved without altering the intracellular concentration of calcium, which minimizes any effects on diastolic relaxation properties. Additionally, it activates potassium-ATP channels in the smooth muscle cells of the vasculature and mitochondria, promoting vasodilatation and possibly affording cardioprotection from myocardial ischemia (although this latter property is controversial and requires further study) [21]. The drug is contraindicated in the setting of severe liver or kidney impairment, and is limited by its side effects, which include an increased risk of atrial fibrillation, ventricular arrhythmias, hypotension, and hypokalemia. Although used in many countries it is not yet approved by the federal drug administration (FDA) for use in the United States.

Vasopressors

Vasopressor agents act predominantly in the peripheral vasculature to achieve vasoconstriction. Consequently, use of these agents typically requires administration through a central line to avoid tissue ischemia that can arise when administered through a peripheral intravenous line or as a consequence of extravasation. These agents include dopamine, norepinephrine, epinephrine, and phenylephrine (Table 7.4). The hemodynamic effects of vasopressor agents are illustrated in Figs. 7.7 and 7.8. The predominant vasoconstrictive properties of these agents results in an increase in cardiac afterload via increased systemic vascular resistance. Thus, while capable of increasing the systemic blood pressure, they do

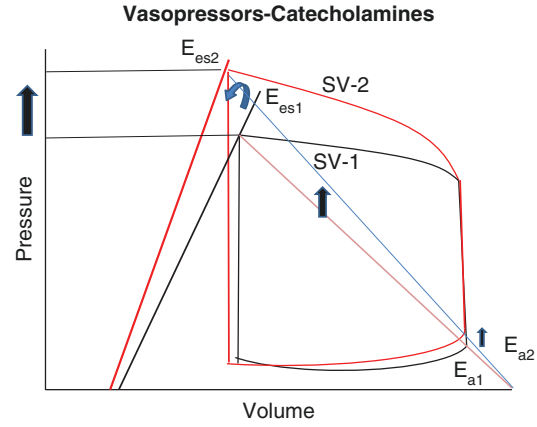

Fig. 7.7 Hemodynamics of catecholamine vasopressor agents. The actions of catecholaminergic vasopressors result in improved contractile function denoted by the slightly leftward shift in the end-systolic pressure-volume relation ($E_{es1} \rightarrow E_{es2}$). However, the dominant effect from these agents is peripheral vasoconstriction leading to an increase in afterload ($E_{a2} > E_{a1}$). Depending on the inotropic effect that these agents confer in comparison to the increased afterload, stroke volume might be expected to increase although to a lesser extent as compared to pure inotropic agents, remain unchanged, or in the setting of an overwhelming increase in afterload, actually decrease (SV1 ≈ SV2). These agents are therefore best suited in cases of vasodilatory shock where their effect in maintaining adequate tissue perfusion pressure is required. Black = baseline hemodynamic profile; red = vasopressor effect; pink = arterial elastance (afterload) at baseline; blue = arterial elastance (afterload) vasopressor effect

Table 7.4 Vasopressor agents

Drug	Brand name	Starting dose	Maintenance and titration
Dopamine	Intropin	3–10 mcg/kg/min	20 mcg/kg/min
Epinephrine	Adrenalin	0.05 mcg/kg/min	0.2–0.8 mcg/kg/min
Norepinephrine	Lovephed	0.02–0.04 mcg/kg/min	0.4–1 mcg/kg/min
Phenylephrine	Neo-Synephrine	100 mcg/min	40–60 mcg/min
Vasopressin	Pitressin	0.01 units/min	0.04 units/min

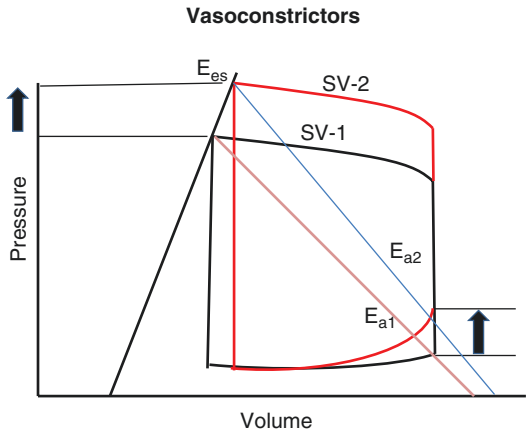

Fig. 7.8 Hemodynamics of pure vasoconstrictors. These agents act primarily to increase the systemic vascular resistance resulting in an upward shift of the pressure-volume relationship. The increase in afterload does not affect intrinsic contractile function but does result in an increase in the end-systolic blood pressure, increased LV end-diastolic pressure, and an increase in the LV afterload ($E_{a1} \rightarrow E_{a2}$). The combined effects result in elevated myocardial oxygen demand and a reduced stroke volume (SV2 < SV1). Therefore, while systemic blood pressure is improved, it comes at the expense of the cardiac output. Black = baseline hemodynamic profile; red = vasoconstrictor effect; pink = arterial elastance (afterload) at baseline; blue = arterial elastance (afterload) vasoconstrictor effect

so at the price of an increased myocardial oxygen demand through elevated heart rate and increased afterload, thereby potentially reducing stroke volume. In the case of the endogenous catecholamine agents such as dopamine, norepinephrine, and epinephrine, these effects are somewhat ameliorated by the slightly enhanced cardiac inotropy.

Catecholamines

Dopamine

Dopamine is an endogenous catecholamine that exhibits unique, dose-dependent pharmacologic actions. Low doses (<5 mcg/kg/min) primarily have dopaminergic receptor (DA1) activity, resulting in vasodilation and increased renal, mesenteric, and coronary blood flow [15]. Historically, low-dose (≤5 mcg/kg/min) dopamine infusion was thought to be renal protective and could aid in the prevention of contrast-induced nephropathy. However, study results have been conflicting and overall show no evidence of a true renal-protective benefit or clinical outcome improvement with renal-dose dopamine [23–25]. Dopamine doses of 3–10 mcg/kg/min will stimulate β_1- and β_2-receptors ($\beta 1 > \beta 2$), enhancing inotropy and chronotropy. At maximal doses of 10–20 mcg/kg/min, alpha-receptor stimulation is dominant and overrides the inotropic effects thereby providing blood pressure support through peripheral vasoconstriction and increased systemic vascular resistance. Due to the increased systemic vascular resistance with doses in this range, myocardial oxygen demand is increased. Pulmonary vein vasoconstriction can occur in patients receiving dopamine, which might compromise the reliability of PCWP measurements as an estimate of left ventricular end-diastolic filling pressures [14, 15].

Norepinephrine and Epinephrine

Norepinephrine and epinephrine are endogenous catecholamines derived from dopamine and characteristically demonstrate mixed receptor activity. Norepinephrine has β_1- and alpha-receptor activity, with lesser affinity for β_2-receptors. This translates clinically into more potent vasoconstrictive properties and less inotropic effects at all dose ranges as compared with dopamine. For this reason, norepinephrine remains the initial catecholamine of choice for septic or vasodilatory shock. Epinephrine is the most potent agonist for the β_1-, β_2-, and alpha-receptors. Use of continuous epinephrine infusion is limited by adverse effects such as cardiac arrhythmias, tissue ischemia, tachycardia, hyperglycemia, cerebral hemorrhage, pulmonary edema, and diminished splanchnic blood flow. As such, epinephrine should be reserved for patients who are unresponsive to dopamine or norepinephrine [8, 14, 26].

Epinephrine bolus dosing in the range of 0.5–1 mg IV (0.1–0.5 mg intracardiac or 0.1 mg/kg via endotracheal tube) has a role in advanced cardiac life support algorithms such as treatment of pulseless ventricular tachycardia, ventricular fibrillation, asystole, or pulseless electrical activity. Another emergent use is in anaphylactoid

reactions to medications, or more commonly contrast. In this setting, depending on the degree of compromise, different doses and routes of epinephrine administration may be appropriate. For systemic anaphylactoid reactions (i.e., hypotension, vasodilatory shock), epinephrine should be given emergently as an intravenous bolus dose of 10 mcg. This dose should be repeated in 1-minute intervals until an intravenous infusion of epinephrine can be initiated or until the patient's hemodynamics have been adequately stabilized. For less severe reactions, epinephrine 0.3–0.5 mg (0.3–0.5 mL of 1:1000 solution) can be given subcutaneously or intramuscularly. Repeated doses are often necessary while steroids and other symptomatic treatments take effect.

Pure Vasoconstrictors

Phenylephrine

Phenylephrine acts as a pure alpha-receptor agonist with almost no β-receptor activity. Consequently, it is a potent vasoconstricting agent and is ideal for the treatment of anesthetic- or vasovagal-induced hypotension as well as vasodilatory shock. Dosing typically begins at 100–180 mcg/min until blood pressures are stable and then infusion is decreased to a maintenance dose of 40–60 mcg/min. The potent vasoconstrictor activity may cause a reflexive decrease in adrenergic drive. Hemodynamically, the dominant effect is an increase in afterload (Fig. 7.8). Therefore, caution should be used in patients with myocardial ischemia or heart failure-induced shock, where inotropy and reduced afterload is needed. Table 7.5 summarizes the hemodynamic effects of vasopressors and inotropes.

Vasopressin

Vasopressin is an endogenous non-catecholamine vasopressor agent secreted primarily by the pituitary gland in response to various physiological stimuli including hypotension, intravascular volume depletion, increased serum osmolality, pain, and hypoxia [8, 14]. It can also be released to a lesser extent by the adrenal glands and myocar-

dium in response to circulating catecholamines and increased wall stress, respectively. Vasopressin binds to two receptors, V_1 and V_2. The V_1 receptors are further classified into V_{1a} and V_{1b} subtypes depending on their localization. For example, V_{1a} receptors are primarily found in the smooth muscle cells of the blood vessels, and V_{1b} receptors are localized to the pituitary gland. V_2 receptors are found exclusive in the renal collecting duct. Whereas stimulation of V_{1a} receptors through binding by vasopressin results in vasoconstriction, binding of V_2 receptors causes retention of water by the kidney. These effects result in an increase in both afterload and preload, thereby raising systemic blood pressure and potentially augmenting cardiac output by invoking Frank-Starling forces on the heart [26, 27]. The effect on afterload, however, predominates and limits any potential increase in cardiac output. Additionally, its vasoconstrictive effects on the coronary and cerebral circulations are relatively mild in comparison to catecholaminergic vasopressor agents. Its primary utility is in the treatment of vasodilatory shock and advanced cardiac life support for cardiac arrest algorithms [28]. One potential advantage of vasopressin, over epinephrine is in patients with acidosis, as catecholamine response is diminished in patients with low pH and in hypoxic environments. Fixed-dose vasopressin infusions are recommended as add-on therapy to norepinephrine in patients with vasodilatory shock as vasopressin may augment the vascular sensitivity to norepinephrine and improve its vasopressor effect.

Conclusion

Although advances in mechanical circulatory support have greatly aided the management of patients presenting with cardiogenic shock, vasoactive pharmacologic agents remain the mainstay of treatment. Therefore, it is imperative that cardiac critical care practitioners understand the pharmacologic and hemodynamic effects of these agents in order to provide better patient care.

Bullet Point Summary

- Intravenous vasodilators, such as nitroglycerin, nitroprusside, and nesiritide play an important role in the management of patients with acute decompensated heart failure associated with volume overload and elevated systemic vascular resistance.
- Inotropic agents dobutamine and milrinone operate at different levels along the ß-receptor pathway to augment ventricular contractility.
- Vasopressors should be used for short-term improvement in perfusion pressures in patients with shock (following adequate fluid resuscitation).
- Selection between vasoactive agents is based on the differences in pharmacology, hemodynamic expectations, and specific clinical scenarios.
- Vasopressin provides only mild vasoconstriction as monotherapy but the effect is magnified when co-administered with IV catecholamine in patients with vasodilatory shock.
- Epinephrine is versatile and may be administered IV, via ET tube, or intracardiac in ACLS, as continuous infusion in certain patients with shock, or IM or SQ in anaphylaxis.
- Esmolol is not a vasodilator and currently has a very limited role in the management of patients presenting with shock.

Case 1

A 57-year-old man with a history of non-ischemic cardiomyopathy (LVEF 30%) presents to the emergency department after 4 weeks of progressive dyspnea, non-productive cough, leg swelling, and reduced urine output. He had been treated at urgent care facilities for community acquired pneumonia but his symptoms persisted and worsened. On presentation, his vital signs are BP 120/95 mmHg, HR 104 bpm. He is afebrile and breathing at a rate of 30 breaths per minute. Oxygen saturation on room air is 90%. Physical examination findings show a well-developed male in respiratory distress. Neck examination shows jugular venous distension and bilaterally

diminished carotid upstrokes. The chest reveals bilateral crackles up to the middle lung fields bilaterally. Cardiac examination demonstrates a regular rate, tachycardia, with a sustained and displaced PMI, soft S1S2, audible S3 gallop, and 3/6 systolic murmur heard best at the apex. The abdomen shows evidence of hepatoabdominal reflux and hepatomegaly. The extremities are warm. An ECG shows diffusely low voltage, sinus tachycardia, 105 bpm, a left anterior fascicular block and no evidence of acute myocardial ischemia. A chest x-ray shows bilateral pulmonary edema. An arterial line and central line are placed and nitroprusside is administered. He is placed on supplemental oxygen and given IV diuretics. Within several minutes, the BP is now 100/60 mmHg, HR 90 bpm and the patient reports being able to breath easier. His urine output and his oxygenation have improved.

Question 1:

In the triage of this patient, which of the following hemodynamic profiles would best describe this patient?

A. Warm, dry
B. Warm, wet
C. Cold, dry
D. Cold, wet

Question 2:

The hemodynamic effect of the treatment given is expected to result in which of the following?

A. Shift the end-systolic pressure-volume relation leftward, thereby increasing stroke volume.
B. Shift the end-systolic pressure-volume relation rightward, thereby increasing stroke volume.
C. Reduce afterload and thereby increase stroke volume.
D. Reduce preload more than afterload and thereby increase stroke volume.

Question 3:

The patient develops a fever on hospital day 2 and becomes hypotensive and tachycardic. Physical examination demonstrates resolved jugular venous distention, improved peripheral edema, and warm extremities. Laboratory studies show a mild leukocytosis. Blood cultures are drawn although results are not yet available. The next best course of action would be which of the following:

A. Start broad-spectrum IV antibiotics, continue IV nitrate and diuretic therapy for decompensated heart failure.
B. Discontinue IV nitrate and diuretic therapy. Withhold antibiotics until culture results are returned.
C. Obtain a procalcitonin level and continue with IV nitrate and diuretic therapy.
D. Start broad-spectrum IV antibiotics, discontinue IV nitrate and diuretic therapy, and consider the need for vasopressor support.

Case 2

A 70-year-old man with CAD and ischemic cardiomyopathy returned from a trip abroad with complaints of fatigue, chest pressure, and progressive dyspnea with minimal exertion. At his last clinic visit 6 months ago prior to his trip, the patient was able to play golf and climb 2 flights of stairs without difficulty. He has been compliant with his medical therapy which includes carvedilol 25 mg BID, sacubitril/valsartan 49/51 mg BID, hydralazine 50 mg TID, isosorbide mononitrate 30 mg daily, and spironolactone 25 mg daily. He was hospitalized with acute decompensated heart failure and pulmonary edema, and treated with IV diuretics. Although he responded initially to this treatment, by hospital day 2 he no longer responded to treatment and his urine output declined precipitously. He developed respiratory failure and was ultimately placed on mechanical ventilatory support. A right heart catheterization was performed which showed the following: SBP 85/50 mmHg, HR 110 bpm, RAP 18 mmHg, RV 68/15, PA pressure 70/30/43, PCWP 28 mmHg, CO 3.6 L/min by thermodilution, CI 1.8 L/min/m^2.

Question 4:

The most appropriate next step in the management of this patient would be which of the following?

A. Discontinue oral medications and begin IV inotropic support.
B. Stop beta-blocker and begin dopamine IV infusion.

C. Discontinue oral medications except carvedilol; add milrinone infusion for inotropic support; continue IV diuresis.
D. Continue oral medications, begin milrinone infusion, and continue IV diuresis.

Question 5:
The combined effect of inotropic support and vasodilator medical therapy would be expected to cause which of the following hemodynamic profiles?

A. A shift of the end-systolic pressure-volume relation leftward, causing stroke volume to increase.
B. A reduced afterload and shift of the end-systolic pressure-volume relation leftward.
C. A reduced afterload and no net change in the end-systolic pressure-volume relation.
D. A reduced preload and afterload and a shift of the end-systolic pressure-volume relation to the left.

Case 3

A 60-year-old woman with a history of diabetes mellitus, HTN, and CKD4 is admitted with an acute anterior ST elevation myocardial infarction. She is immediately transferred to the cardiac catheterization laboratory where she undergoes an emergent diagnostic cardiac catheterization and percutaneous coronary intervention to a thrombotic occlusion of the proximal left anterior descending coronary artery. The patient is noted to have obstructive coronary artery disease in the right coronary artery and a large obtuse marginal branch of the left circumflex coronary artery as well, but these were not intervened upon. A right heart catheterization is also performed and shows the following: RAP 10, RV 35/12, PA pressure 40/25/30, PCWP 25, CO 4.1 L/min/m^2, CI 2.3 L/min/m^2. The patient emerges from the cardiac catheterization lab intubated and sedated. She is receiving infusions of dobutamine, norepinephrine, dopamine, and phenylephrine. Her vitals are as follows: BP 100/70 mmHg, HR 120 bpm, T 37C. An echocardiogram is performed demonstrating severe LV systolic dysfunction with an estimated LV ejection fraction of 20% and global hypokinesis.

Question 6:
In order to optimize cardiac performance, which of the following strategies is most appropriate for this patient?

A. Continue current medical therapy.
B. Wean vasopressor agents while maintaining inotropic support.
C. Add IV diuretic therapy.
D. Prepare for mechanical circulatory support.

Answers

1. B

   The clinical profile that best describes this patient is warm and wet. Clinical findings indicate signs of volume overload are present, and hence, the patient is wet. Furthermore, the patient is warm to palpation, a clinical finding that suggests adequate perfusion. This information can be further supplemented by laboratory and imaging studies. In contrast, a warm/dry profile implies either a normal hemodynamic profile or a patient with adequate perfusion who is intravascular volume depleted. A cold/wet profile implies grossly inadequate tissue perfusion and volume overload, whereas a cold/dry profile suggests inadequate perfusion and intravascular volume depletion.

2. C

   The primary hemodynamic effect of IV vasodilator therapy is a reduction in afterload. This reduction in afterload improves cardiac performance, which may result in an increased stroke volume. This is accomplished without changing the end-systolic pressure-volume relation and without appreciably altering preload. Although the improved cardiac performance can enhance diuresis and therefore reduce preload, the dominant effect of vasodilator therapy is a reduction in afterload.

3. D

   A change in the patient's clinical status is often accompanied by a change in hemodynamics. Therefore, recognition of these changes is imperative to guide changes in treatment strategy. In the case scenario, the patient has developed a bacteremia and clinical signs of septic shock. Thus, despite the

fact that the patient presented initially with signs of acute decompensated heart failure associated with volume overload and was treated with IV vasodilator therapy and diuretics, the clinical circumstances now dictate that the patient requires treatment for septic shock which includes IV antibiotics, volume resuscitation, and potentially vasopressor therapy.

4. D

This patient presents with cardiogenic shock characterized by abnormally low cardiac output and elevated right and left heart filling pressures. The calculated systemic vascular resistance is normal, likely a manifestation of the patient's chronic heart failure therapy. Therefore, the patient is most likely to be helped by an augmentation of LV contractility with the use of inotropes. The elevated right and left ventricular filling pressures are consistent with a volume-overloaded state and suggest that aggressive diuresis is indicated. Discontinuation of the patient's chronic heart failure therapy would likely increase afterload and compromise any potential gain from using inotropic agents. In the event that oral therapy cannot be administered, IV vasodilators may be given. Several studies have also shown that abrupt discontinuation of beta-blockers is associated with adverse clinical outcomes, including an increased risk of ventricular arrhythmias.

5. B

The expected hemodynamic effects of combined vasodilator and inotropic effects include a leftward shift in the end-systolic pressure-volume relation (steeper slope) indicating an improvement in LV contractile function. Simultaneously, the predominant effect of vasodilator therapy would be to reduce afterload, resulting in a reduction of end-systolic pressure. The combined effect is to improve cardiac performance and increase cardiac output.

6. B

According to the right heart catheterization findings, the patient is maintaining a cardiac index, which is borderline normal. Calculated systemic vascular resistance is elevated and the patient is normotensive and tachycardic. Together, these findings suggest that the patient's afterload is inordinately high and is likely due to the effects of the vasopressor agents the patient is receiving. Therefore, the gradual removal of these agents would be expected to further improve cardiac performance and may allow for the eventual discontinuation of inotropic support as well. Ultimately, revascularization of the remaining non-culprit obstructive CAD lesions identified at the time of diagnostic cardiac catheterization prior to hospital discharge will provide the best chance for recovery of LV systolic function.

8 Recently Approved Pharmacologic Agents to Improve Outcomes in Heart Failure

David C. Booth and Navin Rajagopalan

Introduction and Background

Over the past 5 years, two novel FDA-approved agents for the treatment of heart failure have been introduced, the angiotensin receptor-neprilysin inhibitor (ARNi), sacubitril/valsartan (Entresto), and the funny current (I_f) inhibitor ivabradine (Corlanor). Prior to the approval of these agents, hemodynamic optimization – using vasodilators including hydralazine and isosorbide [1, 4, 5] – and neuro-humoral inhibition, combining angiotensin-converting enzyme inhibition, ß-blockade, and mineralocorticoid-receptor antagonism [2, 3, 6–11], have been the evidence-based pharmaceutical approaches to improve outcome in chronic systolic heart failure. The majority of the agents tested in the referenced trials rested on a background of proven hemodynamic benefit. There is a relative paucity of published hemodynamic data for sacubitril/valsartan and ivabradine, as randomized trials for these agents in systolic heart failure have been endpoint-driven. This chapter summarizes the outcome data, quality of life results, and available hemodynamic data for these two drugs. Other modalities which have been shown to improve survival in systolic heart failure include the implantable cardioverter defibrillator, cardiac resynchronization therapy, and left ventricular assist device implantation, but these are not discussed here.

Rationale and Research Leading to Sacubitril/Valsartan

Heart failure activates the sympathetic nervous system (SNS) and the renin-angiotensin-aldosterone system (RAAS), leading to vasoconstriction and increased sympathetic tone, in turn resulting in downregulation of the ß-receptors. Activation of RAAS leads to increased secretion of angiotensin II and aldosterone, which also results in increased ADH secretion. These neurohormonal maladaptations result in fluid retention, perpetuating the cycle of heart failure. ACE inhibition, or angiotensin receptor blockade, ß-blockade, and mineralocorticoid antagonism modulate the effects of the SNS and RAAS.

Since the early 1980s, the natriuretic peptide system (NPS) began to receive attention as a potential target in heart failure treatment. Within the NPS are three hormones, atrial natriuretic peptide (ANP), B-type natriuretic peptide (BNP),

and C-type atrial natriuretic peptide (CNP). While CNP is secreted from endothelial cells and cardiac fibroblasts and has vasodilatory and anti-remodeling effects, ANP and BNP are secreted, respectively, from the atria and the ventricles, are released in response to fiber stretch and volume overload and promote diuresis, natriuresis, and vasodilation, counteracting the maladaptive effects of SNS and RAAS activation [12]. With the development of angiotensin receptor blockers, which exert their effects primarily at the Type 1 angiotensin II receptor, there was hope that a more specific RAAS antagonist would result in further survival improvement in heart failure outcomes. However, while the Valsartan Heart Failure Trial (Val HeFT) [13] (2001) demonstrated reduced heart failure hospitalizations, leading to an FDA-approved indication in heart failure, overall mortality in the valsartan and placebo groups was similar. The demonstration of the beneficial effects of the natriuretic peptides led to the development of human recombinant BNP, namely nesiritide, which was FDA-approved for use in 2001 on the basis of improvement in dyspnea in decompensated heart failure. However, a larger randomized trial released in 2011, the Acute Study of Clinical Effectiveness of Nesiritide in Decompensated Heart Failure (ASCEND-HF) [14], demonstrated no improvement in dyspnea, 30-day mortality, or readmission rates in the nesiritide group. Hypotension was significant in the nesiritide group. As a result, nesiritide is used rarely in practice today, but natriuretic peptide levels remain well established as biomarkers.

Research efforts have been directed at toward identifying agents that could inhibit the enzyme that breaks down endogenous natriuretic peptides, namely, neprilysin. Neprilysin (NEP) is a neutral endopeptidase, and its inhibition increases bioavailability of natriuretic peptides, bradykinin, and substance P, resulting in natriuretic, vasodilatatory, and anti-proliferative effects. The natural hypothesis was that combined inhibition of the RAAS and NEP would result in a better heart failure treatment (Fig. 8.1). This led to the development of omapatrilat, a combined ACEi/NEPi. Several trials of the agent were conducted in heart failure, culminating in the Omapatrilat Versus Enalapril Randomized Trial of Utility in Reducing Events (OVERTURE) Trial [15] in patients with NYHA Functional Class II–IV heart failure. While post hoc analyses appeared to demonstrate potential benefit, there was an increased incidence of life-threatening angioedema, which was substantiated in a subsequent study of the agent in hypertension. These results effectively thwarted ACEi-NPi as a treatment in heart failure.

An important advantage of ARBs over ACE is is that ARBs do not block the degradation of bradykinin, the principal instigator of cough, a side effect noted in at least 10% of patients on an ACE, and do not cause angioedema which can occur in about 0.1% of patients on an ACE [16]. Omapatrilat was subsequently demonstrated to inhibit an enzyme responsible for bradykinin metabolism. A logical solution to the adverse effects of omapatrilat was to combine an ARB with an NEPi, termed ARNI or angiotensin receptor-neprilysin inhibitor – LCZ696, Sacubitril/Valsartan. Sacubitril is a prodrug which is converted in the body to sacubitrilat, which inhibits neprilysin and thereby the degradation of NPs. A Phase III trial [17] published in 2010 comparing sacubitril/valsartan to valsartan showed greater reduction in systolic, diastolic, and pulse pressures with sacubitril/valsartan. The Prospective Comparison of ARNI with ARB on Management of Heart Failure with Preserved Ejection Fraction (PARAMOUNT) Trial [18], published in 2012 was a Phase II randomized trial that assessed NT-proBNP after 12 weeks of sacubitril/valsartan compared to valsartan in patients with heart failure with preserved left ventricular ejection fraction (HFpEF). At 12 weeks, NT-proBNP was significantly lower in the sacubitril/valsartan group, and an echocardiographic reduction in left atrial volume and size was also demonstrated. The NT-proBNP lowering effect appeared to be independent of a blood pressure lowering effect of the drug.

Published in 2014, the Prospective Comparison of ARNI with ACEI to Determine Impact on Global Mortality and Morbidity in Heart Failure (PARADIGM-HF) trial randomized 8399 patients with HFrEF (LVEF $\leq$40%) and NYHA Class II–IV symptoms to sacubitril/valsartan 200 mg PO BID or enalapril 10 mg PO BID (the

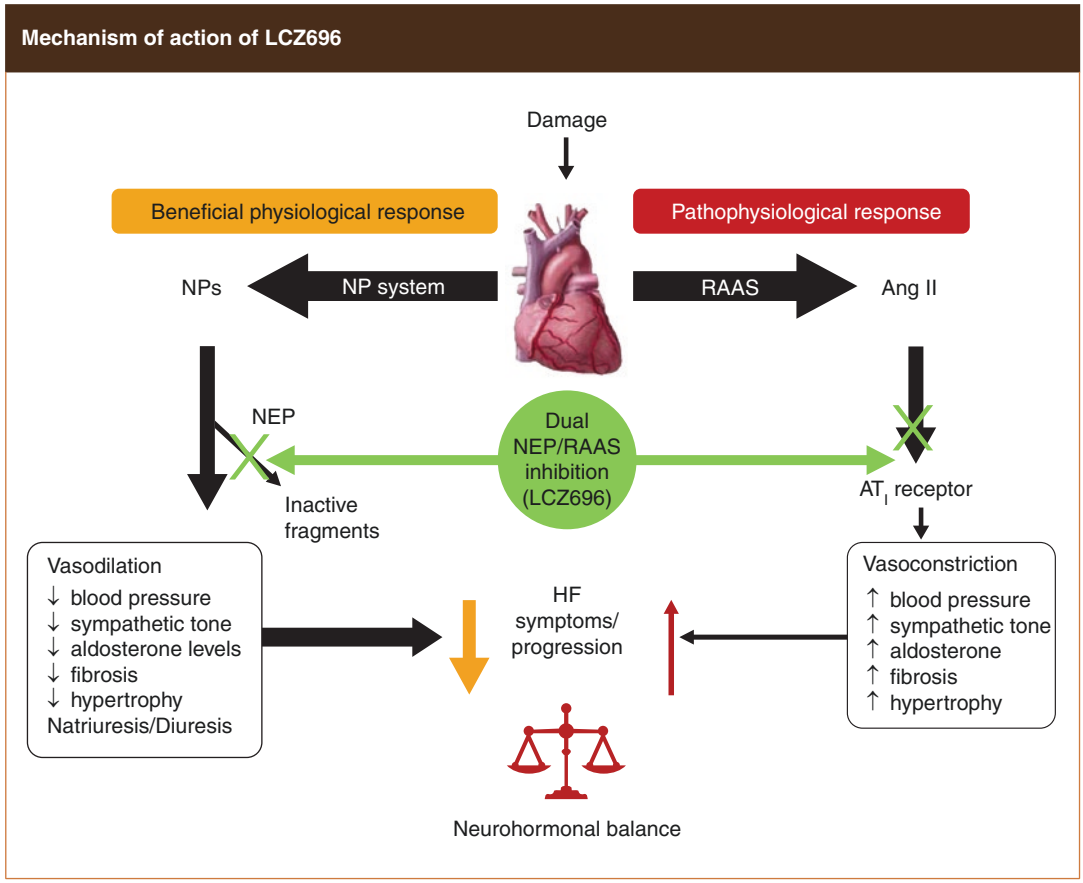

Fig. 8.1 Angiotensin receptor-neprilysin inhibitors have the potential to modulate two counter-regulatory neurohormonal systems in HF: the renin-angiotensin-aldosterone system and natriuretic peptide system. ANG angiotensin, AT1 angiotensin type 1, HF heart failure, NP natriuretic peptide, RAAS renin-angiotensin-aldosterone system. (Indian Heart Journal Volume 70, Supplement 1, July 2018, Pages S102–S110)

goal dose from CONSENSUS and SOLVD), in addition to standard therapy for chronic systolic heart failure. The majority of the study population was receiving ß-blockers and mineralocorticoid antagonists. The primary end point of the trial was the combination of death from cardiovascular causes and heart failure hospitalization. There being insufficient Phase II safety data for sacubitril/valsartan, the PARADIGM protocol stipulated safety and tolerability run-ins for all participants in the trial. If participants tolerated both sacubitril/valsartan and enalapril, they were randomly assigned to the two study arms. This approach allowed assessment not only of the end point of the trial but also provided safety and tolerability data. The study was stopped early, after median follow-up of 27 months, when the study met the prespecified cutoff for significant benefit. The ARNI combination resulted in a 20% decrease in the primary end point, HR = 0.80, $P < 0.001$, giving a Number Needed to Treat of 21. The study drug also reduced the individual components of the combined end point, death from cardiovascular cause by 20% and heart failure hospitalizations by 21%, both $p < 0.001$. All-cause mortality in the sacubitril/valsartan arm was reduced by 16%, HR = 0.84, $p < 0.001$. While sacubitril/valsartanb resulted in 14% experiencing hypotension as compared to 9% in the enalapril arm, the discontinuation rate was not significantly different (sacubitril/valsartan 0.9%, enalapril 0.7%). No significant difference was noted in the occurrence of non-serious angioedema between the two groups.

In secondary analyses, sacubitril/valsartan demonstrated clinical benefits in other indices of heart failure progression, including improved NYHA class, reduced need for intensification of medical treatment, and reduction in the need for emergency department visits, intensive care, and inotropic support. Other findings from PARADIGM-HF include significantly lower NT-proBNP and troponin levels in the sacubitril/valsartan group, significant reduction in the incidence of sudden cardiac death and death from worsening heart failure independent of cardioverter defibrillation implantation, and a nonsignificant reduction in the need for left ventricular assist device implantation and cardiac transplantation. The PARADIGM-HF investigators also carried out a comparison of the sacubitril/valsartan arm with the treatment arms of the SOLVD Trial (enalapril) and the CHARM-Alternative Trial [19] (candesartan) and found substantial relative risk reductions for both the composite end point and for cardiovascular death. Using the Kansas City Cardiomyopathy Questionnaire, the PARADIGM-HF investigators [20] demonstrated remarkable improvement in physical and social activity limitations with sacubitril/valsartan compared to enalapril. The largest improvements were reported in household chores ($p < 0.001$) and sexual relationships ($p = 0.002$); these benefits persisted through 36 months of assessment. In another secondary analysis [21], the PARADIGM-HF investigators found the frequency of episodes of hyperkalemia to be significantly greater in the enalapril arm compared to ARNI, (3.1 versus 2.2 incidents per 100 patient-years, HR = 1.37, CI 1.06–1.76, $p = 0.02$) for patients already taking a mineralocorticoid antagonist.

Criticisms of the PARADIGM-HF Trial include that the study was predominantly white (66%), male (78%), and enrolled predominantly NYHA Functional Class II (70%) patients. Only 5% of the study population was black, perhaps limiting the ability of the study to accurately detect the incidence of angioedema. It has also been suggested that the enalapril dose in PARADIGM-HF was too low [22]. Narrowly defined, only patients with systolic heart failure and an ejection fraction of ≤35% would be candidates for the drug, based on PARADIGM-HF entry criteria. An additional criticism is that neprilysin has been shown to have a role in maintaining homeostasis of amyloid-ß peptide, raising the issue that a neprilysin inhibitor might lead to increased deposits of this protein in brain [11]. However, in a randomized, double-blind trial measuring sacubitril/valsartan levels in cerebrospinal fluid in healthy human subjects [23], sacubitril/valsartan did not cause changes in aggregable amyloid β isoforms compared with placebo, despite achieving CSF concentrations of a metabolite of sacubitril/valsartan sufficient to inhibit neprilysin.

The Prospective Comparison of ARNI with ARB Global Outcomes in HF With Preserved Ejection Fraction (PARAGON-HF Trial) [24], a prospective randomized trial of the impact of sacubitril/valsartan in HFpEF, has completed enrollment and has an estimated study completion date of March 15, 2019 (clinicaltrials.gov). Serial cognitive testing is being carried out in PARAGON-HF in an effort to assess the impact of sacubitril/valsartan on cognition.

In summary, in prespecified measures of nonfatal clinical deterioration of heart failure, the PARADIGM-HF investigators demonstrated that the combination of sacubitril/valsartan prevented the clinical progression of surviving heart failure patients more effectively than did enalapril alone [25]. On the basis of the PARADIGM-HF Trial, sacubitril/valsartan was FDA-approved in July 2015 to reduce the risk of death and hospitalization for heart failure in patients with chronic heart failure (NYHA Class II–IV) and reduced ejection fraction.

The comParIson Of sacubitril/valsartaN versus Enalapril on Effect on nt-pRo-bnp in patients stabilized from an acute Heart Failure (PIONEER-HF) trial (PMID:30415601) enrolled 881 patients with heart failure with reduced ejection fraction who were hospitalized for acute decompensated heart failure at 129 sites in the United States. After hemodynamic stabilization, patients were randomly assigned to receive either sacubitril–valsartan (target dose, 97 mg of sacubitril with 103 mg of valsartan twice daily) or enalapril (target dose, 10 mg twice daily). The primary efficacy outcome was the time-averaged proportional change in the N-terminal pro–B--type natriuretic peptide (NT-proBNP) concentra-

tion from baseline through weeks 4 and 8. Key safety outcomes were the rates of worsening renal function, hyperkalemia, symptomatic hypotension, and angioedema.

The investigators noted that time-averaged reduction in the NT-proBNP concentration was significantly greater in the sacubitril–valsartan group than in the enalapril group. In addition, the two drugs appeared to be equally safe; the rates of worsening renal function, hyperkalemia, symptomatic hypotension, and angioedema did not differ significantly. In an analysis of exploratory clinical outcomes, the in-hospital initiation of sacubitril–valsartan therapy was associated with a lower rate of rehospitalization for heart failure at 8 weeks than enalapril therapy.

Pharmacokinetics of Sacubitril/Valsartan

Absorption of sacubitril/valsartan is rapid, with maximum levels of sacubitril, sacubitrilat, and valsartan all achieved by 2–3 h [26]. With twice-daily dosing, steady-state concentrations are reached within 3 days. Sacubitril is eliminated as predominantly sacubitrilat by the kidney, while valsartan is eliminated by the biliary route. In heart failure patients, area under the concentration-time curves for sacubitril, sacubitrilat, and valsartan was higher. Renal impairment had no impact on sacubitril or valsartan, but increased the area under the concentration-time curve for sacubitrilat. Moderate hepatic impairment increased the area under the concentration-time curve of valsartan and sacubitrilat approximately two-fold. Regarding drug-drug interactions, sacubitril/valsartan increased plasma concentrations of atorvastatin. Pharmacokinetics of the drug were not affected by age, sex, or ethnicity.

Hemodynamic Impact of Sacubitril/Valsartan

Surprisingly little specific functional and hemodynamic data are available regarding sacubitril/valsartan. A post hoc analysis of the PARAGIGM-HF demonstrated that the drug was effective at reducing cardiovascular death and heart failure hospitalization across the spectrum of left ventricular ejection fraction (LVEF), when assessed in stepwise 5-point reductions in LVEF [27]. Addition of sacubitril/valsartan in patients with advanced systolic heart failure may be a useful strategy to improve hemodynamics and to potentially facilitate the transitioning from intravenous HF therapies.

Ivabradine

Background and Pharmacology

The search for a direct sinoatrial node inhibitor began four decades ago. Ivabradine was the first drug specifically developed as a heart rate lowering agent, and in Europe was initially considered for the treatment of angina pectoris. Sinoatrial myocytes have the capacity to develop slow diastolic depolarizations, driving membrane voltage toward the threshold for initiating an action potential (Fig. 8.2). Sinoatrial node activity involves several ionic currents flowing through channels, including the funny or hyperpolarization-activated cyclic nucleotide-gated channel that regulates the I_f current, so-called for its unusual properties compared with other channels at the time of its discovery. The I_f current is carried across the sarcolemma by both sodium and potassium ions, is directly activated by cyclic adenosine monophosphate (cAMP), and is related to I_h neuronal channels. Ivabradine has substantial selectivity for inhibiting the I_f channel at doses that allow heart rate slowing [28]. Studies in experimental models have demonstrated that ivabradine has a pure heart rate lowering effect, does not affect LV contractile state [29], and does not have negative lusitropic properties. In healthy volunteers, equipotent doses of ivabradine (30 mg) and propranolol (40 mg) had similar effects on heart rate and heart rate variability, whereas propranolol was associated with significant systolic and mean blood pressure lowering, and a greater decrease in cardiac output measured noninvasively, compared to ivabradine, placebo, or both [30]. Under fasting conditions, peak plasma ivabradine concentrations are reached in approximately

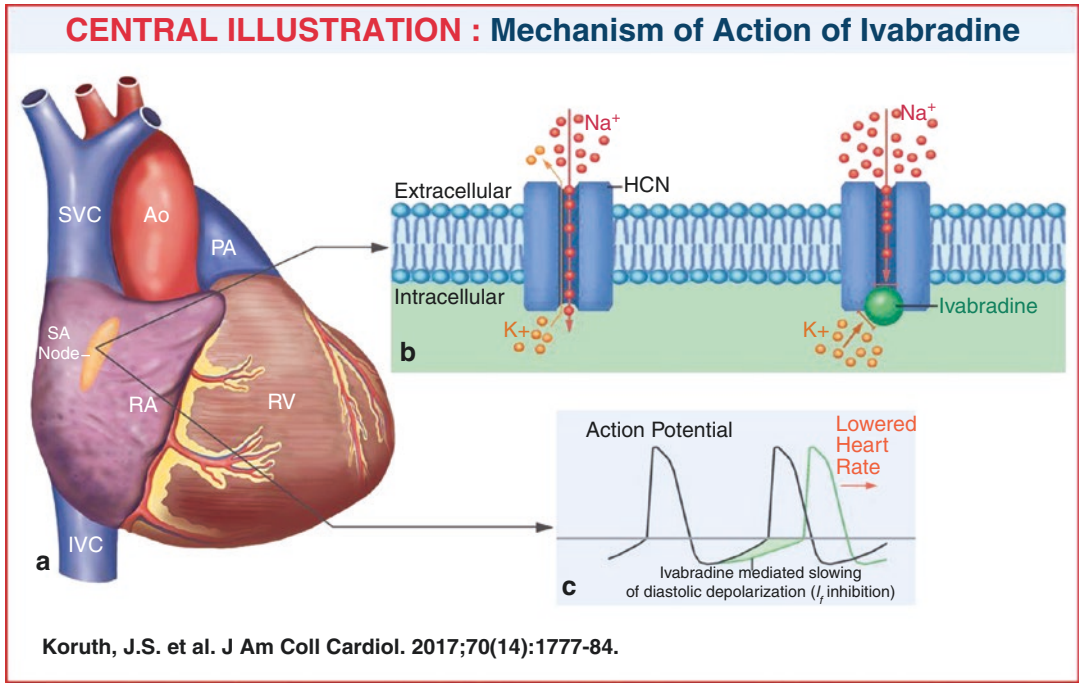

Fig. 8.2 Ivabradine's primary mechanism of action on cardiac tissue is on the sinoatrial (SA) node, which occupies a predominantly subepicardial position at the junction of the superior vena cava (SVC) and the right atrium (RA). (**a**) Heart with position of the Sinoatrial (SA) node. (**b**) In the sinoatrial node, ivabradine blocks the intracellular aspect of the hyperpolarization-activated cyclic nucleotide-gated (HCN) transmembrane channel, which is responsible for the transport of sodium (Na^+) and potassium (K^+) ions across the cell membrane, in the open state. This results in the inhibition of the inward funny current ($\mathbf{I_f}$), which is specifically activated at hyperpolarized membrane potentials. (**c**) By selectively inhibiting $\mathbf{I_f}$, there is a reduction in the slope of diastolic depolarization of the pacemaker action potential (shaded region) and an increase in the duration of diastole, without altering other phases of the action potential. This results in heart rate reduction. Ao aorta, IVC inferior vena cava, PA pulmonary artery, RV right ventricle. (PMID:28958335)

1 hour. Food delays absorption by approximately 1 hour but appears to increase plasma levels of the drug. Ivabradine is extensively metabolized in the liver. The excretion of ivabradine and its metabolites is both renal and hepatic. The half-life of ivabradine and its metabolites requires twice-daily dosing. There is no direct effect of ivabradine on the QT interval. Phosphenes, the off-target effect of ivabradine, are bright sensations not mediated by retinal stimuli, due to effects on hyperpolarization-activated channels in the retina.

While ivabradine was initially targeted as a drug for heart rate control, randomized data failed to demonstrate a significant advantage in patents with stable coronary artery disease without clinical heart failure [31]. Similarly, ivabradine compared to placebo did not significantly improve the change in physical limitation score at 1 year in patients with anginas pectoris [32], although ivabradine patients had better angina scores compared to placebo on the Seattle Angina Questionnaire on every visit to 36 months. Ivabradine did not result in significant exercise tolerance testing benefit, compared to low-dose atenolol, and no advantage was noted when added to full-dose amlodipine [33, 34].

Because of the documented beneficial effect of heart rate lowering in heart failure with reduced ejection fraction, ivabradine was tested in this setting, beginning with the Morbidity-Mortality Evaluation of the I_f Inhibitor Ivabradine in Patients With Coronary Artery Disease and Left Ventricular Dysfunction (BEAUTIFUL) Trial [35], a randomized double-blind, placebo-controlled trial of

10,917 patients. Enrollment characteristics included LVEF <40%, 85% NYHA Class II and III, 83% male, and 87% were taking ß-blockers. At a median of 19 months of follow-up, no difference was found between the ivabradine and placebo groups for the composite end point of cardiovascular death, hospitalization for myocardial infarction (MI), or hospitalization for worsening heart failure. A subgroup analysis of 14% of patients with activity-limiting angina had reduction in hospitalization for MI and borderline reduction in the composite end point ($p = 0.05$); the difference was statistically significant for patients in this subgroup with baseline heart rate ≥ 70 [36].

To investigate the potential benefits on ischemia seen in this subgroup, the SIGNIFY [37] Trial was undertaken, enrolling 19,102 patients with stable coronary artery disease who did not have clinical heart failure. This study again enrolled predominantly male patients; 75% had angina pectoris, and the mean LV ejection fraction was 56%. While heart rate was significantly reduced by ivabradine, there was no significant benefit of ivabradine on the primary composite end point of cardiovascular death or nonfatal MI after median follow-up of 28 months. When the prespecified subgroup with activity-limiting angina was analyzed for the composite outcome, there was in fact evidence of harm with ivabradine therapy; an absolute increase in the composite end point of 1.1% ($p = 0.02$). The reason or reasons for this adverse outcome remain unclear, but the conclusion to be drawn from trials of ivabradine in angina pectoris without LV systolic dysfunction is that no benefit occurs, and even though there may be symptomatic improvement, those patients appear to be at greater risk of an adverse effect of the drug.

The Systolic Heart Failure Treatment with the I_f-inhibitor Ivabradine (SHIFT) Trial [38] randomized 6505 patients with ischemic and nonischemic heart failure, NYHA Class II–IV but predominantly Class II–III, LVEF ≤35%, to ivabradine or placebo. The trial randomized no patients from the United States; most patients were male, 89% taking ß-blockers, 91% ACEi or ARB, 60% aldosterone antagonists, 22% a digitalis preparation. More than two-thirds achieved the target dose of 7.5 mg ivabradine twice daily. Compared to placebo, the composite end point of cardiovascular death or first hospitalization for heart failure was significantly reduced (hazard ratio 0.82, $p < 0.0001$, driven primarily by reduction in HF hospitalization) (Fig. 8.3) Trends were detected for less benefit in patients also receiving ß-blockers and greater benefit for nonischemic patients. There were significant improvements in the NYHA Class and Kansas City Cardiomyopathy Questionnaire summary scores [39]. When patients with baseline heart rate ≥70 from BEAUTIFUL and SHIFT were pooled, no significant impact on mortality could be demonstrated. An echo substudy [40] from SHIFT of 275 patients demonstrated a small but significant increase on LVEF after 8 months of ivabradine therapy (4 ± 10%, $p = 0.004$).

Shortcomings of the SHIFT Trial include that 25% of trial participants were not taking a ß-blocker for HRrEF and that ivabradine did not significantly reduce any end point in patients with baseline HR ≤ 75 bpm. Whereas trials of carvedilol, metoprolol succinate, and bisoprolol demonstrated consistent survival benefit, a similar heart rate reduction by ivabradine resulted in no all-cause survival benefit. Another SHIFT subgroup analysis demonstrated that a statistically significant improvement for the primary end point occurred only for patients <50% of target ß-blocker doses [41]. Thus, ivabradine appeared to exert a beneficial effect only in patients who were also being treated with ß-blockers in whom a heart rate goal of ≤75 bpm had not been achieved. Regarding adverse effects, ivabradine increased the frequency of bradycardia, both asymptomatic and symptomatic, was associated with an increased incidence of atrial fibrillation, and resulted in some ivabradine withdrawals due to phosphenes, which resolved upon discontinuation of drug. The 1.7% increase in the risk of atrial fibrillation noted in pooled BEAUTIFUL and SHIFT data underscore the importance of observing patients on ivabradine for this rhythm disturbance, especially in view of the negative prognostic impact of atrial fibrillation on systolic heart failure. The FDA approved ivabradine in April 2015 for patients with HFrEF

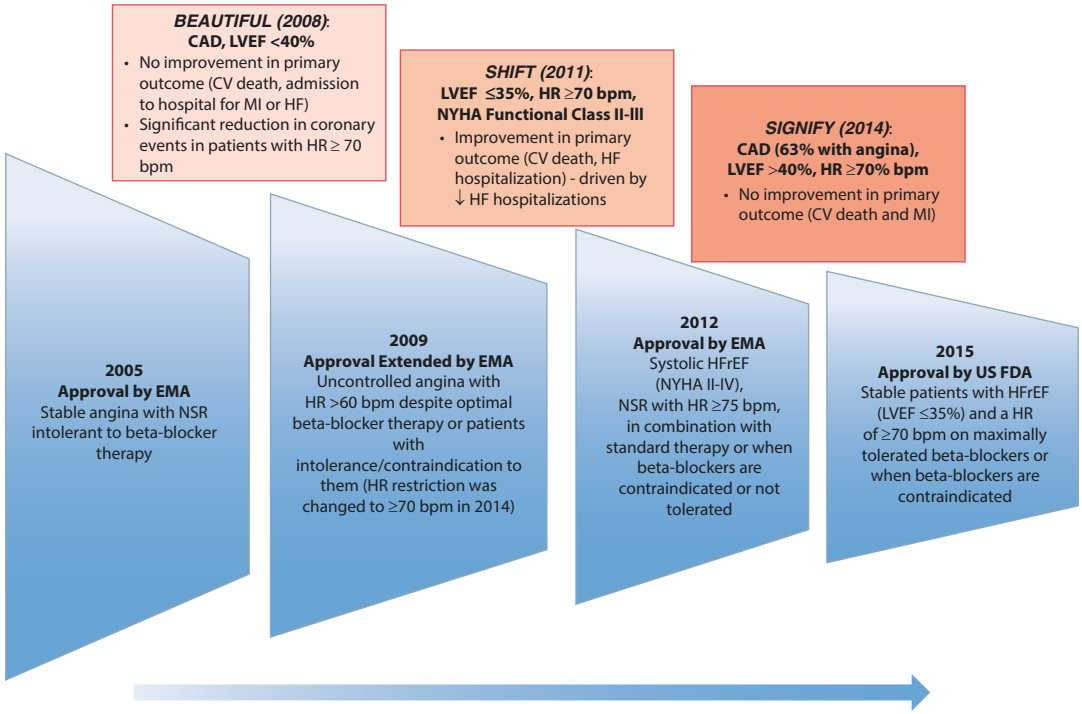

Fig. 8.3 Approval timeline of ivabradine across Europe and the United States. The indications for the use of ivabradine have evolved over time and differ based on region. Since it was first approved for use in angina by the European Medicines Agency (EMA) in 2005, the findings of several randomized controlled trials have resulted in expanded indications to include select heart failure patients and only recent approval by the US Food and Drug Administration (FDA) for this indication. BEAUTIFUL Morbidity-Mortality Evaluation of the I_f-Inhibitor Ivabradine in Patients With Coronary Disease and Left Ventricular Dysfunction, CAD coronary artery disease, CV cardiovascular, HFrEF heart failure with reduced ejection fraction, LVEF left ventricular ejection fraction, MI myocardial infarction, NYHA New York Heart Association, NSR normal sinus rhythm, SHIFT Systolic Heart Failure Treatment with the I_f-Inhibitor Ivabradine Trial, SIGNIFY Study Assessing the Morbidity-Mortality Benefits of the I_f-Inhibitor Ivabradine in Patients With Coronary Artery Disease. (PMID:28958335)

with LVEF ≤35% on a ß-blocker at the maximum tolerated dose, with HR ≥ 70 bpm (Fig. 8.4). The drug is contraindicated in patients with sinus node dysfunction or atrioventricular block. The FDA approval underscores the prerequisite for guideline-based treatment with maximally tolerated ß-blockers proven effective in HFrEF. In such patients in whom HR remains >70–75 beats per minute, the addition of ivabradine is reasonable. For patients with HFrEF who are proven intolerant of ß-blockers, treatment with ivabradine appears reasonable, keeping in mind that while ivabradine results in decreased heart rate, the exact mechanism of benefit remains uncertain.

Questions remain regarding the efficacy of ivabradine. From a recent meta-analysis of the ivabradine trials [42], the authors concluded that while use of ivabradine in patients with HFrEF in sinus rhythm with HR ≥ 70 to reduce HF hospitalization was supported by the literature, the strength of the evidence was such that more widespread adoption of ivabradine in HF would require additional randomized trials. Recent guideline updates [43] emphasize adherence to the ivabradine FDA package indication.

On the other hand, the guidelines advise that for any patient in NYHA Class II–IV HFrEF not on an ARNI, the threshold to consider discontinuing an ACEi or ARB in favor of sacubitril/valsartan should be low [44]. The number of women and ethnicities different from white in many of the foregoing trials is low enough that one might

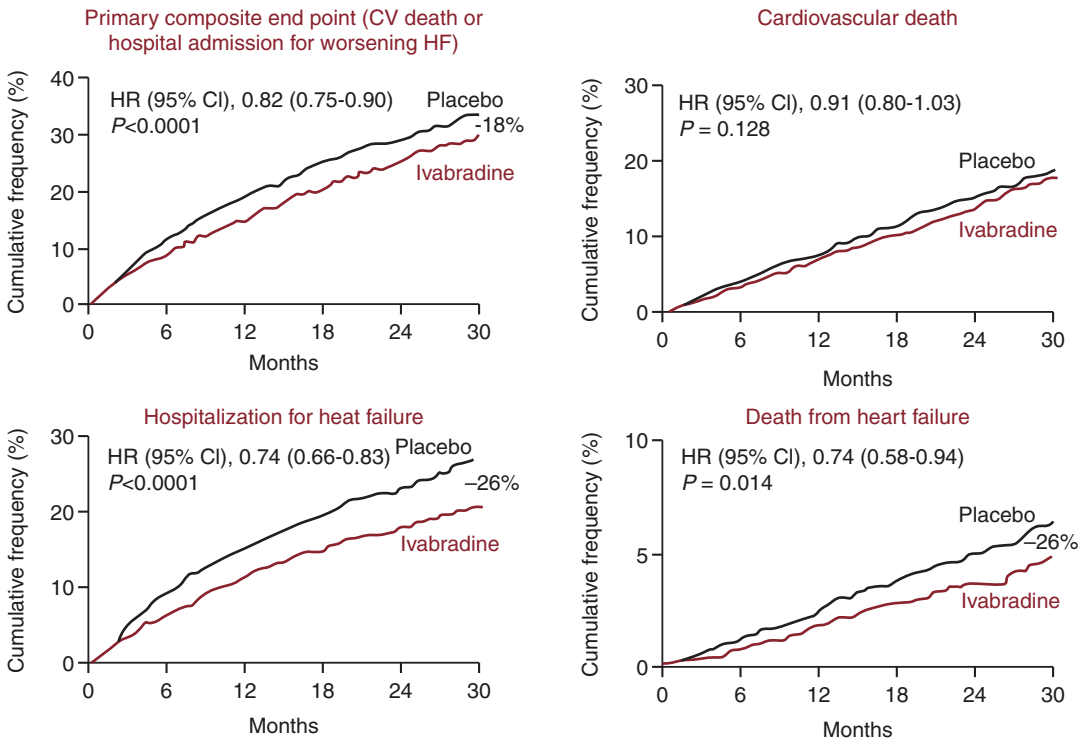

Fig. 8.4 Kaplan-Meier cumulative event curves for different end points in SHIFT. Mechanical Circulatory Support

9

Daniel H. Katz and Marwa A. Sabe

Hemodynamics of Cardiogenic Shock

A clear understanding of the unique hemodynamic changes in CS is critical to understanding the downward spiral of CS (Fig. 9.1) and the unique benefits of various MCS devices. The loop in Fig. 9.2a shows a standard pressure-volume loop for a normal heart. As a reminder, the end-systolic pressure-volume relationship (ESPVR) represents the intrinsic systolic function of the heart, and the slope of the ESPVR, the end-systolic elastance (Ees), is an approximation of contractility. The end-diastolic pressure-volume relationship (EDPVR) defines the diastolic function of the heart. The specific pressure-volume loop assumed by the heart depends on the preload and afterload at any given time but is bounded by the ESPVR and EDPVR. The shift in Fig. 9.2b represents the expected change when the heart suffers an acute insult to intrinsic contractile function, such as an AMI. In general, the contractile function of the heart decreases, which manifests as a drop in the slope of the ESPVR. The resulting pressure-volume loop represents a dilated left ventricle (increased end-diastolic volume) and a weak contractile force that produces a much smaller stroke volume.

A critical problem that drives cardiogenic shock can be demonstrated by considering the energetics of the normal heart compared to the acutely insulted heart. The heart requires energy according to the space bounded by the ESPVR, EDPVR, and the pressure-volume loop. It can be divided into the energy needed to maintain the heart shape and electrical function, termed potential energy (PE), and the energy of actually pumping blood, termed stroke work (SW). Together these make up the pressure-volume area which is directly proportional to myocardial oxygen demand. As you can see by comparing Fig. 9.2c, d, in an acute insult, SW may decrease substantially, but PE remains relatively high. Since SW represents not only a demand for oxygen, but also the supply of oxygen, it is easy to see how such a change in the energetics of the heart could precipitate an imbalance in myocardial demand and supply. This imbalance leads to further ischemia, even in the absence of further coronary obstruction, and drives the downward spiral of CS.

To intervene on this pathophysiologic process, clinicians have several tools at their disposal. In the setting of an AMI, urgent reperfusion remains

the standard of care [1]. However, several CS states are not driven by coronary occlusion, so thrombolysis and/or percutaneous coronary intervention will offer limited benefit. Traditionally, vasopressors and inotropes have formed the basis of management in CS, as these agents are widely available, have rapid onset of action, and require minimal staff resources to uti-

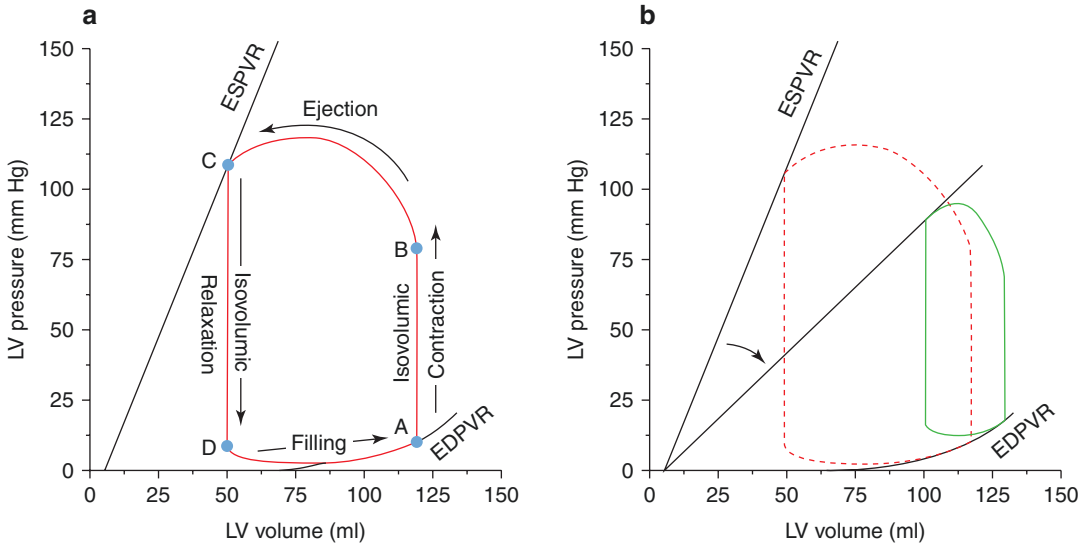

Fig. 9.2 (**a**) The standard pressure-volume loop for a normal heart is shown. The process from point A to point B represents isovolumic contraction where pressure increases without a change in volume. The aortic valve opens at B and ejection occurs with a drop in volume. Ejection occurs until point C when the aortic valve closes, which is followed by isovolumic relaxation to point D. The mitral valve opens at point D and the left ventricle fills. (**b**) In an acute insult, the systolic function of the heart weakens and the ESPVR decreases in slope. This results in a smaller volume of ejection and dilation of the ventricle overall. (**c**) Highlights the components of the pressure-volume area (PVA), which is made up of the stroke work (SW) and the potential energy (PE). (**d**) Shows the change in PE and SW when there is an acute insult to the heart. (Adapted from Uriel et al. JACC 2018 with permission [2])

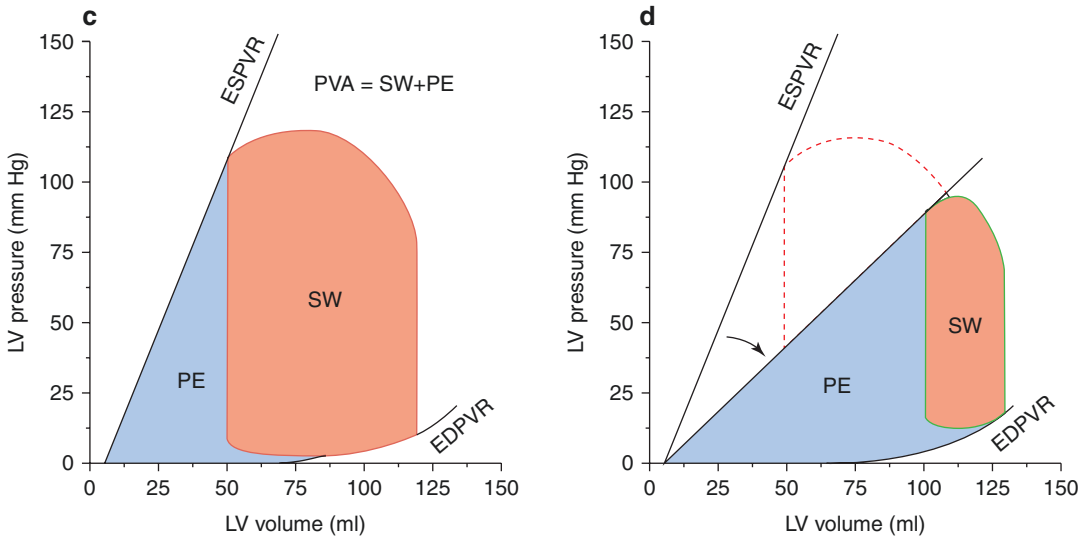

Fig. 9.2 (continued)

lize. However, they also increase myocardial oxygen demand, and may impair end-organ microcirculation, and, thus far, no randomized trials have in fact shown benefit [3]. While these agents are useful for short-term stabilization of hemodynamic collapse, MCS provides a therapeutic intervention that not only supports cardiac output and improves tissue perfusion but also *reduces* myocardial oxygen demand by unloading the ventricle and therefore directly interrupts the spiral of ischemia and myocardial dysfunction that leads toward death [2].

Systems for Temporary Mechanical Circulatory Support

There are numerous devices that provide direct left ventricular (LV) unloading in the setting of CS. They vary in the degree of cardiac output they contribute, and each has unique benefits and challenges. What follows is a general review of the most commonly used devices in clinical practice.

Intra-Aortic Balloon Pump (IABP)

The IABP is the most commonly used form of MCS [4], likely due to the ease of implantation and familiarity in practice. It consists of a conical balloon loaded on a catheter, which is then inserted peripherally so that it may sit in the descending aorta between the left subclavian artery and the renal arteries [5]. Insertion is typically through the femoral artery, but can also be done via the axillary artery directly or through a conduit [6]. Balloon sizes range from 25 cc to 50 cc, and the inflation of the balloon, typically with helium gas, is timed along with the intrinsic heart rate, guided either by the ECG or with fiber-optic monitoring of blood flow. The access cannula is usually 7.5F, the smallest of the various MCS systems.

Hemodynamic Effects

The IABP performs two useful functions in each cardiac cycle. During diastole, the balloon inflates (Fig. 9.3a). This significantly enhances the diastolic pressure within the proximal aorta and therefore enhances the coronary perfusion pressure and the resulting coronary flow [7], thereby directly improving myocardial oxygen supply. The balloon deflates during systole, which results in a significant decrease in afterload. The decrease in afterload allows for earlier opening of the aortic valve, which decreases oxygen demand during isovolumic contraction. In a heart with available contractile reserve, this

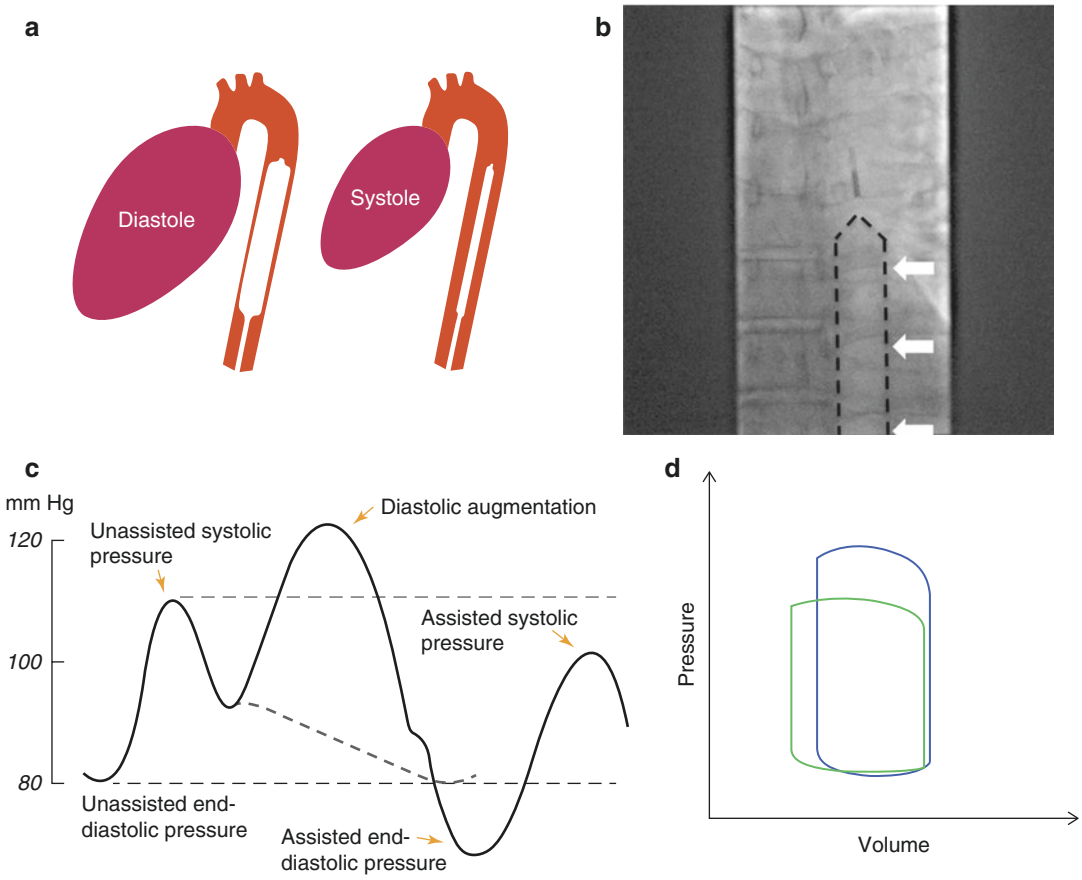

Fig. 9.3 (**a** and **b**) The Intra-aortic balloon pump is peripherally inserted in the descending aorta under fluoroscopy. It inflates during diastole and deflates during systole. (**c**) Diagram of the IABP's effects on systemic blood pressure. When the balloon inflates during diastole, it augments the diastolic pressure, ideally above the normal (unassisted) systolic pressure. Then, with deflation during systole, the systolic pressure is reduced slightly below what it is normally. This is referred to as the assisted systolic pressure. (**d**) Pressure-volume loop with insertion of the IABP is shown in green. Note that with reduction in the afterload, the aortic valve opens at a lower pressure and there is greater volume of ejection. (Reproduced with permission from Briceno et al. [8])

unloading leads to greater stroke volume (Fig. 9.3) [2, 5]. The decrease in systemic vascular resistance without a significant decrease in systemic blood pressure can be extremely useful in cases of acute severe mitral regurgitation or when systemic vascular resistance is high but blood pressure remains low, a state that limits use of afterload reducing medications such as sodium nitroprusside.

Limitations

IABPs are estimated to increase cardiac output somewhere between 0.5 and 1.0 L/min, although this augmentation can be variable in different individuals [5]. However, IABPs themselves provide little intrinsic cardiac output. The LV unloading they provide can enhance LV systolic ejection, similar to vasodilators in acute heart failure (without the side effect of peripheral hypotension, as noted above), but the increase in cardiac output is quite modest. IABPs are also more limited in patients with very high heart rates and arrhythmias due to issues with inflation timing, although this is somewhat mitigated in newer devices that operate by fiberoptic monitoring rather than ECG. IABPs also are contraindicated in patients with any more than mild aortic insufficiency, as inflation during diastole will

exacerbate the degree of aortic insufficiency. Access site bleeding is a present but controllable risk, as the insertion sheath is modest in size.

Study Data

The most important randomized clinical trial of IABPs was the IABP SHOCK II trial which compared IABP to standard treatment in approximately 600 patients with CS related to AMI. There was no benefit in mortality seen at 30 days; however, the trial is noted to have substantial issues with crossover with ~10% of patients in the conventional group receiving IABP, and there are ongoing questions regarding timing of placement, particularly in AMI [3, 8, 9]. This has decreased the strength of recommendations for the use of IABP, but in practice the hemodynamic benefits and the caveats of the IABP-SHOCK II trial have led to continued high-volume use of IABPs.

Ultimately, IABPs are likely to be best suited for situations when the need to increase systemic perfusion is modest, coronary ischemia is a predominant driver of CS, or when a reduction in afterload is expected to be of substantial benefit. IABPs continue to be used for temporizing patients with AMI awaiting CABG, acute mitral regurgitation awaiting surgery, and in selected chronic heart failure patients presenting with cardiogenic shock.

Impella

The Impella (Abiomed, Danvers, Massachusetts) is a percutaneously implanted left ventricular assist device that utilizes an axial flow impeller to pump blood from the LV to the aorta. There are three models presently used in practice which include the Impella 2.5, the Impella CP (3.5), and the Impella 5.0. Access site cannulae are 12F, 14F, and 21F respectively. The model numbers correspond to the upper limit of flow rate achievable, with the CP achieving a maximum of ~4.0 L/min, though actual flow rates are usually somewhat lower than these maximums. The impeller is fixed to a pigtail catheter which is advanced across the aortic valve to the LV either through the femoral artery or through the axillary artery (used frequently for the 5.0 model given the much larger size) (Fig. 9.4).

Hemodynamics

Unlike the IABP, which only reduces afterload, the Impella actively reduces the LV pressure and volume, reducing both preload and afterload. As can be seen in Fig. 9.4, the Impella reduces both wall stress (afterload) and end-diastolic pressure (preload), which leads to a dramatic reduction in both myocardial stroke work and potential energy. This leads to a reduction in myocardial oxygen demand. At the same time, the Impella directly increases cardiac output, which can increase myocardial oxygen supply (Fig. 9.4d). The resulting change in the balance of supply and demand suggests a direct interruption of myocardial ischemia that improves the dangerous spiral of CS.

Limitations

Impella use is growing, though operator familiarity and adequate staff training remain a barrier to use in some care settings. Impellas also use larger access cannulae compared to IABPs, which can lead to an increased bleeding risk. This can be exacerbated by hemolysis related to the axial pump [10], acquired von Willebrand syndrome [11], as well as the necessity of anticoagulation, which is not always necessary for IABPs when the balloon inflates with every beat (1:1). The limitations of duration for Impella use are somewhat uncertain. The FDA has approved the device for 6 days, but some sites have used the Impella 5.0 up to a maximum of 35 days [12]. Femoral access duration is more limited than axillary access due to immobility issues.

Study Data

The small ISAR SHOCK trial observed that even the Impella 2.5 had superior hemodynamic effects compared to the IABP [13]. As a corollary of the benefit of greater cardiac output achieved with this device, registry data also suggested a benefit for patients who received an upgrade from Impella 2.5 to Impella 5.0 [14]. Unfortunately, randomized data for hard out-

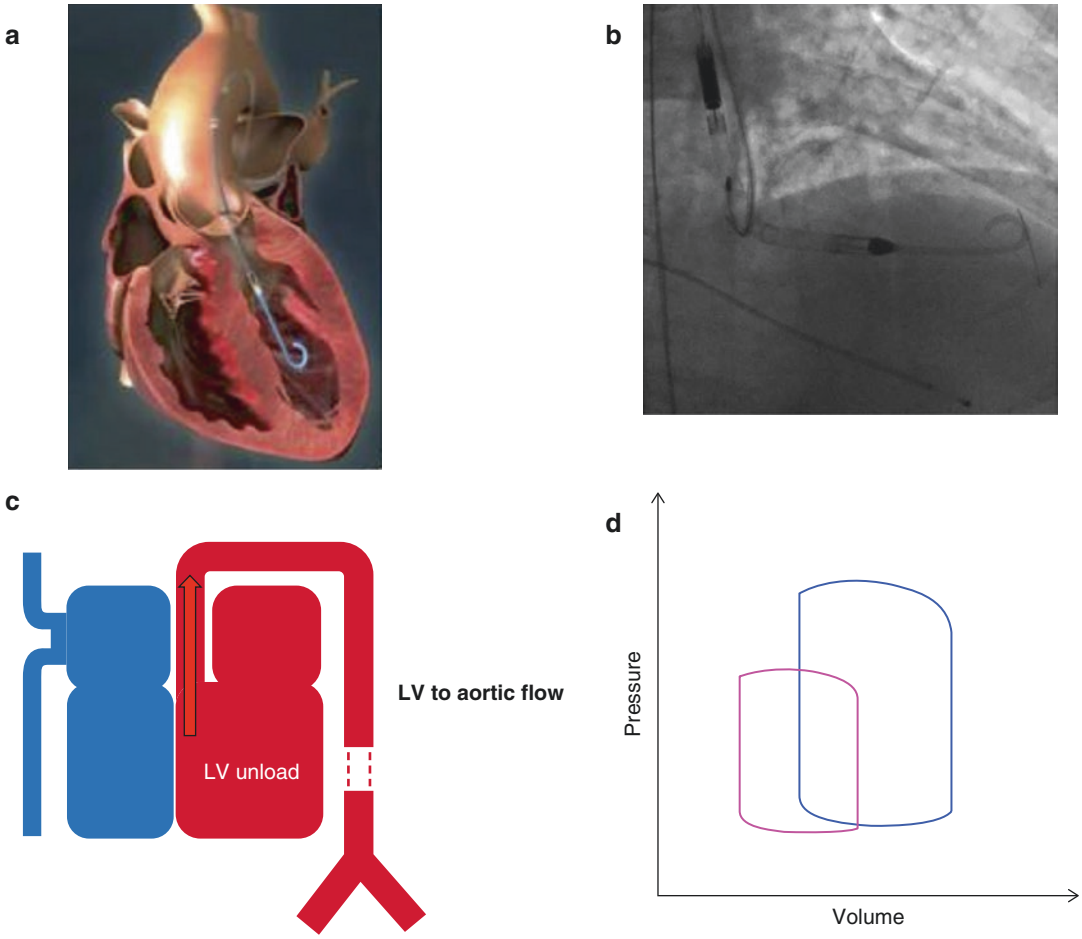

Fig. 9.4 (**a** and **b**) The Impella is inserted fluoroscopically across the aortic valve. (**c**) The Impella directly unloads the LV into the aorta. (**d**) The resulting pressure-volume loop (purple) reflects the unloading of the Impella, as the left ventricular end-diastolic volume significantly decreases. Note that the loop reflects a lower LV stroke volume; however, overall global cardiac output is supported by the Impella. (Reproduced with permission from Briceno et al. [8])

comes are lacking. The Impella CP and IABP were compared in 48 patients with AMI and CS, with no observable difference in 30-day mortality [15]. There is registry data to suggest that for those patients in whom an AMI is the trigger for CS, Impella use prior to coronary intervention was superior to its use afterward [16]. As a result of the experience with Impella at the time of coronary intervention, these devices are frequently deployed in AMI complicated by CS. However, there are some data for use in acute decompensated heart failure, as a bridge to a decision regarding heart transplantation or left ventricular assist device (LVAD) implantation [17, 18].

Extracorporeal Pumps

IABPs and Impellas are both peripherally placed, intracorporeal pumps. As a result, the volume of flow they can deliver, the durability of their use, and their anatomic flexibility are limited. Extracorporeal pumps, on the other hand, use large, robust centrifugal pumps capable of higher flow rates. The inflow and outflow cannulae can be placed in numerous orientations, either peripherally or centrally, depending on anatomy and the desired effect on hemodynamics. A membrane oxygenator can also be placed in-line with an extracorporeal pump to provide blood oxygenation if needed. Like the Impella, these

systems require anticoagulation to reduce the risk of thromboembolism. This section covers the more commonly encountered platforms.

TandemHeart

In many ways, the TandemHeart (CardiacAssist Inc., Pittsburgh, Pennsylvania) mimics the Impella. It is percutaneously placed and directly unloads the LV; however, it uses an extracorporeal centrifugal pump. A 21F inflow cannula is inserted into the femoral vein up to the right atrium and passes across the septum (by transseptal puncture) into the left atrium. The blood is pumped directly into the femoral artery through a 17F cannula (Fig. 9.5) [19]. The hemodynamic profile is similar to that of the Impella. In addition to the routine risks of percutaneous femoral access (bleeding, infection, limb ischemia, etc.), trans-septal puncture increases the possibility of tamponade. Trans-septal puncture is also more technically difficult, and thus this system is not as widely used as the Impella [8]. When compared to IABP, the TandemHeart improved hemodynamic parameters but showed no mortality benefit [20, 21].

CentriMag

The CentriMag (Abott Laboratories, Abbott Park, Illinois) is quite similar to the TandemHeart. It also consists of an extracorporeal centrifugal

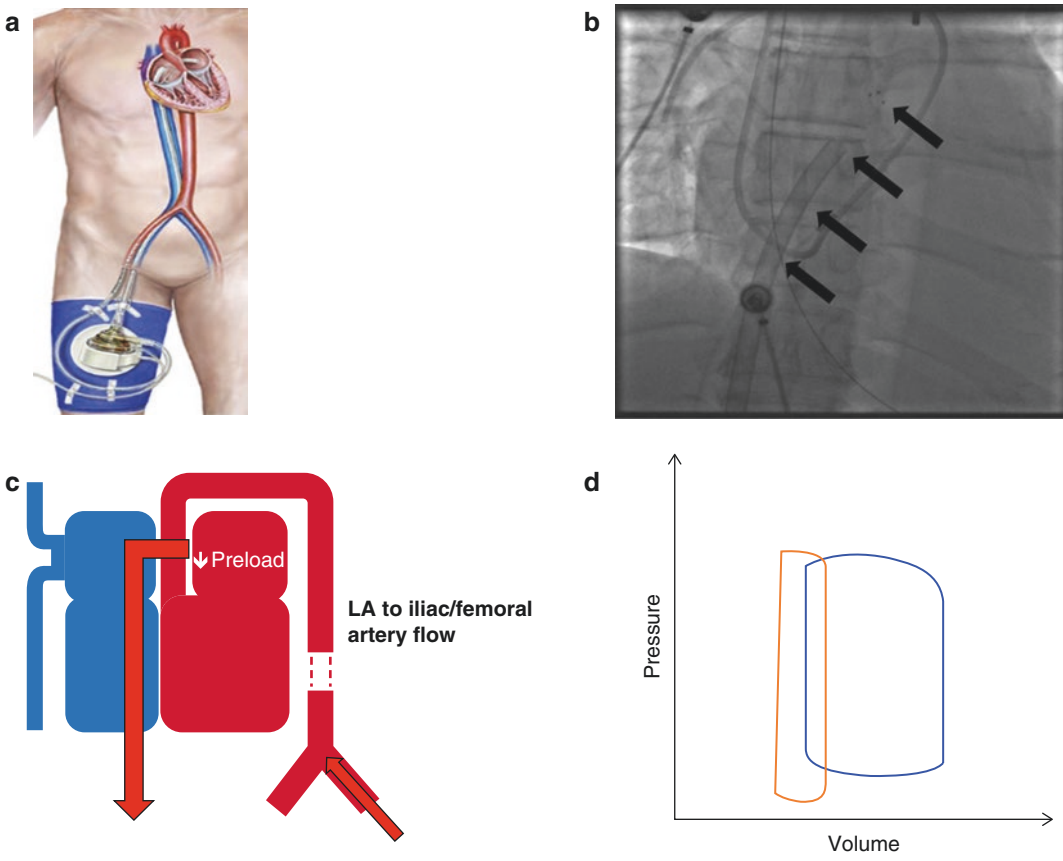

Fig. 9.5 (**a** and **b**) The TandemHeart is placed percutaneously under fluoroscopic guidance. (**c**) The inlet cannula advances up the femoral vein to the right atrium, and crosses to the left atrium, where it drains blood and reduces LV preload. (**d**) Hemodynamic benefits include reduction in preload and reduction in the left ventricular end-systolic volume. Note that the TandemHeart increases afterload on the LV by delivering blood to the femoral artery (Reproduced with permission from Briceno et al. [8])

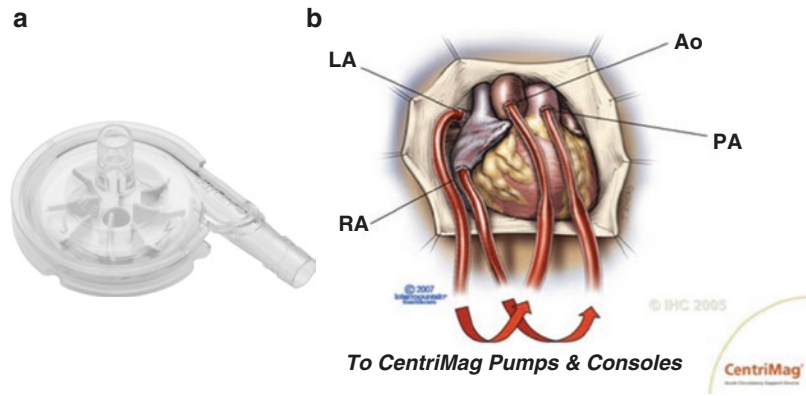

Fig. 9.6 (**a**) The CentriMag is a high flow centrifugal pump. (**b**) The CentriMag can pump blood from the right atrium to the pulmonary artery or the left atrium to the aorta. Other configurations are possible. (Images reproduced with permission from Abbott Laboratories)

pump. The key difference is that the system is implanted through central cannulation (usually by a cardiothoracic surgeon), rather than peripherally. Most commonly the inflow cannula is in the left atrium, and the outflow cannula is in the aorta (Fig. 9.6). However, depending on the situation, the inflow cannulae can be placed in the pulmonary vein or in the left ventricle directly, and for right-sided support can be placed in the right atrium. It is noted that CentriMag is somewhat more flexible in the cannulae it can use and the range of flows it can provide (up to 10 L/min). As a result, surgeons find it useful in post-pericardiotomy syndrome, and the extended duration makes it useful in patients for whom extended mechanical support is needed, as either a bridge to recovery, durable LVAD, or orthotopic heart transplantation [22].

Venoarterial Extracorporeal Membrane Oxygenation (VA-ECMO)

ECMO is any system that uses an external membrane to provide oxygenation and removal of carbon dioxide, and is thus suitable for refractory respiratory failure. If that is all that is required, and the patient does not need hemodynamic support, then veno-venous ECMO (VV-ECMO) is adequate. In the setting of CS complicated by respiratory failure, where support of cardiac output is also needed, the membrane oxygenation is paired with a high flow centrifugal pump, and oxygenated blood is pumped from the venous system into the arterial system, hence, venoarterial ECMO (VA-ECMO). Blood is typically removed from the right atrium and returned to the femoral artery after oxygenation, although central cannulation of the aorta by a surgeon is also possible. Alternately, if needed, the inflow can come via the right internal jugular vein and the outflow returned to the right subclavian artery. The venous cannulae range from 19F to 25F and the arterial cannulae are 15F to 24F. Whatever the orientation, the heart and lungs are all bypassed and replaced by the system, such that VA-ECMO is essentially the same as cardiopulmonary bypass (Fig. 9.7). This arrangement takes over the work of both ventricles and therefore is most commonly used in the setting of acute biventricular failure, also complicated by hypoxemic respiratory failure. This is most often seen in AMI, myocarditis, or primary graft failure following orthotopic heart transplant [23].

Hemodynamics

The hemodynamic effects of VA-ECMO are notably different than other MCS systems discussed thus far. Because VA-ECMO drains the venous system, usually from the right atrium, the right ventricle is unloaded, but the LV is not; blood still crosses the pulmonary and coronary vascular circuits and drains into the LV. In fact, not only does ECMO not unload the LV, it then delivers blood flow to the aorta, which in fact increases the afterload on the LV. If left unmanaged, an LV incapable of unloading itself against the afterload of ECMO may develop increased filling pressures and LV distension, which can lead to both increased myocardial oxygen demand and ischemia, as well as pulmonary edema. Furthermore, if the ventriculo-aortic

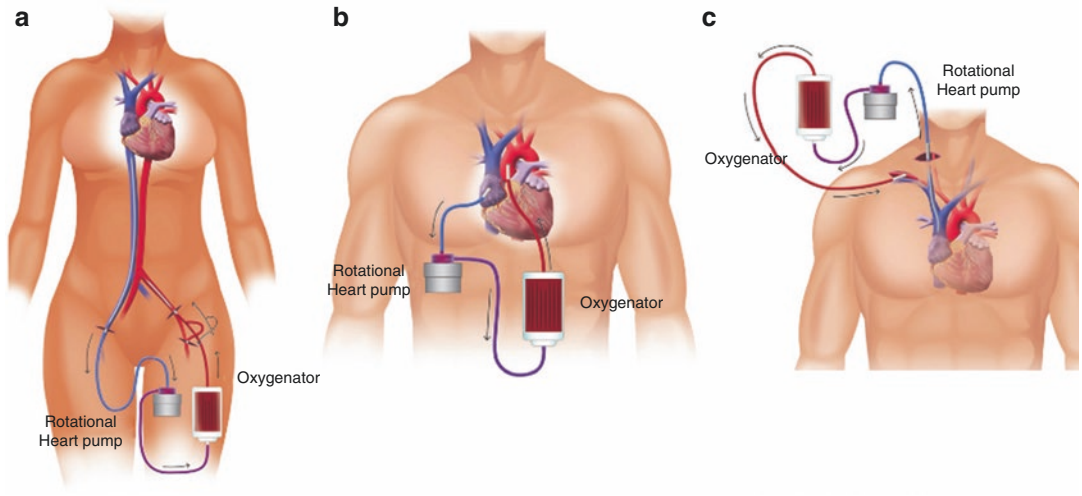

Fig. 9.7 Three possible configurations for VA ECMO. The heart pump and the oxygenator connect a venous inflow to an arterial outflow. Configurations include (**a**) femoral vein to femoral artery, (**b**) right atrium to aorta ("central cannulation"), or (**c**) right internal jugular vein to right subclavian artery. (Reproduced with permission from Rao et al. [23])

coupling is so adverse that the aortic valve does not open, stasis of blood in the LV can increase the patient's risk for thromboembolic events [23].

To manage this problem, ECMO flows could be reduced, though this is limited by the demands of adequate tissue perfusion. Instead, a variety of left ventricular venting options can be employed (Fig. 9.8). Venting options include inotropes or vasodilators, IABP or Impella placement, atrial septostomy (to allow for left atrial to right atrial shunting), or simply a cannula placed directly in the left atrium or LV that drains into the ECMO circuit [23]. Impellas are a frequently used ventilation strategy in patients on VA-ECMO, and simultaneous use of Impella with ECMO support ("ECPELLA") has been shown to be associated with improved 30-day mortality and lower inotrope use in patients requiring VA-ECMO [24].

While it is critical for the LV to be adequately vented to prevent the aforementioned complications, it should also be noted that in patients with substantial respiratory compromise, the blood coming from the LV is poorly oxygenated. If the LV vents itself vigorously, or is supported by any of the strategies listed, enough flow can be generated such that deoxygenated blood preferentially finds its way into the peripheral circulation.

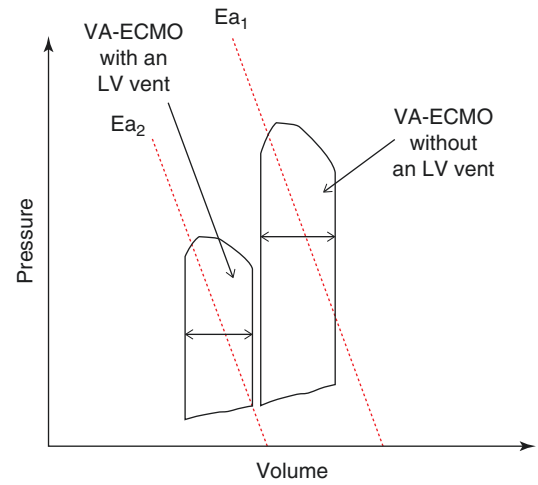

Fig. 9.8 Effect of an LV vent on LV hemodynamics. The vent reduces LV end-diastolic volume and also reduces end-systolic pressure. (Reproduced with permission from Kapur et al. [25])

The at-risk organs are those most proximal, namely, the heart, upper extremities, and head. Thus, this phenomenon is known as North-South syndrome, or Harlequin syndrome (Fig. 9.9) [26]. The phenomenon is best monitored using pulse oximetry or radial artery access in the right arm, wherein arterial supply comes from the

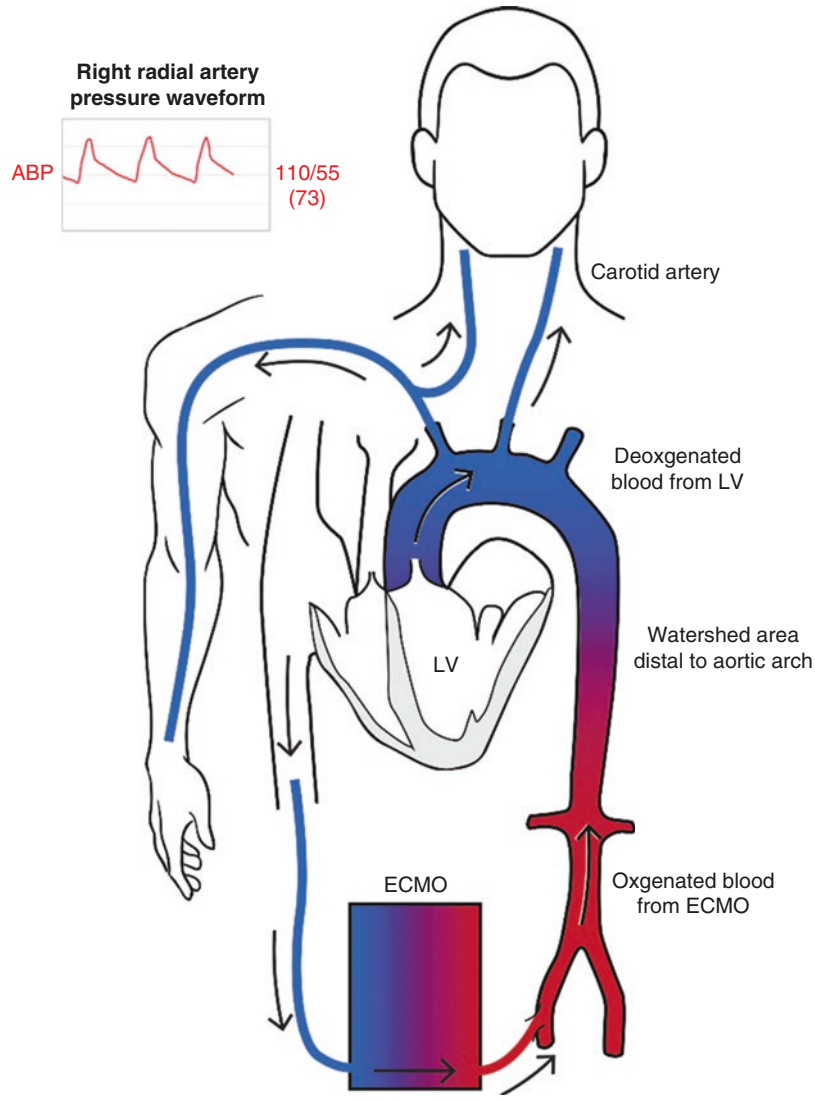

Fig. 9.9 North-South syndrome or Harlequin syndrome. Oxygenated blood from the ECMO circuit mixes with deoxygenated blood from the LV. If this mixing occurs distal to the aortic arch, oxygen to the upper extremities and head can be compromised (Reproduced with permission from Rao et al. [23])

most proximal branch of the aortic arch. If oxygen saturation dips relative to the left arm, or the arterial wave form looks more like the pulsatile work of the LV rather than the continuous flow of ECMO, this can indicate North-South syndrome (or Harlequin syndrome) [23]. If it occurs, increasing ECMO flows can be helpful. Alternative solutions include weakening the stronger LV with an esmolol drip or returning some oxygenated blood back to the RA (which would then make its way to the LV by the normal route), a system referred to as veno-arterio-venous ECMO (VAV-ECMO) [27].

Risks and Limitations

Here again the risks of peripheral cannulation and anticoagulation must be considered: infection, bleeding, and limb ischemia. Because of the particularly large cannulae used with ECMO, the leg distal to the insertion site is frequently cannulated to provide direct antegrade flow and prevent limb ischemia [28]. The ECMO circuit also tends to be more thrombogenic and inflammatory than systems with just a pump, and as a result, peripheral vasodilation and thrombotic events are an ever-present concern [29].

Indications and Contraindications

The principal indication for VA-ECMO is in patients requiring biventricular support as well as respiratory support. The membrane oxygenator carries much of the added risk of ECMO compared to other forms of MCS discussed above, so adding this element should only be done if it is necessary to support the patient. The most important contraindication to initiation of VA-ECMO is the absence of an exit strategy to allow removal of the circuit, whether that is recovery of the heart, durable MCS (discussed below), or heart transplant. Relative contraindications include coagulopathy, obesity, age, and other life-limiting comorbidities particularly malignancy. These issues factor into the likelihood of the patient surviving their time on the ECMO circuit.

Durable Mechanical Circulatory Support

The MCS systems described above are temporary interventions in the setting of cardiogenic shock. In this sense, they are utilized as a bridge to some other more permanent outcome. In some cases, this is a bridge to myocardial recovery, for example, following reperfusion, or of certain types of myocarditis by means of immunosuppressive therapy. However, in patients with CS due to acute on chronic decompensated heart failure or in whom myocardial recovery does not occur, temporary MCS should not even be initiated unless some sort of exit strategy is possible. For more and more patients, that exit strategy is a durable LVAD, and for those who are not heart transplant candidates, durable LVADs represent destination therapy.

Durable LVAD Systems

In general terms, the continuous flow LVADs that are most commonly used in clinical practice are not substantially different from the extracorporeal systems covered above. A high flow pump directly unloads the left ventricle and pumps blood into the proximal aorta. The critical difference is that the pump is surgically implanted in the chest or abdomen. Only a driveline, which powers the pump, is tunneled externally to the skin.

Two categories of pumps are in common use: centrifugal and axial flow pumps, both of which are continuous flow pumps. The HeartWare HVAD (Medtronic, Minneapolis, Minnesota) and the HeartMate 3 (HM3) (Abbott Laboratories, Abbott Partk, Illinois) use centrifugal flow pumps which are implanted with a short inflow cannula into the LV apex, while the HeartMate II (HMII) is an axial flow pump that is implanted just below the diaphragm with a slightly longer inflow cannula connected to the LV apex (Fig. 9.10) [30]. All three systems have a driveline that tunnels out through the abdominal wall and connects externally to a controller which can be powered by

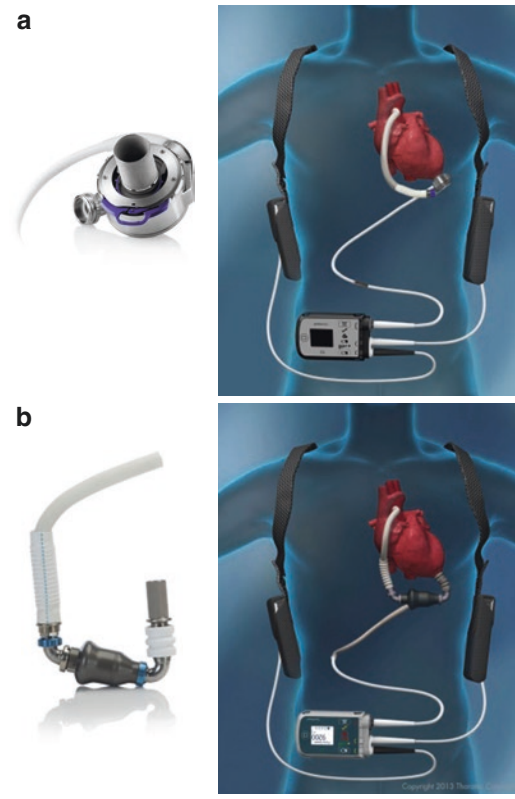

Fig. 9.10 Left ventricular support devices. (**a**) Shows the centrifugal flow pump the HeartMate 3 device. HeartWare (not shown here) is also a centrifugal flow pump. (**b**) Shows the axial flow pump HeartMate II device. Both are connected to external systems with a driveline. Inflow cannulas sit in the LV and outflow cannulas in the aorta. (Reproduced with permission from Abbott Laboratories)

battery or wall outlet. These devices support cardiac output, allowing patients to leave the hospital and resume daily living.

Hemodynamics

In the acute setting, LVADs are hemodynamically similar to other LV-to-aorta MCS systems discussed, such as Impella. However, because the patient's total cardiac output is a combination of their intrinsic LV function, which is pulsatile, and part continuous flow pump, it is worth considering how the two interact. The only externally controllable setting on the LVAD is the speed, measured in rotations per minute. The actual flow that this generates, however, depends on multiple factors, including the preload, afterload, and viscosity of the blood. More directly, as seen in Fig. 9.11, the flow generated by the device is indirectly proportional to the head pressure, which is the pressure gradient between the LV and the aorta. In diastole, the head pressure is high, since LV pressure is relatively low. The high head pressure means flow across the LVAD is lower. During systole, the head pressure is much lower as the LV generates higher pressures at the LVAD inflow cannula. With the low head pressure, LVAD flow increases. Therefore the actual flow generated by the device fluctuates with the cardiac cycle. Because of this effect on flow, increases in the afterload experienced by the LVAD lowers the flow generated by the LVAD, while increases in preload increases flow based on their effect on the head pressure [30]. In fact, the LVAD is more sensitive than the heart to these changes, and it is therefore critical to tightly control blood pressure and volume status in LVAD patients.

The unloading that the LVAD provides manifests in several ways. First, it directly reduces the LV volume and pressure, with subsequent decrease in LV size on echocardiogram. There is evidence that the unloading of the LV myocytes can have long-term beneficial effects on LV remodeling [2]. The direct unloading of the LV also means that the LV itself provides a reduced component of the cardiac output. As a result, the peripheral arterial flow is less pulsatile and more continuous; the greater the LVAD's contribution to the total cardiac output, the lower the pulsatility observed in peripheral arteries [30]. Because of this hemodynamic effect, LVAD patients often do not have blood pressure that can be measured by a typical cuff. Rather a Doppler probe is used to determine the pressure at which flow returns to a peripheral artery. This is commonly referred to as the opening pressure, and it is recommended to keep this below 80 mmHg, given the afterload sensitivity of these devices [31].

LVADs also directly impact the RV. LV unloading reduces left-sided filling pressures, resulting in a drop in RV afterload. However, there are negative consequences for the RV as well. The increased flow from the LVAD can return to the RV and cause RV distension and dysfunction. At the same time, the intraventricular septum can be pulled toward the inflow cannula by the pump, decreasing the septal contribution to RV contractility, and weakening RV performance. For those at risk, these issues can cause early RV failure after LVAD implantation. There is also evidence for late RV failure, the cause of which remains unclear, but may be related to chronic impacts of the above phenomena [30].

Pump Parameters

When in clinic or in the hospital, the HeartMate and HeartWare systems are connected to interfaces that display relevant information about function. Each system uses a different interface for displaying these pump parameters, but in general, pump speed, pump power, pump flow, and some indication of the degree of pulsatility should be readily apparent. The pump speed is set directly. The pump power is directly measured by the VAD and is directly proportional to the amount of actual flow through the VAD. Flow itself is not directly measured by the VAD, but rather calculated from pump power, pump speed, and blood viscosity, with viscosity derived from the hematocrit which has to be entered into the interface (in the HeartWare and HM3 device; this option is not available in the HMII device). For this reason, entering a new hematocrit can cause a sudden shift in the calculated flow.

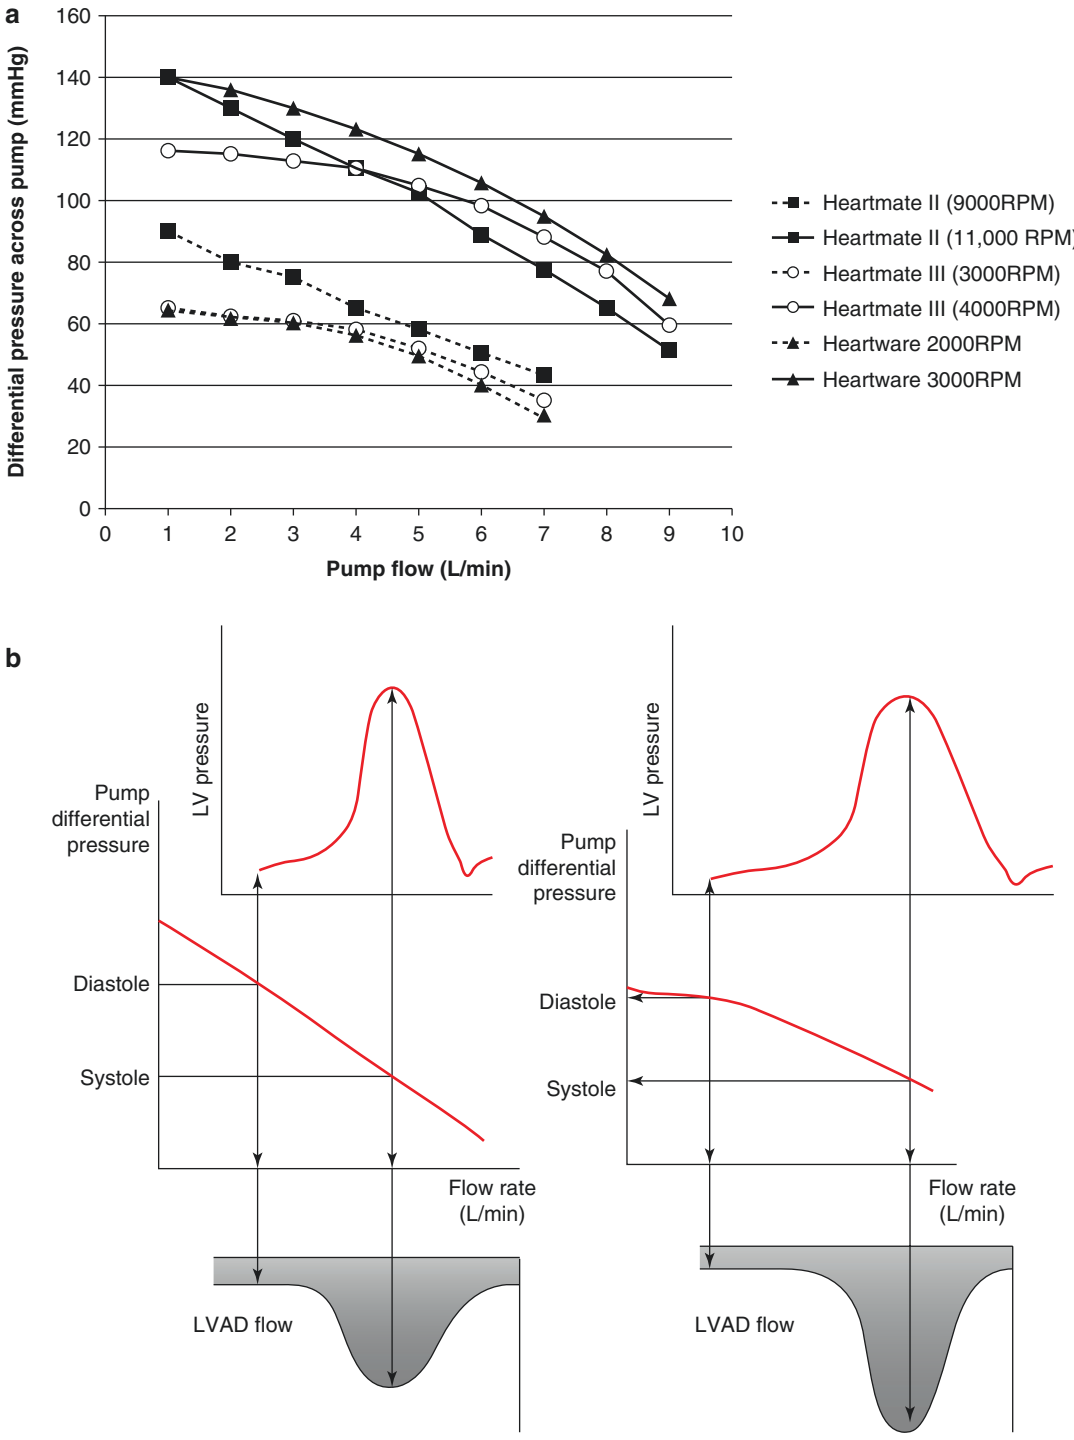

Fig. 9.11 LVAD hemodynamics. (**a**) The actual flow generated by an LVAD varies by the type, speed, and head pressure. (**b**) Actual flow rates in an LVAD vary throughout the cardiac cycle. During systole, the pressure gradient between the LV and the aorta shrinks, so flow increases. The right panel shows an LVAD that is more sensitive to changes in head pressure, with larger fluctuations in flow rate. (Reproduced with permission from Lim et al. [30])

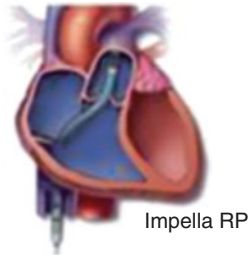

Fig. 9.12 Impella RP. The impeller pumps blood from the inferior vena cava to the pulmonary artery. (Reproduced with permission from Kapur et al. [32])

Right Ventricular Support

The above examples of MCS all focused on left ventricular support, save for ECMO which provides biventricular support. RV support, either in addition to LV support or in isolation can also be achieved with many of the systems already covered. Percutaneous VADs can be placed with cannulae in the right atrium and pulmonary artery, thereby unloading the right heart. There is also an Impella RP, specifically designed for RV support (Fig. 9.12) [25, 32]. Simultaneous use of Impella 2.5, CP, or 5.0 and Impella RP can be used for hemodynamic support in patients with biventricular shock [33]. Durable RVAD is also an option, both in patients with RV failure related to LVAD implantation and in patients with biventricular failure requiring bridge support prior to orthotopic heart transplantation.

Review Questions

Case 1: A 34-year-old female with no past medical history presents with 4 days of progressive dyspnea. She had a mild upper respiratory infection 2 weeks ago. Her vital signs show a temperature of 37 °C, heart rate of 132 in sinus rhythm with frequent ventricular ectopy, blood pressure of 78/59, and an oxygen saturation of 82% on BiPAP with 60% FiO2. On exam, she has an elevated jugular venous pulsation to 14 cm H_2O, crackles in both lung fields, an S3 gallop, and cool, mottled extremities. She is in visible distress. Bedside echocardiogram shows biventricular systolic dysfunction, 2+ mitral regurgitation and no aortic insufficiency. During the echocardiogram, she becomes unresponsive and a code is called for PEA arrest. She is intubated, and after two rounds of CPR and one dose of epinephrine, she has return of spontaneous circulation, though her oxygen saturation remains 83% on appropriate ventilator support and her blood pressure is 76/58.

1. What type of support would be most appropriate at this time?
   A. Dobutamine and norepinephrine
   B. Transfer to the OR for emergent durable RVAD and LVAD
   C. Impella 5.0 via axillary cutdown
   D. VA-ECMO

This patient presents with likely myocarditis with profound biventricular failure and respiratory compromise. This situation favors VA-ECMO. Inotropes and vasopressors are less likely to provide adequate support, and an Impella fails to support the RV. While durable RVAD and LVAD could offer adequate circulatory support, it fails to address the respiratory failure and is potentially unnecessary as near term recovery is possible.

2. The above patient is started on VA-ECMO via right femoral vein and left femoral artery cannulation. Twelve hours after initiation the patient is noted to have frothy secretions in the endotracheal tube. Bedside echo shows a markedly dilated LV with 4+ mitral regurgitation without flail. The aortic valve is not noted to open.

   What is the next best step in management?

A. Placement of an Impella CP
B. Transfer to the OR for emergent mitral valve repair
C. Increasing ECMO pump speed
D. Increasing ventilator oxygenation support

This patient needs LV unloading given their very poor LV function, which can be achieved with an Impella device, acting as a direct LV vent. The mitral regurgitation is a functional con-

sequence of LV dilation, and is not the primary driver of the situation. Increasing ECMO pump speed will increase flow in the proximal aorta and worsen the situation. Increasing ventilator oxygenation support may increase overall oxygenation to a small extent, but does not address LV unloading.

Case 2: A 59-year-old man with a history of hypertension and diabetes presents after 4 days of intermittent chest pressure at rest. Today his chest pressure has persisted for several hours, and he is markedly short of breath prompting his presentation. Vital signs show a heart rate of 95, blood pressure of 92/68, and an oxygen saturation of 92% on room air. His EKG shows ST elevations in V1-V4 with associated q-waves and reciprocal ST depressions. He is given aspirin, ticagrelor, and a bolus of heparin. The catheterization laboratory is activated. Via right radial artery access, he is found to have a proximal LAD occlusion. As the intervention is about to begin, blood pressure is noted to be 75/55, and the patient becomes less responsive.

3. What is the next best action?
   A. Complete the procedure while closely monitoring vital signs
   B. Place an Impella CP
   C. Start a norepinephrine drip
   D. Cannulate for VA-ECMO

This patient is developing cardiogenic shock from an AMI. The primary need is for rapid left ventricular support. Fixing the lesion without support could allow the cycle of CS to continue. It is preferred to start some form of hemodynamic support and then complete the procedure. Norepinephrine would not be an ideal agent as it does not decrease myocardial demand or increase coronary perfusion. VA-ECMO is not necessary as the patient does not have RV or respiratory failure.

Case 3: A 52-year-old male with diabetes, hypertension, and hyperlipidemia with infrequent medical care presents with 3 days of progressive dyspnea and fatigue. He has noted 10 lbs weight gain in the last week. He is noted to be tachycardic to 105 bpm and his blood pressure is 85/56. His extremities are cool to the touch and he is noted to have trouble paying attention during the history. EKG shows inferolateral T-wave inversions with ST depressions. Troponins are sent. Bedside echocardiogram shows EF 15% with wall motion abnormalities. He is given 325 mg aspirin and bolused with 5000 U of IV heparin for presumed acute coronary syndrome. He is started on a dopamine drip and transferred to the cath lab which shows severe three vessel coronary disease with small distal vessels. There is no culprit vessel on which to intervene.

4. What is the next best intervention?
   A. Start sodium nitroprusside
   B. Place an IABP
   C. Book the OR for placement of a left atrium to aortic CentriMag
   D. Book the OR for placement of a durable LVAD

The patient has exacerbation of likely long-standing ischemic coronary disease. He is developing CS and reperfusion is not an option. Temporary MCS with an IABP would be valuable here. It would help to unload the struggling ventricle and increase coronary perfusion pressure to the likely ischemic heart. Sodium nitroprusside would be risky given low blood pressure. A CentriMag would provide hemodynamic support, but is much more invasive than an IABP and may not be necessary at this point. Similarly durable LVAD would be premature as LV recovery is possible in the near term.

After 3 days on the IABP, his mentation has improved and he is diuresed back to his dry weight. However, there is no improvement in the patient's intrinsic LV function, and the cardiothoracic surgeons have decided his coronaries are insufficient for coronary artery bypass surgery. The IABP is unable to be weaned without decrease in blood pressure. He and his family would like to know what further options he has at this point.

5. What option would be best at this time?
   A. Continued monitoring on IABP
   B. Upgrade to CentriMag

C. Evaluate for LVAD/orthotopic heart transplant
D. Transition to comfort care

This patient should begin an urgent evaluation for LVAD and/or heart transplant. Upgrading to CentriMag at this time is not necessary as the patient is adequately supported on IABP, but further monitoring on IABP is unlikely to yield further improvement in his LV function, and is not worth the daily risk for complications from IABP. Transitioning to comfort care is not appropriate as LVAD support is an option and the patient and family are seeking further care.

From inability to let well alone;
from too much zeal for the new and contempt for what is old;
from putting knowledge before wisdom, science before art, and cleverness before common sense;
from treating patients as cases;
and from making the cure of the disease more grievous than the endurance of the same, Good Lord, deliver us.

– Sir Robert Hutchison MD FRCP (1871–1960)

Case 1

A 65-year-old male, with history of coronary artery disease, anterior wall myocardial infarction 10 years ago, and ischemic cardiomyopathy with left ventricular ejection fraction of 30%, presents to the emergency room with worsening dyspnea on exertion and orthopnea for 1 week. On examination, his heart rate is 88 beats per minute and regular, blood pressure is 126/74 mm Hg, and respiratory rate is 18 per minute with oxygen saturation measuring 94% at room air. The jugular venous pressure is elevated to 14 cm of water. Examination of the lungs is notable for bibasilar rales. Cardiovascular exam reveals a laterally displaced apical impulse. The S1 is normal, S2 is physiologically split, and there is a moderately loud S3. There is no audible murmur. Abdominal examination reveals mild hepatomegaly, with the edge 2 cm below the costal margin, with no evidence of ascites. The lower extremities demonstrate moderate pitting edema to the mid-calf bilaterally.

This patient is in acute decompensated heart failure (ADHF), which, even today, remains a clinical diagnosis performed at the bedside, based primarily on history and physical examination, rather than on laboratory data. The most important clues to this diagnosis are symptoms related to dyspnea and signs related to biventricular congestion and volume overload. Of the symptoms, orthopnea correlates best with elevated pulmonary capillary wedge pressure (PCWP), with a sensitivity approaching 90% [1]. Clinically evident edema usually indicates a volume excess of at least 3–4 L. Measuring blood pressure is of critical importance in patients with ADHF since hypotension is one of the strongest predictors of poor outcomes [2] and has important implications for therapy.

Jugular venous pressure (JVP) is a cardinal aspect of the cardiovascular examination in the assessment of volume status in patients in general, and in those with ADHF in particular. However, estimation of JVP is highly dependent on examiner skill, experience, and patience. An abnormally elevated JVP is a pressure defined as >5 cm of water. If the patient is sitting at a 45 degree angle to the bed, there should be no visible pulsations above the angle of Louis. JVP reflects right atrial (RA) pressure. It is often used

as a surrogate for left ventricular filling pressure; however right heart failure is often absent in patients with left-sided heart failure. The most common cause of right ventricular failure is left ventricular failure. In a study consisting of 1000 consecutive patients with advanced heart failure undergoing right heart catheterization, RA pressure was found to somewhat reliably predict PCWP (r = 0.64), and the positive predictive value of RA pressure >10 mm Hg for PCWP >22 mm Hg was 88% [3]. Hepatojugular reflux (HJR) is jugular venous distension induced by firm pressure over the liver. An increase in JVP >3 cm by this maneuver is a positive HJR, which is a sign of right-sided volume overload. The presence of jugular venous distension, at rest or inducible, is the bedside clinical sign that has the best combination of sensitivity (81%), specificity (80%), and predictive accuracy (81%) for prediction of elevation of PCWP (≥18 mm Hg) [4].

The third heart sound (S3) occurs in early diastole due to abrupt cessation of rapid early diastolic left ventricular inflow as a consequence of increased LV filling pressures and an abnormally stiff, non-compliant left ventricle [5]. It is a fairly specific marker for LV dysfunction and correlates with BNP levels [6]. However, it is not as sensitive as other bedside findings. In a comprehensive analysis evaluating all studies published between 1966 and 2005 which assessed the precision and diagnostic accuracy in diagnosing the cause of dyspnea, the S3 was found to increase the likelihood of ADHF more than any other part of the physical examination (likelihood ratio 11, 95% Confidence Interval 4.9–25.0) [7]. The S3 is associated with elevated LV filling pressures [8]. In a comprehensive study of the physiology of the S3 comparing findings from phonocardiography, tissue Doppler echocardiography, BNP, and invasive LV hemodynamics, patients with an audible S3 were found to have a higher early mitral inflow velocity (E), a more rapid deceleration time (DT) of early mitral inflow, reduced mitral annular velocity (e'), and therefore higher E/e' ratio. The E/e' ratio has been correlated with elevated LV filling pressures [9, 10].

Hepatomegaly results from increased central venous pressure and is often accompanied by right upper quadrant tenderness. Based on various components of the history and physical examination, patients with ADHF can be assigned to one of the quadrants of a 2 × 2 table, each of which represents a distinct hemodynamic profile defined by the presence or absence of congestion (wet or dry) and low or normal perfusion (cold or warm) (Fig. 10.1) [11]. This strategy is very useful in selecting initial therapy and identifying prognosis in patients with ADHF.

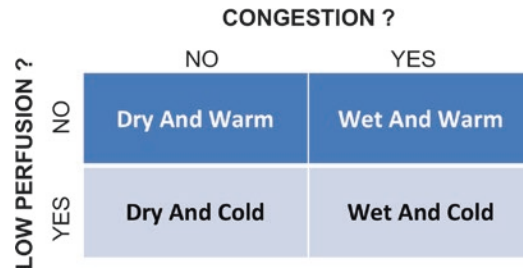

Fig. 10.1 Hemodynamic profiles in ADHF. Evidence for *congestion* (the "yes-no" delineation of the two columns) includes orthopnea, elevated JVP, hepatojugular reflux, S3, rales, hepatomegaly, ascites, peripheral edema, and a loud P2. Evidence *for low perfusion* (the "yes-no" delineation of the two rows) includes narrow pulse pressure, cool and clammy extremities, altered mentation, and oliguria

Case 2

A 54-year-old lady with known history of a heart murmur for over two decades presents with symptoms of worsening fatigue, dyspnea on exertion, and palpitations for the last 2 years. On examination, her pulse is irregular with a heart rate of 110 beats per minute and her blood pressure is 132/84 mm Hg. The jugular venous pressure is elevated to 12 cm of water. Cardiovascular exam reveals laterally displaced, brisk, enlarged, and hyperdynamic apical impulse. The S1 is normal and there is a loud 3/6 holosystolic murmur radiating to the axilla and to the left paravertebral region. In addition, a parasternal right ventricular heave is palpable and a loud P2 is audible. The pulmonary exam is notable for bibasilar rales. Abdominal examination is unremarkable and there is trace bilateral pedal edema.

This patient has chronic severe mitral regurgitation (MR), likely secondary to mitral valve

prolapse (MVP). Although this patient's history and physical findings are classic, clinical findings in MR vary depending on acuity, severity, and the mechanism. For example, in acute severe MR, sometimes caused by acute papillary muscle rupture or endocarditis, the apical LV impulse is not displaced because the LV has not had a chance to dilate. In acute severe MR, the systolic murmur may be early in timing and decrescendo in configuration due to rapid systolic equalization of pressures between the left ventricle and the left atrium (LA). The LA pressure would have a large "V" wave during ventricular systole. MVP is sometimes associated with (1) one or more systolic clicks, produced by sudden tensing of the elongated chordae tendineae as the leaflets prolapse, and (2) a holosystolic or late systolic murmur. In less than severe MR, it is useful to observe the onset of the murmur and the timing of systolic click in MVP, both of which move earlier in systole with maneuvers which reduce left ventricular end diastolic volume (such as standing and the Valsalva maneuver), while the murmur becomes louder. Conversely, the onset of the murmur and the timing of systolic click in MVP are delayed later in systole with maneuvers that increase left ventricular end diastolic volume (such as squatting) and the murmur becomes softer (Fig. 10.2) [12]. Severe MR is often associated with a holosystolic murmur that radiates

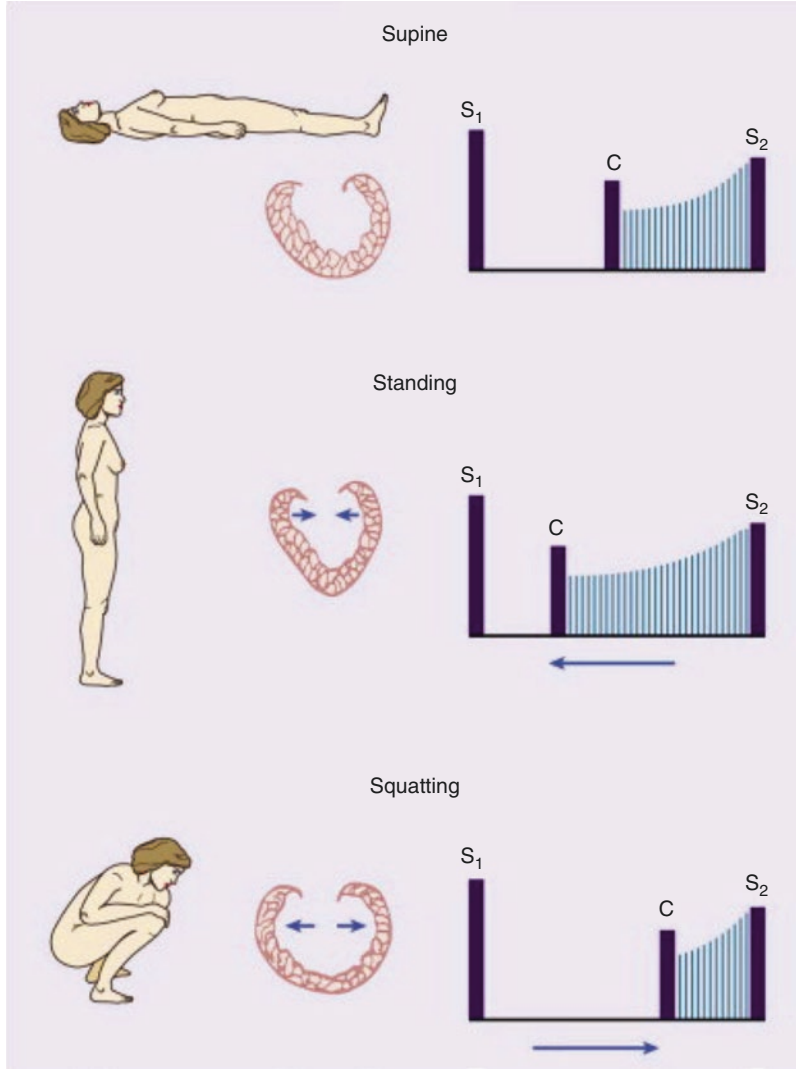

Fig. 10.2 Behavior of the nonejection click (C) and systolic murmur of mitral valve prolapse. The top panel shows the first heart sound (S1), the mid-systolic click (C), and the second heart sound (S2), with the late systolic murmur of moderate mitral regurgitation while the patient is supine. With standing, (middle panel) venous return decreases, the heart becomes smaller, and the prolapse occurs earlier in systole. The click and murmur move closer to S1. With squatting, (lower panel) venous return increases, causing an increase in left ventricular chamber size. The click and murmur occur later in systole and move away from S1. (From Shaver et al. [27])

posteriorly to the axilla and around to the left paravertebral region in the back, irrespective of which mitral leaflet is involved. As mitral regurgitation becomes chronic, left ventricular volume overload leads to left atrial enlargement and atrial fibrillation is common. With development of pulmonary hypertension, the P2 component of the second heart sound becomes louder. The S2 splitting may widen with more severe MR, due to a combination of early A2 as a result of decrease in left ventricular ejection time and delay in P2.

Case 3

A 64-year-old man with history of coronary artery bypass grafting (CABG) 15 years ago presents with complaints of increasing dyspnea on exertion over the last 12 months. Recently he has also noted worsening leg edema and increasing abdominal girth. On examination, his heart rate is 90 beats per minute and regular, and his blood pressure is 108/74 mm Hg. The jugular venous pressure is elevated to 14 cm of water with a prominent, rapidly collapsing *y* descent and a positive Kussmaul sign. The apical impulse is not displaced. The S1 and S2 are normal and there is a high-pitched early diastolic sound, corresponding with the prominent y descent seen in jugular venous waveform, which is heard best at the LV apex. Abdominal examination reveals pulsatile hepatomegaly with evidence of ascites. Bilateral lower extremity edema is present.

This patient likely has pericardial constriction, based on his history and physical findings. Subsequent imaging and cardiac catheterization confirmed this diagnosis. Constriction is characterized by thickened, scarred, and/or calcified pericardium that markedly limits diastolic filling of the heart. The jugular venous waveforms help clarify hemodynamics in constrictive pericarditis. Jugular venous pressure contour normally has two distinct positive waves (*a* and *v* wave) and two negative waves (*x* and *y* descent) (Fig. 10.3a). The *a* wave occurs with right atrial systole and follows the P wave on EKG and precedes the first heart sound (S1). The *x* descent normally occurs as RA pressure falls after the *a* wave and ventricular systole pulls the tricuspid valve and the RA downward. The *c* wave interrupts the *x* descent

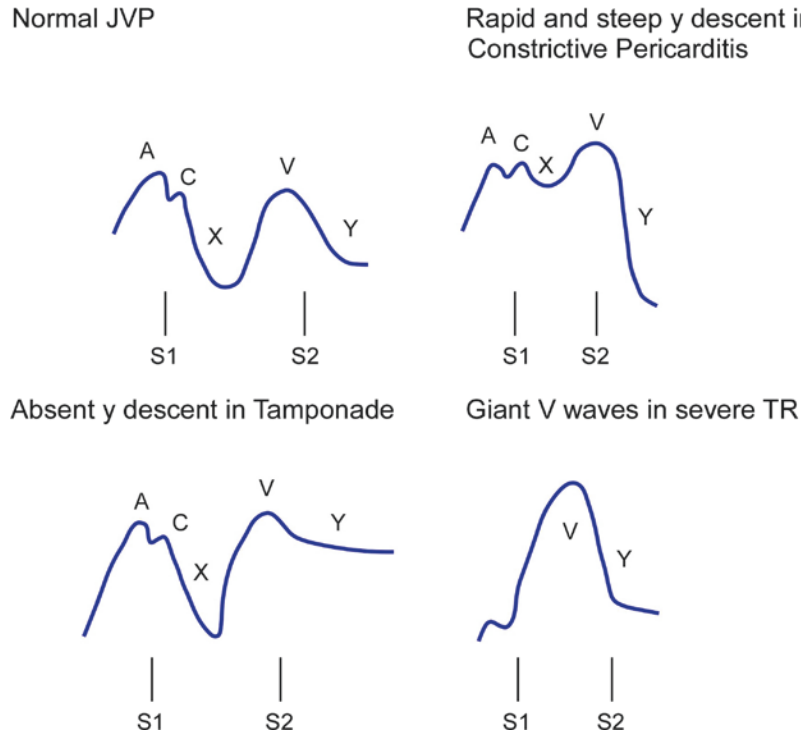

Fig. 10.3 Jugular venous waveform patterns – (**a**) normal patients, (**b**) (constrictive pericarditis), (**c**) pericardial tamponade and (**d**) (severe tricuspid regurgitation) (TR). JVP jugular venous pressure, S1 first heart sound, S2 second heart sound. The A, C, and V positive waves, and the X and Y negative waves, are explained in the text

during early ventricular systole as the tricuspid valve is briefly pushed in to the right atrium as the ventricle begins contracting, thereby elevating RA pressure briefly. The *v* wave occurs with RA filling at the end of ventricular systole, just after the second heart sound (S2). The *y* descent follows the v wave and occurs with fall in RA pressure after the tricuspid valve opens and fills the RV in diastole. Regarding the abnormal jugular venous pressure waveform in constrictive pericarditis, the most prominent wave is the rapid *y* descent, as the ventricles fill rapidly during early diastole due to elevated atrial pressures. Once the pericardial constraining volume is reached, however, ventricular filling slows abruptly due to the development of high ventricular pressure, which is manifested as the characteristic dip and plateau in ventricular diastolic pressures. The JVP contour therefore has an M or W-shaped contour (Fig. 10.3b), with a prominent, rapidly collapsing *y* descent, along with a normal or reduced *x* descent. Another feature of constriction is the respirophasic changes in jugular venous pressure. In normal individuals, JVP falls with inspiration as a reflection of the reduction in the intrathoracic pressure; the increased venous return is accommodated by the compliant right ventricle. In constrictive pericarditis, the increased venous return is not accommodated well; the increased venous return meets the stiff and inelastic pericardium, resulting in a rise in jugular venous pressure with inhalation, characteristically referred to as Kussmaul sign [13]. The classic (sometimes the only) auscultatory finding in constrictive pericarditis is a high-pitched early diastolic sound, referred to as pericardial knock, which occurs due to the abrupt cessation of blood during early diastolic ventricular filling. The pericardial knock corresponds in timing with the prominent y descent in JVP [14].

Case 4

A 66-year-old lady with history of metastatic breast carcinoma presents with worsening dyspnea on exertion for the last 3 days. On examination, her heart rate is 110 beats per minute, blood pressure is 88/56 mm Hg, and there is a paradoxical pulse of 20 mm Hg. The jugular venous pressure is markedly elevated to the angle of the jaw, with an absent *y* descent. The apical impulse is reduced and the heart sounds are muffled and distant. Pulmonary examination reveals clear breath sounds bilaterally.

The triad of hypotension, elevated JVP, and muffled heart sounds, also known as Beck's triad, should alert one to the possibility of cardiac tamponade. This was first described in 1935 by Claude Schaeffer Beck, who was Professor of Cardiovascular Surgery at Case Western Reserve University. Cardiac tamponade occurs when fluid of any kind accumulates in the pericardial space, to an extent where high intrapericardial pressure limits cardiac filling. This leads to markedly elevated venous pressures and reduced cardiac output, which can be rapidly fatal if not treated promptly. A relatively small amount of fluid that accumulates rapidly in the pericardial space can lead to tamponade. In case of a slowly accumulating pericardial effusion, a much larger volume of fluid may be necessary to cause tamponade as the pericardial pressure-volume relation shifts to the right, with greater compliance of the parietal pericardium [15, 16]. In either situation, once a critical amount of fluid has accumulated in the pericardial space, the intrapericardial pressure rises significantly even with relatively smaller rises in volume. The increased intrapericardial pressure may impair cardiac filling and reduce cardiac output. As a compensatory mechanism for maintaining cardiac output and blood pressure, tachycardia is nearly always present in tamponade. One exception to this rule is when the underlying cause for pericardial effusion and resultant tamponade is hypothyroidism. The JVP in pericardial tamponade is almost always elevated, and is sometimes associated with venous distension in the forehead and scalp. The jugular venous waveform is characterized by an absent *y* descent (Fig. 10.3c) due to restricted or diminished ventricular filling even in early diastole with the markedly elevated pericardial pressure. This pattern is in contrast to constrictive pericarditis where ventricular filling in early diastole is rapid and abbreviated prior to its cessation in mid-diastole due to the pericardial constraint.

Pulsus paradoxus, described by Adolf Kussmaul in 1873, is a helpful sign of cardiac tamponade. Pulsus paradoxus is defined as an abnormally large (>10 mm Hg) decline in systolic blood pressure during inhalation and is a consequence of exaggerated ventricular interdependence and exaggerated effects on left- and right-sided filling due to changes in intrathoracic pressure (Fig. 10.4). Normally, the inspiratory decrease in intrathoracic pressure causes an increase in systemic, venous return and a decrease in pulmonary venous return, with a small movement of

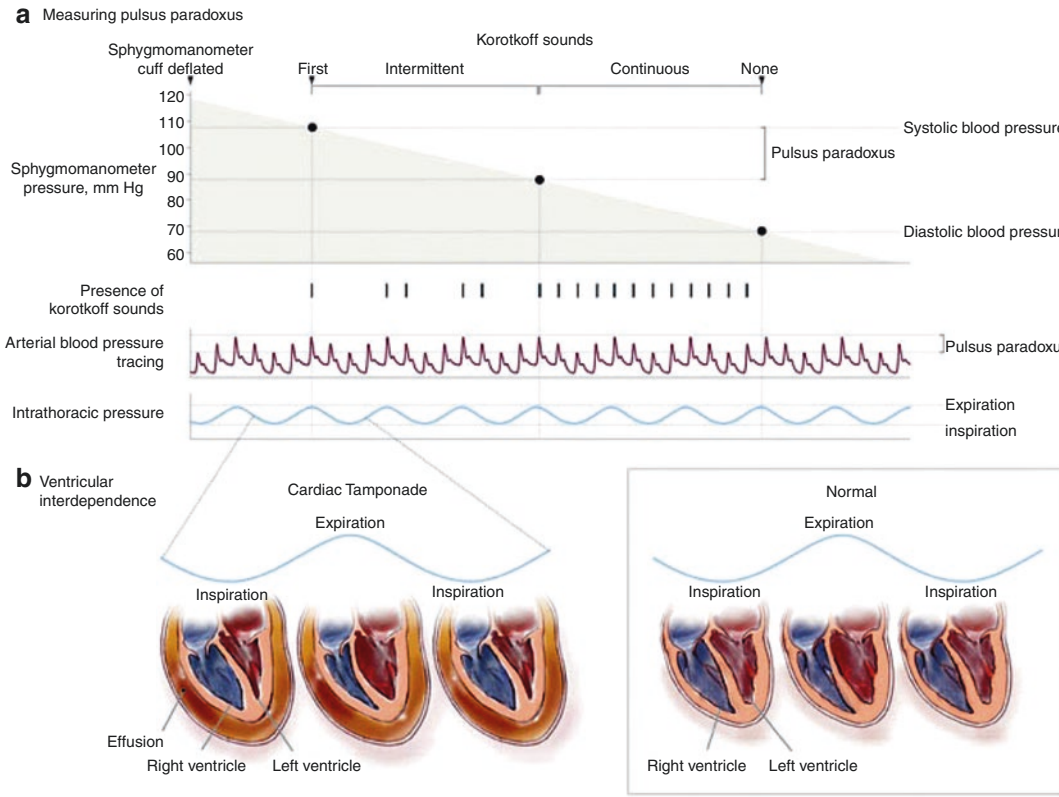

Fig. 10.4 Measurement and mechanism of pulsus paradoxus (**a**) The examiner inflates the sphygmomanometer cuff fully, listens for Korotkoff sounds as the cuff is slowly deflated, and then notes the pressure at which Korotkoff sounds are initially audible only during expiration. As the cuff is further deflated, the examiner notes the pressure at which Korotkoff sounds become audible during expiration and inspiration. The difference between these two pressures is the pulsus paradoxus, which can normally be from 0 to 10 mm Hg. In cardiac tamponade, the pulsus paradoxus measures greater than 10 mm Hg. Inspiratory diminution in the arterial blood pressure tracing represents the pulsus paradoxus. A similar phenomenon may be observed on a pulse oximeter waveform. (**b**) During inspiration in the normal heart, negative intrapleural pressures increase venous return to the right ventricle and decrease pulmonary venous return to the left ventricle by increasing the pulmonary reservoir for blood. As a result of increased right ventricular distention, the interventricular septum bows slightly to the left, and the filling and stroke volume of the left ventricle are mildly reduced. In expiration, these changes are reversed, resulting in the septum bowing to the right and a mild reduction in right ventricular filling. In the presence of cardiac tamponade, the reciprocal changes seen in the normal heart are exaggerated when the pericardial sac is filled with fluid, thus limiting distensibility of the entire heart. This results in a more dramatic reduction in filling of the left ventricle during inspiration, exacerbating the normal inspiratory decrease in stroke volume and blood pressure. (From Roy et al. [28])

the interventricular septum toward the left. The small decrease in left ventricular stroke volume and aortic peak systolic blood pressure results primarily due to inspiratory decrease in LV filling from the decrease in intrathoracic pressure. With tamponade, in presence of pericardial fluid compressing all the walls of the heart, these respiratory changes in venous return are exaggerated. With inhalation, the drop in left-sided filling reduces left ventricular stroke volume and the systemic systolic blood pressure drops by a greater extent than in normal physiology, i.e., more than 10 mm Hg. In patients with true tamponade, pulsus paradoxus can be masked by the presence of numerous conditions, including severe hypotension, pericardial adhesions, right ventricular hypertrophy, severe aortic regurgitation, a stiff left ventricle or other conditions which elevate LV filling pressure, and atrial septal defect [16].

Case 5

A 78-year-old male with history of hypertension, hyperlipidemia, and diabetes mellitus presents with worsening dyspnea on exertion over the last 2 years. On examination, he has a slow-rising, late-peaking, low-amplitude carotid contour by palpation. His heart rate is regular at 88 beats per minute and blood pressure 108/66 mm Hg. The jugular venous pressure is normal. The apical impulse is sustained and non-displaced. Cardiac auscultation reveals normal S1, a soft S2 without splitting, and a 3/6 late peaking systolic ejection murmur, best heard in the right second intercostal space and radiating to the carotids. Pulmonary examination reveals clear breath sounds bilaterally. Abdominal examination is unrevealing and he has no pedal edema.

Based on clinical findings, this patient likely has severe aortic stenosis (AS). Hemodynamically, AS is characterized by a pressure gradient between the left ventricle and aorta during systole (Fig. 10.5a), and the magnitude of this pressure gradient is an indication of the severity of AS. Several physical findings have been shown to correlate with severity of AS, including the characteristic carotid pulse contour, a reduced or absent S2, and the timing and intensity of murmur (Table 10.1) [17]. The quality of carotid pulse in severe AS has classically been described as "parvus et tardus," i.e., weak and slow-rising and delayed. This can be best assessed best by simultaneously palpating the carotid pulse and auscultating the heart. In severe AS, the weak and delayed carotid pulse reflects severe obstruction, with a reduced early systolic rate of blood flow across the aortic valve into the arterial circulation. Delay between brachial and radial pulse (brachioradial delay) has also been described as a clinical indicator of severe AS [18]. With worsening AS, the aortic valve leaflets become increasingly calcified and immobile, leading to a soft or inaudible A2 component of the second heart sound. A normal intensity of A2 implies flexible and mobile aortic valve leaflets and can essentially be very helpful in ruling out severe senile AS. However, the A2 may still be normal in severe AS in young people whose stenosis reflects more congenital fusion of the cusps and less calcific restriction. The gradient between the left ventricle and aorta in AS is greatest in mid-systole and is relatively small early and late in systole. The murmur therefore has a diamond shape; it starts soft and builds to a peak in mid-systole and then becomes quiet in late systole immediately before S2 (Fig. 10.5a). It is referred to as a systolic ejection murmur, since it begins after S1 and ends before S2. The intensity of murmur correlates generally with severity of AS, but there are many exceptions to that correlation. It is best heard at the base of the heart in the second right intercostal space and radiates to the carotids. The timing of the peak intensity of systolic ejection murmur also corresponds to the severity of AS. With mild AS, the maximum instantaneous gradient between the left ventricle and aorta occurs early in systole;

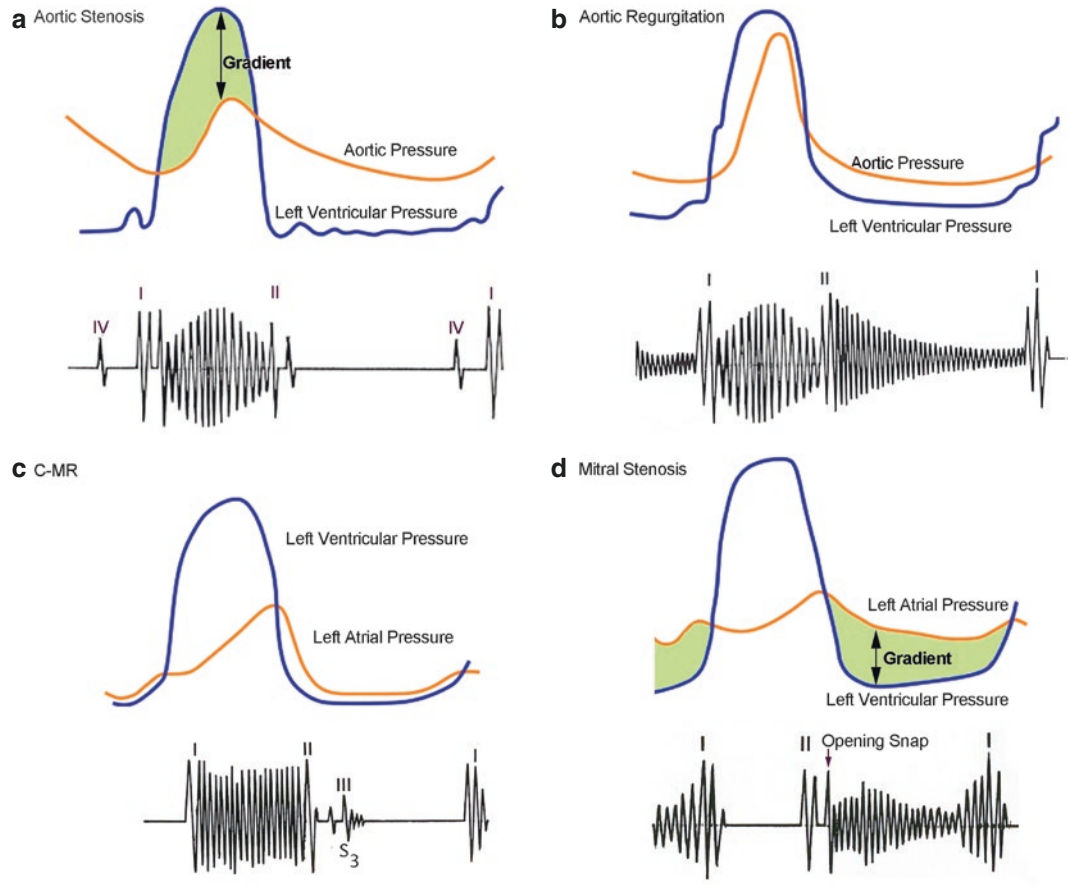

Fig. 10.5 Relationship of murmurs to LV, aortic, and LA pressure waveforms and hemodynamics in various valve diseases. (**a**) *Aortic stenosis (AS).* The gradient between the left ventricle and aorta in AS is greatest in mid-systole and is relatively small early and late in systole. The murmur therefore has a diamond shape, i.e., starts soft and builds to a peak in mid-systole and then becomes quiet in late systole immediately before S2. In young AS patients, there may be an early ejection sound. In senile AS, A2 becomes diminished or absent. An S4 is common due to LV noncompliance. (**b**) *Aortic regurgitation (AR)*. The early diastolic murmur (EDM) begins with S2 and has a decrescendo contour. The duration of the murmur continues for a variable time in diastole, depending on severity and acuity of AR. Notice that aortic diastolic pressure is low. (**c**) *Mitral regurgitation*. There is a pansystolic murmur with a flat profile due to the regurgitant flow into the left atrium. Note that the left atrial pressure rises during systole, a "v" wave. An early diastolic S3 or flow rumble may occur. (**d**) *Mitral stenosis (MS)*. A loud S1 is heard since the mitral gradient is high and the leaflets are not very thickened or calcified. An important indicator of the severity of MS is the time interval between the S2 and opening snap (OS), which is the time it takes for LV pressure to fall from late systolic aortic pressure to early diastolic left atrial pressure. The mitral valve snaps open due to the increased gradient, causing an opening snap (OS). The diastolic murmur correlates with the gradient across the mitral valve, which is largest in early diastole, and increases again in late diastole in this patient in sinus rhythm

hence the systolic murmur peaks in early systole. As the severity of AS worsens, the maximum instantaneous gradient between the left ventricle and the aorta occurs progressively later in systole, and correspondingly the murmur peaks late. No single physical examination finding rules in or rules out severe AS; however, a combination of slow and delayed carotid impulse, reduced intensity of S2, and mid to late peaking systolic ejection murmur at the base radiating to the neck is fairly accurate in diagnosing severe AS clinically [19].

Table 10.1 Physical findings in severe aortic stenosis

Examination	Finding
Carotid pulse	Weak, slow rising, and delayed carotid pulse (pulsus parvus et tardus)
Second heart sound (S2)	Soft or inaudible A2 component of S2
Murmur	Mid to late peaking in systole, radiating to the neck

Case 6

A 56-year-old asymptomatic male is referred for evaluation after his primary care physician heard a heart murmur. On examination, he has a rapidly collapsing pulse with a regular heart rhythm, heart rate of 90 beats per minute and blood pressure of 144/40 mm Hg, and therefore a pulse pressure of 104 mm Hg. Cardiac examination reveals a wide and hyperdynamic apical impulse that is displaced laterally and inferiorly. A high-frequency, blowing decrescendo diastolic murmur is heard, best at the left sternal border in end expiration with the patient sitting up. There is also a short early systolic murmur of moderate intensity. In addition, a systolic and diastolic bruit is heard when the femoral artery is partially compressed and popliteal systolic cuff pressure is >170 mm Hg. Pulmonary and abdominal exam are unremarkable.

No other disease condition in cardiovascular medicine has more eponymous signs associated with it than chronic aortic regurgitation (AR) (Table 10.2). The principal hemodynamic abnormality in chronic AR responsible for these signs is the wide pulse pressure (Fig. 10.5b). The low diastolic arterial pressure results from the rapid run-off of blood from the aorta back into the left ventricle. There is an increase in left ventricular end diastolic volume and hence an increase in left ventricular stroke volume and the pulse pressure. The arterial pulse contour has a rapidly rising and collapsing pulse referred to as "water hammer" pulse, or Corrigan's sign, first described by Sir Dominic Corrigan in 1832. The carotid upstroke is rapid resulting from the increased stroke volume. Few studies have systematically assessed the predictive value of these eponymous signs in Table 10.1; however Duroziez's sign, Corrigan pulse, and Hill's sign are perhaps most important useful signs in detecting severe chronic AR [20]. In a literature review, the presence of a diastolic decrescendo murmur as heard by a cardiologist was the most useful finding for detecting AR (positive likelihood ratio of 8.8), and its absence was most useful in ruling out AR [21]. The diastolic murmur of chronic AR is high-pitched and blowing in character and is best heard along the left sternal border at the left third or fourth intercostal space, with the patient sitting up and leaning forward, with held exhalation. The severity of chronic AR correlates somewhat with the duration of the murmur, while its intensity varies widely. With severe chronic AR, the murmur can be holodiastolic. However, in very severe AR, particularly sudden onset acute AR, the murmur may be early diastolic and short, due to rapid equilibration of LV and aortic pressure. Most patients with severe AR also have an early peaking systolic flow murmur which results from the increased stroke volume even in the absence of concomitant AS. Finally, an apical mid-late diastolic rumble, referred to as the Austin-Flint murmur is audible

Table 10.2 Eponymous signs of chronic aortic regurgitation

Sign	Description
Hill's sign	Exaggerated difference in lower and upper extremity blood pressure
Corrigan's sign	Rapidly collapsing arterial pulse
Duroziez's sign	Systolic and diastolic bruit heard on partial femoral artery compression
Quincke's sign	Exaggerated capillary pulsations of the nail beds
deMusset's sign	Head bobbing with each heart beat
Traube's sign	Pistol shot sound heard over the femoral artery
Mueller's sign	Pulsatile uvula
Becker's sign	Pulsatile retinal arteries
Rosenbach's sign	Pulsatile liver
Gerhard's sign	Pulsatile spleen
Mayne's sign	More than 15 mm hg drop in diastolic blood pressure with arm elevated compared to arm in standard position

in occasional patients with chronic severe AR, reflecting the impact of the AR jet on the anterior mitral valve leaflet; this should not be confused with the diastolic rumble of mitral stenosis.

Case 7

A 62-year-old male with 30 pack-year history of smoking, hypertension, hyperlipidemia, and diabetes mellitus presents to the ER after experiencing worsening substernal chest discomfort radiating to the left arm for 8 hours. On arrival, he appears diaphoretic with a heart rate of 104 beats per minute, blood pressure of 90/68 mm Hg and he is tachypneic with a respiratory rate of 20 per minute and an oxygen saturation of 94% on room air. He is drowsy and somewhat disoriented. Stat 12 lead EKG reveals widespread 3 mm ST segment elevation in precordial leads V1 through V6 and reciprocal ST segment depression in inferior limb leads. Cardiovascular examination reveals elevated JVP at 12 cm and normal heart sounds with no murmurs, rubs or gallops. Pulmonary examination reveals bibasilar rales. Abdominal examination is unrevealing and he has no lower extremity edema, but his extremities are cold and clammy. With a diagnosis of acute ST segment elevation myocardial infarction (STEMI) and cardiogenic shock, he is emergently taken to the cardiac catheterization laboratory. The proximal left anterior descending coronary artery (LAD) is found to be totally occluded, so it is opened and stented. Pulmonary artery catheterization shows a PCWP of 28 mm Hg, with a cardiac index of 1.7 L/min per m^2, and an intra-aortic balloon pump (IABP) is placed. Emergent echocardiogram did not show any evidence of mechanical complications of MI.

Cardiogenic shock is characterized by end-organ hypoperfusion due to cardiac dysfunction and is hemodynamically defined by persistent hypotension (systolic blood pressure <80 to 90 mmHg or mean arterial pressure 30 mmHg lower than baseline) with severe reduction in the cardiac index (<1.8 L/min per m^2 without support or <2.0 to 2.2 L/min per m^2 with support) and adequate or elevated filling pressures [22]. The most common cause of cardiogenic shock is acute myocardial infarction (MI) with left ventricular failure. In the setting of MI, it is very important to rule out mechanical complications such as acute severe MR secondary to papillary muscle dysfunction, ventricular free wall rupture, or ventricular septal defect, all of which can contribute to cardiogenic shock. Other causes of these alarming hemodynamics include acute severe LV or RV dysfunction of any etiology, valvular heart disease such as acute mitral or aortic regurgitation, pericardial tamponade, massive pulmonary embolism, acute aortic dissection, hypertrophic obstructive cardiomyopathy, and acute myocarditis. The hallmark of cardiogenic shock is hypoperfusion of the extremities and vital organs. Loss of cardiac output from any cause increases sympathetic activation, which increases arteriolar constriction and systemic vascular resistance, in an attempt to maintain blood pressure and tissue perfusion. Clinically, cardiogenic shock manifests with signs of reduced end-organ perfusion such as altered mental status, oliguria, respiratory distress due to pulmonary congestion, and cool, clammy extremities. Such patients are typically in the bottom right on the hemodynamic profile chart presented in Fig. 10.1, i.e., wet and cold. However, not all patients in cardiogenic shock have vasoconstriction and elevated systemic vascular resistance. Almost a fifth of patients with cardiogenic shock studied in the SHOCK trial had hemodynamic findings of low systemic vascular resistance, similar to patients with sepsis. This probably results from inappropriate vasodilation, which may represent a systemic inflammatory response state (SIRS) similar to sepsis [22, 23]. Cardiogenic shock can be diagnosed based on clinical findings, but invasive hemodynamic monitoring helps confirm and quantify the degree of vasoconstriction or vasodilation, quantifying filling pressures and cardiac output and ultimately guiding therapy.

Case 8

A 78-year-old woman is brought to the ER with fever, cough, shortness of breath, and altered mental status. She has had intermittent fever

and cough with productive sputum for the last 3 days. On arrival to the ER, she is drowsy but arousable and confused. She is febrile with a temperature of 39 °F, heart rate of 120 beats per minute and regular, blood pressure of 80/50 mm Hg, tachypneic with a respiratory rate of 22 beats per minute, and an oxygen saturation of 90% on room air. Cardiovascular examination reveals no jugular venous distension and rapidly collapsing jugular vein distension even when supine. She has normal heart sounds and no murmurs, rubs, or gallops. Pulmonary exam reveals bronchial breath sounds and rales in the right lower zone with egophony and dullness on percussion. Abdominal exam is unrevealing, and peripheral extremities are warm to touch with capillary refill >3 seconds and mottling of skin. Chest X-ray confirms right lower lobe consolidation.

This patient is in septic shock. It is similar to the patient in case 7; however the mechanism and pathophysiology are different. Also called distributive or vasodilatory shock, the hallmark of septic shock is profound vasodilation and inadequate tissue extraction of oxygen. Vasodilation is mediated by three mechanisms: activation of ATP-sensitive potassium channels in the vascular smooth muscle cell plasma membranes, activation of inducible nitric oxide synthetase, and deficiency of vasopressin [24]. This is followed by leukocyte migration and activation and release of pro-inflammatory markers such as tumor necrosis factor (TNF) and interleukins, which lead to tissue damage and organ dysfunction, which manifest as a systemic inflammatory response state (SIRS).[25] SIRS is defined by the presence of one of the following:

- Temperature >38.5 °F or <35 °F
- Heart rate >90 beats per minute
- Respiratory rate >20 per minute or PaCO2 <32 mm Hg
- WBC >12,000 cells/mm^3, <4000 cells/mm^3, or >10% immature band forms

Sepsis is defined as SIRS in presence of an infection. Similarly, severe sepsis and septic shock are largely clinical diagnoses [25]. Severe sepsis is defined as the presence of sepsis and one of the following signs of organ dysfunction:

- Areas of mottled skin.
- Capillary refilling requires 3 seconds or longer.
- Urine output <0.5 mL/kg for at least 1 hour, or the need for renal replacement therapy.
- Elevated blood lactate levels >2 mmol/L.
- New decrease in mental status.
- Platelet count <100,000 platelets/mL.
- Disseminated intravascular coagulation.
- Acute lung injury or acute respiratory distress syndrome (ARDS).
- Cardiac dysfunction, as defined by echocardiography or direct measurement of the cardiac index.

Septic shock is defined by the presence of severe sepsis and one of the following:

- Systemic mean blood pressure <60 mm Hg (<80 mm Hg if previous hypertension) after adequate fluid resuscitation or PCWP between 12 and 20 mm Hg
- Need for dopamine >5 mcg/kg per min or norepinephrine or epinephrine <0.25 mcg/kg per min to maintain mean blood pressure above 60 mm Hg (80 mm Hg if previous hypertension)

Thus sepsis has a continuum of severity ranging from sepsis manifesting as SIRS to severe sepsis and septic shock. Despite optimal management, mortality from severe sepsis and septic shock can range from 40% to 50% or higher. The key for successful outcome is early identification of the severity of this continuum and of a potential infectious focus.

Case 9

A 54-year-old man with history of chronic alcohol abuse and liver cirrhosis presents with hematemesis. On examination, he is afebrile with a heart rate of 78 beats per minute and blood pressure of 130/80 mm Hg when supine and 110 beats

per minute and 102/60 mm Hg when standing. He feels dizzy on standing. His tongue, axillae, and mucous membranes are moist. Cardiac, pulmonary, and abdominal exams are unrevealing.

This patient has hypovolemia likely secondary to blood loss, in this case, bleeding esophageal varices. Hypovolemia occurs when extracellular sodium and fluid are lost at a rate greater than intake. This may occur by way of gastrointestinal losses (hemorrhage, vomiting, diarrhea), renal losses (diuresis, salt wasting), loss from skin (burns), or third space sequestration (acute pancreatitis, acute intestinal obstruction, fracture). One of the most common causes of hypovolemia is excessive use of diuretic medications. History and physical examination are important in identifying the presence, etiology, and severity of hypovolemia, perhaps even more so than laboratory testing. For example, the initial hemoglobin correlates poorly with the degree of blood loss, even in patients whose hypovolemia is due to gastrointestinal hemorrhage. Similarly prerenal azotemia is a late finding in acute dehydration. Postural assessment of systolic blood pressure is the most rapid and reliable bedside tool, in the absence of autonomic neuropathy or over-use of antihypertensive drugs. A drop of more than 10 mm Hg when the patient goes from supine to standing is indicative of at least a 10% deficit in intravascular volume. In a systematic review of physical findings in assessment of patients with blood loss and hypovolemia, severe postural dizziness and an increase in pulse rate $\geq$ 30 beats per minute were found to be the most sensitive and specific findings for large blood loss [26]. In the same study, the presence of dry axilla supported the diagnosis of hypovolemia in patients with vomiting, diarrhea, or decreased oral intake. Moist mucous membranes and a normal furrowed appearance of the tongue were found to argue against it. It is important to remember that postural blood pressure and heart rate should be measured with the intervention of the patient standing still for 1 minute. Jugular venous pressure is usually low in patients with hypovolemia, and it may be necessary to lay the patient down to see the venous pulsations above the clavicle. Normal skin has elasticity or turgor, i.e., it immediately returns to its normal position after being pinched and released. This is due to elastin content in the subcutaneous tissue, which is affected by moisture content and age. In younger individuals, poor skin turgor may represent hypovolemia.

Case 10

A 53-year-old lady with history of rheumatic heart disease with long-standing history of mitral stenosis, s/p balloon mitral valvotomy 15 years ago, and mitral valve replacement 8 years ago presents with worsening fatigue, exercise intolerance, abdominal distension, and lower extremity swelling. On examination, she has an irregularly irregular pulse with a heart rate of 80 beats per minute, blood pressure of 110/68 mm Hg, and respiratory rate of 16 per minute. Jugular venous pressure is elevated to 14 cm of water with a prominent V wave and a sharp y descent. Cardiac exam reveals a palpable right ventricular heave. On auscultation, the P2 is loud and a 3/6 holosystolic murmur is audible at the left lower sternal border. The murmur increases in intensity with inspiration. Abdominal examination reveals a pulsatile and enlarged liver with evidence for ascites. Moderate bilateral pedal edema is also present.

Tricuspid regurgitation (TR) is a valve lesion that occurs commonly, as a result of right ventricular dilatation from any cause, through the effects of secondary pulmonary hypertension. The most frequent cause is left-sided heart failure due to mitral valve disease or left ventricular dysfunction. TR also occurs in the setting of cor pulmonale, from intrinsic lung disease, or from primary pulmonary hypertension. Pathophysiologically, long-standing pulmonary hypertension causes right ventricular pressure overload, which causes dilatation of the right ventricle and tricuspid annulus. In patients with chronic severe TR, the JVP waveform is characterized by the loss of x descent and a prominent systolic V wave (or C-V wave) caused by markedly increased right atrial pressure during ventricular systole, which is followed by a rapid y descent (Fig. 10.3d). Auscultation usually reveals a loud P2 in pres-

ence of pulmonary hypertension. There may be a pansystolic murmur, loudest in about the fourth intercostal space in the left or right parasternal region. Classically, the systolic murmur intensity increases with inspiration (Carvallo sign) as the venous return on the right side of the heart increases; however, this finding is inconsistent. Many patients with significant TR do not have respirophasic variation, and some have an unimpressive murmur. In the absence of pulmonary hypertension, TR may also occur as a primary valve abnormality, due to trauma, or endocarditis classically in patients who have used intravenous drugs, but increasingly in patients with infected pacemaker leads. In severe TR, there is an increase in diastolic flow, so many patients have a diastolic rumble (sometimes quite loud) along the left sternal border and/or a right sided S3. With severe long-standing TR, the pressure gradient between the right atrium and right ventricle is minimized, and the TR murmur may be short early systolic, barely audible, or absent. A pulsatile liver is often present in severe TR, and ascites and extremity edema are commonly present.

Case 11

A 52-year-old male, with no risk factors for coronary artery disease, presents with symptoms of shortness of breath on exertion and two episodes of near syncope. He has family history of sudden death. On examination, his carotid pulse has a rapid upstroke, followed by a second peak. His heart rate is 60 beats per minute and blood pressure 120/80 mm Hg. His jugular veins are not distended. The apical impulse is wide, sustained, and laterally displaced. On cardiac auscultation, S1 is normal and S2 is paradoxically split. A harsh crescendo-decrescendo 3/6 systolic murmur, heard best at the left sternal border, increases in intensity with the Valsalva maneuver, breath holding with increased abdominal pressure. His lungs are clear on auscultation, and abdominal examination is unrevealing.

Based on physical findings, this patient has hypertrophic cardiomyopathy (HCM). HCM is a common genetic cardiovascular disease and is defined as significant myocardial hypertrophy in the absence of an identifiable cause. The most common sites of ventricular hypertrophy are, in decreasing order, the septum, apex, and mid ventricle. It is further classified as obstructive or non-obstructive, depending on whether a dynamic left ventricular outflow tract (LVOT) gradient is present, either at rest or with provocative maneuvers. LVOT obstruction is the main pathophysiologic mechanism in HCM. The hypertrophied proximal interventricular septum combines with systolic anterior motion (SAM) of the mitral valve leaflets toward the septum, which causes LVOT obstruction and also mitral regurgitation. LVOT obstruction in HCM is dynamic, in contrast to valvular or membranous AS where obstruction to LV outflow is fixed. In dynamic LVOT obstruction, the degree of obstruction varies with cardiac contractility and loading conditions, whereas in case of fixed obstruction such as AS, the degree of obstruction doesn't vary as much with maneuvers. Purposeful alterations in cardiac hemodynamics can be very useful at the bedside in differentiating systolic murmurs of HCM and AS (Table 10.3). Almost all cardiac murmurs decrease in intensity with the Valsalva maneuver except the murmur of HCM. The Valsalva maneuver decreases preload which results in reduced filling of the left ventricle and hence an increase in LVOT obstruction, thus increasing the intensity of systolic murmur in HCM. Similarly, change in position from squatting to standing reduces venous return and preload, thus increasing

Table 10.3 Effect of maneuvers on hypertrophic cardiomyopathy and aortic stenosis

Maneuver	Hemodynamic effect	AS murmur intensity	HCM murmur intensity
Valsalva	Decreased preload	Decreases	Increases
Squat to stand	Decreased preload	Decreases	Increases
Stand to squat	Increased preload	Increases	Decreases
Amyl nitrite inhalation	Decreased preload	No change	Increases

murmur intensity in HCM. Inhalation of amyl nitrite results in vasodilation and decreased preload, which again worsens LVOT obstruction in HCM and the murmur intensity increases. The gradient also increases in the beat after a premature ventricular complex (PVC) and during other types of positive inotropic activity, such as intravenous or endogenous catecholamines. Presence of a loud murmur of at least grade 3/6 usually implies LVOT outflow gradient of greater than 30 mm Hg. The carotid pulse in patients with HCM is characterized by an initial rapid upstroke as no LVOT obstruction exists in early systole. This is followed by a collapse in the pulse as LVOT obstruction develops, followed by a second peak as left ventricular pressure increases to overcome the obstruction. This is referred to as bisferiens pulse, which contrasts markedly from the carotid contour in valvular AS, as mentioned above. The second heart sound in HCM is normal in intensity, and can be paradoxically split due to prolonged ejection time with severe LVOT obstruction.

Case 12

A 45-year-old female, who immigrated from India, presents with new onset palpitations and dyspnea on exertion. She recalls having a prolonged febrile illness during childhood, followed by a murmur. On examination she has an irregularly irregular pulse with a heart rate of 84 beats per minute at rest and a blood pressure of 110/70 mm Hg. Her jugular veins are not distended. The apical impulse has a tapping quality and is undisplaced. A parasternal RV heave is felt along with a palpable P2. On auscultation, S1 is loud, P2 is loud, and an opening snap is heard just after the second heart sound. A low-pitched "rumbling" early diastolic murmur is heard at the apex with the bell of the stethoscope, with the patient in left lateral decubitus position, in held exhalation. Bibasilar rales are heard on lung auscultation. Abdominal and lower extremity exam is unrevealing.

This patient likely has significant mitral stenosis (MS) secondary to rheumatic heart disease. MS is characterized by a pressure gradient between the left atrium and left ventricle during diastole (Fig. 10.5d). The transmitral pressure gradient for any given valve area depends on the transvalvular flow rate. Increase in transmitral flow, most commonly due to exercise, leads to increased pressure gradient and elevated left atrial pressure, which in turn raises pulmonary venous and pulmonary capillary pressures, resulting in dyspnea. Atrial fibrillation or any pathologic state involving an increased heart rate, such as anemia, hyperthyroidism, or others, shortens diastole more than systole. Because the time available for flow across the mitral valve is shorter, the heart spends more percentage of the time in the early phase of diastolic mitral valve flow, when gradients are higher, contributing to marked elevation in left atrial pressure. Chronic pulmonary venous and capillary hypertension leads to pulmonary arterial hypertension and often right-sided heart failure, though not yet in this patient. Atrial fibrillation with rapid ventricular response is often a precipitating or exacerbating factor of the onset of symptoms in patients with MS and may result in pulmonary edema. In fact, MS with rapid AF is a condition where pulmonary edema responds well to beta blocker therapy. Diastolic filling time increases with reduction in heart rate, which reduces the left atrial pressure (because the mitral flow spends more time in "mid to late diastole" when the gradient is lower) and hence the pulmonary venous and capillary pressures are lower.

The physical findings in MS are attributable to two aspects of the inflammatory rheumatic process that leads to fibrosis: (1) thickening and fibrosis of the valve cusps and (2) commissural fusion. The classic auscultatory signs in mild MS, before the leaflets are very thickened, calcified, or markedly immobile, include a loud S1 and an audible opening snap (OS) after S2. The intensity of S1 and presence of the opening snap (OS) reflect the pandiastolic pressure gradient. An important indicator of the severity of MS is the time interval between the S2 and OS, which is the time it takes for LV pressure to fall from late systolic aortic pressure to early diastolic

left atrial pressure. With more severe MS, the left atrial pressure is higher and mitral valve opening occurs closer to S2, causing the S2-OS interval to decrease (Fig. 10.5d). With marked calcification and immobility of the mitral valve leaflets, both S1 and the OS become softer. The murmur of MS is a low-pitched rumbling diastolic murmur at the apex, best heard with the bell of the stethoscope with the patient in left lateral decubitus position. Listening in held exhalation brings the heart closer to the stethoscope and stops the interference of respiratory sounds. The diastolic murmur of MS can be accentuated by brief period of exercise, even just walking or running in place, due to the increased heart rate and the increase in cardiac output. In severe MS, the murmur is usually longer. In patients in sinus rhythm, the rumble is loudest when the gradients are highest, in very early and late diastole (during the atrial kick). The pre-systolic (late diastolic) accentuation of the diastolic murmur is lost when atrial fibrillation occurs.

Self-Assessment Questions

1. A 40-year-old asymptomatic lady presents for evaluation of a murmur that was heard by her primary care physician. On examination, her vital signs are normal. Her jugular veins are not distended and carotid upstrokes are normal. There is a systolic click followed by a 2/6 mid-late systolic murmur at the apex. In order to confirm your suspicion of mitral valve prolapse, you ask the patient to perform squatting and standing maneuvers. What happens to the click and the murmur with squatting and standing maneuvers in a patient with mitral valve prolapse?
   A. The click and murmur move closer to S1 with squatting and away from S1 with standing.
   B. The click and murmur move closer to S1 with standing and away from S1 with squatting.
   C. There is no change in the click or the murmur with standing or squatting.
   D. The click and the murmur decrease in intensity with standing and increase in intensity with squatting.
2. Each of the following statements regarding the JVP waveform and cardiac hemodynamics is true *except*:
   A. Constrictive pericarditis is characterized by a prominent and steep or rapidly collapsing y descent.
   B. Cardiac tamponade is characterized by an absent y descent.
   C. Cannon A wave is present in severe tricuspid regurgitation.
   D. The x descent is lost in severe tricuspid regurgitation.
3. A 52-year-old lady with history of rheumatic heart disease, with history of open mitral commissurotomy 20 years ago, presents with new onset dyspnea on exertion and worsening palpitations. On examination she has an irregularly irregular pulse with a heart rate of 118 beats per minute and a blood pressure of 100/60 mm Hg. Her jugular veins are distended. The apical impulse has a tapping quality and is undisplaced. A parasternal RV heave is felt along with a palpable P2. On auscultation, a low-pitched rumbling mid-diastolic murmur is heard at the apex with the bell of the stethoscope, with the patient in left lateral decubitus position. Bibasilar rales are heard on lung auscultation. What is the next best step in the management of this patient?
   A. Sodium nitroprusside for afterload reduction
   B. Intravenous nitroglycerin infusion for preload reduction
   C. Intravenous morphine
   D. Intravenous beta blocker therapy for rate control
4. All of the following increase the murmur intensity in patients with hypertrophic obstructive cardiomyopathy, except:
   A. Squatting
   B. Standing
   C. Valsalva maneuver
   D. Inhalation of amyl nitrite
5. Each of the following is a finding in severe aortic stenosis, except:
   A. Pulsus parvus et tardus
   B. Soft or inaudible A2
   C. Mid-late peaking systolic murmur
   D. Bisferiens pulse

Answers to Self-Assessment Questions

1. B.
   Standing leads to reduction in venous return and preload. The left ventricle therefore becomes smaller, and prolapse occurs earlier in systole, i.e., closer to S1. Concurrently the intensity of the murmur increases. Squatting leads to increase in preload, causing an increase in LV chamber size; therefore the click and murmur occur later in systole and move away from S1.
2. C.
   Cannon A wave is present in tricuspid stenosis or complete heart block where the right atrium contracts against a closed tricuspid valve due to atrio-ventricular dissociation. All other statements are true.
3. D.
   This patient has rheumatic mitral stenosis and is in heart failure secondary to atrial fibrillation with rapid ventricular response. Tachycardia shortens diastole more than systole, thus reducing the time available for flow across the mitral valve and contributing to marked elevation in left atrial pressure and pulmonary edema. Pure mitral stenosis is the only condition where acute heart failure is treated with beta blocker therapy for heart rate control.
4. A.
   Decrease in preload, secondary to any maneuver (valsalva, standing, and inhalation of amyl nitrite) results in reduced filling of the left ventricle and hence LVOT obstruction increases, thus increasing the intensity of systolic murmur in HCM. Squatting on the other hand increases preload, increasing ventricular volume and reducing the LVOT gradient, hence making the murmur softer in intensity.
5. D.
   In severe AS, the weak and delayed (parvus et tardus) carotid pulse reflects severe obstruction of blood flow across the aortic valve into the peripheral circulation. With worsening AS, the aortic valve leaflets become increasingly calcified and immobile, leading to a soft or inaudible A2 component of S2. With mild AS, the maximum instantaneous gradient between the left ventricle and aorta occurs early in systole; hence the systolic murmur peaks in early systole. As the severity of AS worsens, the maximum instantaneous gradient between the left ventricle and the aorta occurs progressively later in systole, and correspondingly the murmur peaks late. Bisferiens pulse is seen in patients with severe AR or HOCM.

Echocardiography

11

Omeed Zardkoohi and Richard A. Grimm

Introduction

Echocardiography is a powerful, noninvasive imaging tool that can provide useful hemodynamic information to guide patient management. Intracardiac pressures, cardiac output, vascular resistance, shunt fractions, and valve lesions can be assessed by using a combination of two-dimensional imaging, color Doppler, pulse and continuous wave Doppler, and tissue Doppler. While echocardiography can provide data complementary to catheter-derived measurements and in some situations has even supplanted invasive monitoring, its application requires meticulous technique, an understanding of basic principles of physics, and an appreciation of potential limitations of the method.

Basic Physics of Echocardiography

Doppler Principle

The Doppler principle explains that the frequency of a wave increases as the source of the wave moves toward an observer, while the frequency of a wave decreases as the source moves away from an observer [1]. The change in the frequency of the sound wave depends on the velocity of the moving object, the velocity of sound, and the angle at which the sound wave hits the object. Echocardiography extrapolates this principle of frequency shift to determine the velocity of blood flow in the heart. When a sound wave is transmitted from the transducer crystal at a given frequency, it is reflected by a red blood cell at a certain frequency back to the transducer (Fig. 11.1). If the red blood cell is moving toward the sound waves, the frequency will increase, but if the red blood cell is moving away from the sound wave, the frequency will decrease. The Doppler shift is the change in frequency between the transmitted sound and the reflected sound and is expressed in the following Doppler equation [2]:

$$\Delta f = f_r - f_0 = \frac{2 f_0 (\cos\theta)(v)}{c}$$

where f_0 = transmitted frequency; f_r = reflected frequency; θ = angle between the ultrasound beam and blood flow; v = velocity of red blood cells; and c = speed of ultrasound in blood (1540 m/s).

Algebraic rearrangement of the equation allows one to solve for velocity:

$$v = \frac{(c)(\Delta f)}{2(f_0)(\cos\theta)}$$

https://doi.org/10.1007/978-3-030-19131-3_11

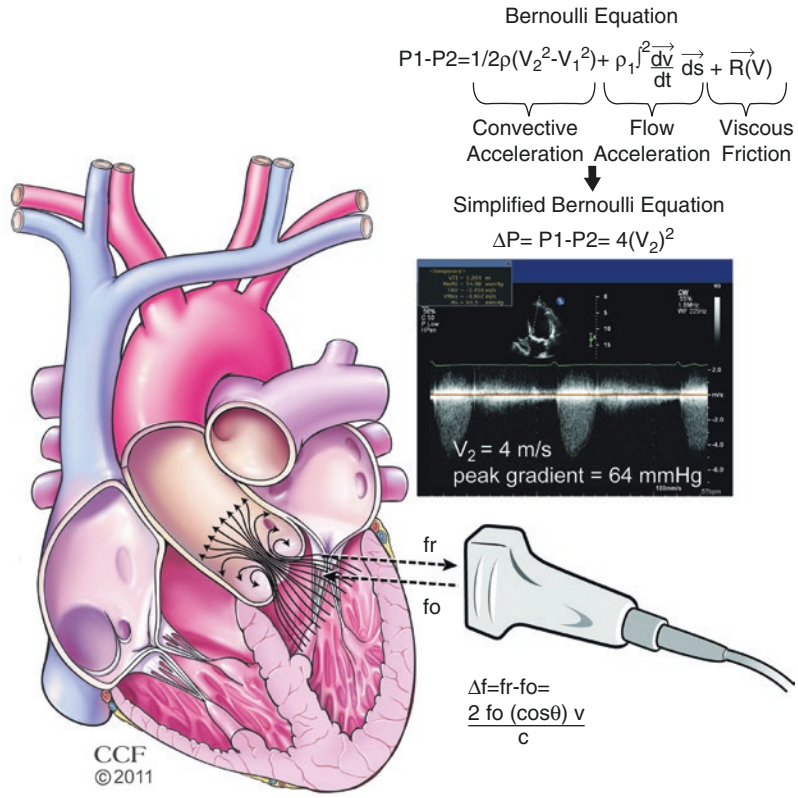

Fig. 11.1 The Doppler principle and Bernoulli equation. *Bottom right*: The echo transducer sends ultrasound waves at a given frequency (f_0) to the heart, and the sound waves are reflected back to the transducer at a different frequency (f_r). The difference between (f_0) and (f_r) is the *Doppler shift*. As shown in the equation, the Doppler shift is directly proportional to the transmitted frequency (f_0), the cosine of the angle of incidence θ (angle between the ultrasound wave and vector of the red blood cell), and the velocity of the red blood cells, however, is inversely proportional to the speed of ultrasound in the medium (c). Rearrangement of the equation allows one to determine the velocity of the red blood cells. *Top right*: The Bernoulli equation enables one to determine the pressure gradient across a stenosis, in this case, a stenotic aortic valve. Flow accelerates just before and at the level of the stenosis. The velocity proximal to the stenosis is V_1, and the velocity distal to the stenosis is V_2. Based on certain assumptions (see text), the Bernoulli equation can be simplified to $P1 - P2 = \Delta P = 4(V_2)^2$. In this case, the peak gradient is 64 mmHg based on the peak velocity across the aortic valve (V_2) of 4 m/s. Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2011

Note that the number "2" in the equation results from the fact that there are actually two Doppler shifts: one when the sound wave sent from the transducer strikes the red blood cell, and the other when the wave reflected from the red blood cell is sent back to the transducer. Doppler echocardiography is highly angle-dependent. *The angle should ideally be <20 ° which results in <10% underestimation of true flow velocity* [2]. When the ultrasound beam is ideally oriented parallel to the direction of blood flow, that is, when the angle θ is 0 °, the equation is simplified since the cosine of 0 ° is 1. Using the simplified Bernoulli principle (Fig. 11.1), it follows that velocity can be used to estimate pressures.

Continuous Wave Versus Pulse Wave Doppler

Two forms of Doppler echocardiography are pulse wave (PW) Doppler and continuous wave (CW) Doppler. Pulse wave Doppler employs a single crystal that emits short bursts or pulses of

ultrasound at a certain rate per second, known as the *pulse repetition frequency (PRF)*, which is dependent on the depth of interrogation. These pulses are sent to a particular sampling location or depth, and the same crystal waits for the reflected frequency (Fig. 11.2a). Because the same crystal sends and receives the ultrasound wave, the maximum velocity that can be measured is limited by the time it takes to send and receive the wave. This is called the *Nyquist limit*, which is one-half the PRF. *The PRF and the Nyquist limit are solely determined by the depth of the sample volume and not by the transducer frequency*. The shallower the sample volume, the higher the PRF or number of pulses sent per second by the transducer. If the Doppler frequency shift is greater than the Nyquist limit, then the velocities above this limit are cut off the spectral

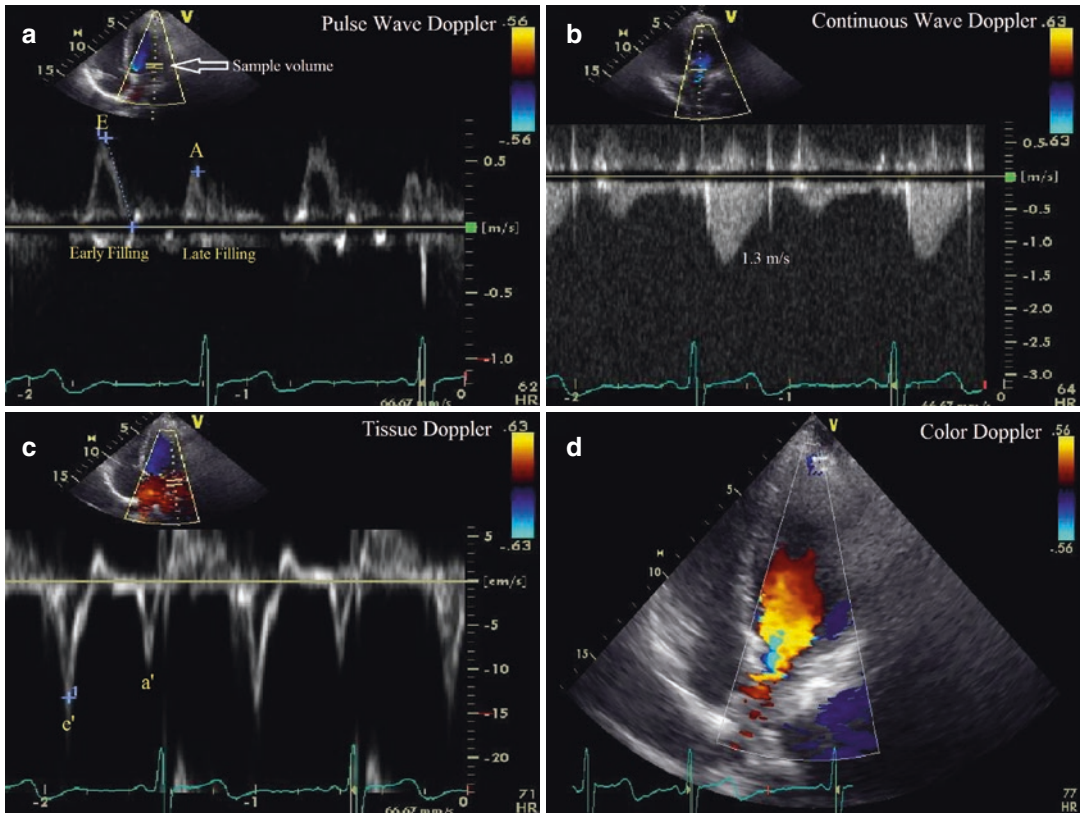

Fig. 11.2 Various forms of Doppler in echocardiography. (**a**) Pulse wave (PW) Doppler of the mitral inflow with the sample volume placed at the leaflet tips. In PW, the same transducer crystal sends and receives waves to determine the Doppler shift at a particular sample volume, marked by the *white arrow*. Because PW obtains information about a particular location, it is said to have "range specificity or range resolution," but it is prone to aliasing. Note that in diastole there is early filling (*E* wave) and Late Filling (*A* wave). Diastasis is known as the period between the *E* and the *A* wave. The *E* velocity is 68 cm/s. (**b**) Continuous wave (CW) Doppler across the aortic valve. In CW, one crystal sends sound waves continuously and another crystal receives the sound waves. Because the CW profile represents all the velocities along the path of interrogation (represented by the *dotted line*), the peak velocity cannot be localized based on the CW signal alone. This phenomenon is known as "range ambiguity." The *y* axis is velocity and the *x* axis is time, and therefore the area under the curve is the velocity time integral (VTI), or the aortic valve VTI, in units of distance (cm). In this example, the peak velocity is 1.3 m/s and the Aortic Valve VTI is 22 cm. (**c**) Tissue Doppler of the mitral annulus characterizes annular velocities, with the corresponding annular e' and a' waves. These waves correspond temporally with the *E* and *A* waves of the mitral inflow. Because $E = 68$ cm/s and $e' = 13$ cm/s, the ratio E/e' is roughly 5, suggesting normal PCWP pressures. (**d**) Color Doppler in which the color pixels represent the mean velocity vector at a particular location

Doppler profile and wrap around to the opposite direction, a phenomenon known as aliasing [1]. Anyone who has watched a wagon wheel in a Western movie appreciates this phenomenon. As the wagon starts to move away, the wheel appears to be moving clockwise. But as the wagon wheel picks up speed and exceeds the "Nyquist limit" of the movie camera, the wheel appears to be moving counterclockwise, which is the equivalent of aliasing. An example of aliasing in echocardiography can be found in Fig. 11.4c, in which PW is used to determine the right ventricular outflow tract (RVOT) velocity. Note that during diastole, the pulmonary regurgitation jet velocity exceeds the Nyquist limit of 1 m/s and wraps around (aliases) to the negative portion of the spectral Doppler profile. Therefore, PW *is suited for measuring low velocity flow (<2 m/s) at specific locations in the heart*, such as the left ventricular outflow tract (LVOT), right ventricular outflow tract (RVOT), mitral inflow, tricuspid inflow, and hepatic vein inflow. PW has the property of "range specificity" in that it provides information at a specific location. Figure 11.2a shows PW of the mitral inflow with sample volume at the leaflet tips, demonstrating the three phases of diastole: early filling (*E* wave), diastasis, and late filling (*A* wave).

Because continuous wave (CW) Doppler employs two crystals, one continuously emitting ultrasound waves and the other continuously receiving reflected waves, it does not fall under the Nyquist limitation (Fig. 11.2b). This allows for interrogation of higher velocities without aliasing. *In CW, all the velocities along the ultrasound beam are recorded, rather than the velocities at one particular location. The peak velocity cannot be localized based on the CW signal alone, a phenomenon known as* "range ambiguity." CW is used to assess gradients in aortic stenosis and mitral stenosis, peak mitral regurgitation velocity, peak tricuspid regurgitation velocity, and intracardiac shunt velocity.

Finally, tissue Doppler is a specialized form of PW that allows the interrogation of myocardial and annular velocities by focusing on lower velocities of higher amplitude with a high frame rate (Fig. 11.2c). Tissue Doppler imaging is employed in the estimation of intracardiac pressures, quantification of wall motion in stress echo, detection of diastolic dysfunction, and intraventricular dyssynchrony, among other applications.

Color Doppler

Color Doppler provides a visual representation of intracardiac flow by translating the velocity vector into color: red and yellow represent flow moving toward the transducer while blue hues represent flow moving away from the transducer (Fig. 11.2d). Note that in the color scale which appears to the right of Fig. 11.2d, the darker the color shade, the closer to zero the velocity becomes, with black representing 0 m/s. The color image is constructed by the summation of multiple scanning lines which translates Doppler shifts into mean velocity, and then the mean velocity into a color based on the color scale. To determine real-time, accurate blood velocities along the path of multiple scanning lines, the transducer must rapidly send multiple groups of pulses or "packets" with pulse wave Doppler. While having more pulses per "packet" increases the accuracy of velocity measurements, this occurs at the expense of temporal resolution because more time is needed to acquire the information from the pulses. Because color Doppler relies on PW, if the velocity of flow is greater than the Nyquist limit, color aliasing occurs, in which color may reverse from blue to yellow, for example.

Bernoulli Equation

The *Bernoulli equation* has applications for echocardiography-based hemodynamic assessment. It is used to calculate the gradient across a stenosis, a regurgitant valve, or a septal defect between two cardiac chambers, and it consists of three components: *convective acceleration, flow acceleration*, and *viscous friction* (Fig. 11.1) [3].

$$P1 - P2 = \underbrace{\frac{1}{2}\rho\left(V_2^2 - V_1^2\right)}_{\text{Convective acceleration}} + \underbrace{\rho\int_1^2 \frac{\overrightarrow{dV}}{dt}\overrightarrow{ds}}_{\text{Flow acceleration}} + \underbrace{R\left(\vec{V}\right)}_{\text{Viscous friction}}$$

where $P1$ = pressure proximal to stenosis; $P2$ = pressure distal to the stenosis, ρ = mass density of blood (1.06×10^3 kg/m^3); V_1 = velocity at proximal location; V_2 = velocity at distal location; ds = acceleration distance; and R = viscous resistance.

Convective acceleration is the increase in kinetic energy that corresponds to the pressure drop across the orifice, and is analogous to the conversion of potential energy to kinetic energy that occurs when an object falls by gravity [3]. The *flow acceleration* component describes the pressure drop required to accelerate the blood by overcoming the blood's inertial forces. Finally, the *viscous friction* component describes the frictional, viscous force that results from neighboring blood cells moving at different velocities.

There are some features of blood flow in the human heart that allow for simplification of the Bernoulli equation. First, the *viscous friction* term is negligible because the velocity profile of blood through a stenotic valve is relatively flat (little variation in blood velocity and therefore little friction), as well as because orifice diameters in the heart are relatively large, minimizing the effect of friction at the center of the orifice. In addition, previous studies have indicated that in most clinical situations the *flow acceleration* component is negligible [3]. In single, stenotic lesions, the proximal velocity term V_1 is typically small (<1 m/s) and can be ignored. Therefore, because in most clinical scenarios the *viscous friction*, *flow acceleration*, and V_1 components are negligible, the Bernoulli equation is simplified to $P1 - P2 = \Delta P = 4(V_2)^2$ (Fig. 11.1).

Intracardiac Pressures

The guide through echocardiographic assessment of various cardiac chamber pressures will follow the same sequence as during a diagnostic right heart catheterization, beginning with the right atrium. A summary of the equations discussed is presented at the end of the chapter (Fig. 11.10).

Right Atrium

Right atrial pressure is reflected in the size of the inferior vena cava (IVC), its response to changes in intrathoracic pressure, and the hepatic vein Doppler profile. Interrogation of the IVC by transthoracic echocardiography can be performed with the subcostal view (Fig. 11.3a, c). An *IVC diameter ≤2.1 cm that collapses >50% with sniffing (which causes an acute drop in intrathoracic pressure resulting in decreased venous return) suggests a normal RA pressure of 3 mmHg (range 0–5 mmHg)* [4]. *An IVC diameter >2.1 cm that collapses <50% with a sniff suggests a high RA pressure around 15 mmHg (range 10–20 mmHg)*. IVC profiles that do not fit into these two categories (i.e., IVC ≤ 2.1 cm but <50% collapse or IVC > 2.1 cm but >50% collapse) can be designated as an intermediate RA pressure of 8 mmHg. Other additional parameters such as hepatic vein profile can be used to further refine this estimated pressure. Young healthy adults may have dilated IVCs but normal RA pressure, and estimation of RA pressure using the IVC index may not be reliable in patients who are intubated [4]. An additional estimate of right atrial pressure is derived from the ratio of the tricuspid inflow diastolic E wave velocity and the right ventricular annular e' velocity, which is the right-sided correlate of estimating left atrial pressure by tissue Doppler. A ratio of $E/e' > 6$ is suggestive of high right atrial pressures. This method can be used in situations where IVC measurements are unobtainable or inaccurate [5].

Because the hepatic vein drains into the IVC, which then drains into the RA, the hepatic vein Doppler profile can provide complementary information regarding right atrial and ventricular hemodynamics. The hepatic vein profile consists of two main antegrade flow waves (systolic (S) and diastolic (D) waveforms) and a retrograde atrial wave (a) (Fig. 11.3b). The S, D, and a waves correspond to the x, y, and a waves of the jugular venous pressure waveform, respectively.

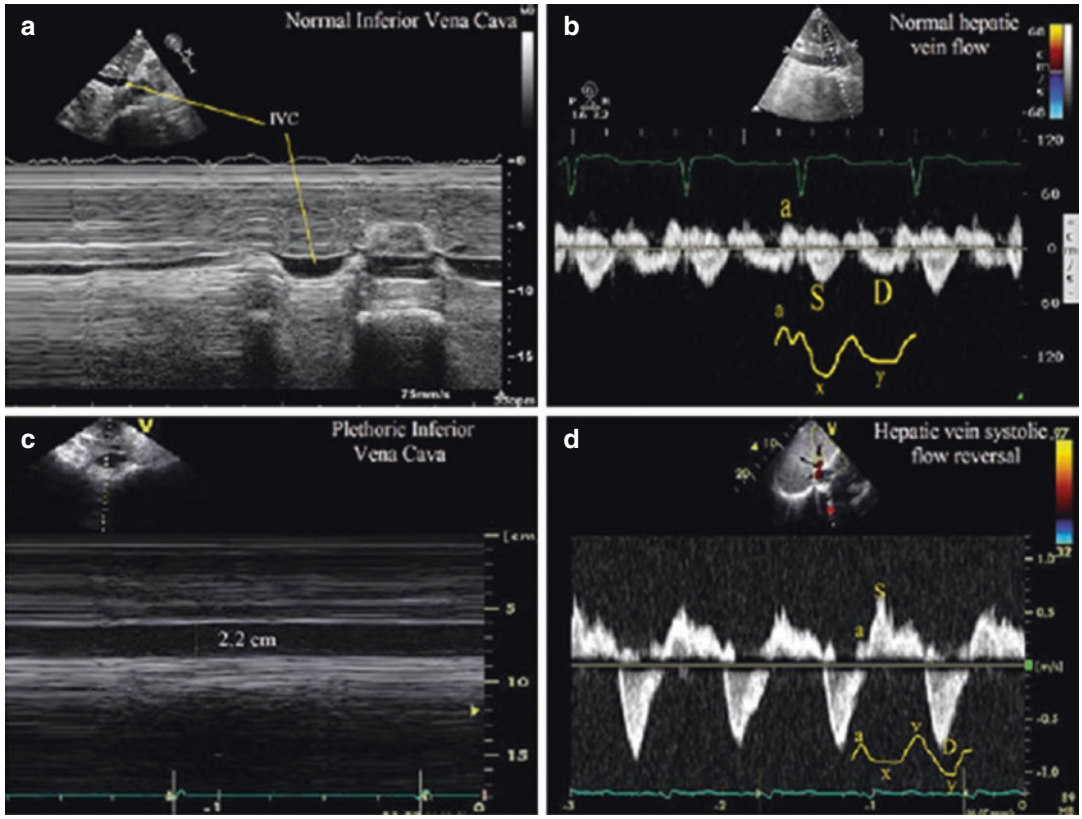

Fig. 11.3 Right-sided pressures. (**a**) M-mode through the IVC from the subcostal view. Note that the IVC size is <2.1 cm and collapses greater than 50%, suggesting normal right atrial pressure (0–5 mmHg). (**b**) Pulse wave (PW) Doppler of the hepatic vein showing normal hepatic vein flow. Note that there are two antegrade waves (*S* and *D*) and one retrograde wave (*a* reversal). The representative portions on the JVP waveform are shown (*S* corresponds to the *x* descent, and *D* corresponds to the *y* descent). The onset of the *S* wave corresponds to the onset of the QRS (isovolumic contraction), although the peak occurs in mid to late systole. In this example, the velocity of the *S* wave is larger than the *D* wave, indicating normal right atrial pressures. (**c**) A plethoric IVC greater than 2.1 cm in width which does not collapse, suggesting a right atrial pressure between 10 and 20 mmHg. (**d**) Systolic flow reversal in the hepatic veins in severe tricuspid regurgitation. Notice that the *S* wave is above the baseline, indicating flow reversal. This corresponds to the blunted *x* descent and tall *v* wave in the JVP waveform

Flow in the hepatic vein is sensitive to respiration, with increasing antegrade flow during inspiration and decreasing flow during expiration. With normal RA pressure, there is a predominance of the *s* wave in the antegrade waveform, whereas with elevated RA pressure, because the pressure gradient between the RA and the hepatic vein is lower, the *s* wave is blunted and the *d* wave predominates. *More quantitatively, a ratio of the s wave velocity divided by the sum of the s and d wave velocity* $[V_s/(V_s + V_d)]$ *less than 55% is highly correlated with an elevated RA pressure* [6]. In addition, in severe tricuspid regurgitation, there may even be systolic wave reversal, which is the echocardiographic equivalent of the loss of the *x* descent in the jugular venous waveform (Fig. 11.3d). In pulmonary hypertension, there may be prominent flow reversal during atrial systole (prominent *a* wave) due to high pulmonary pressures transmitting back to the atrium during diastole. Utilizing the ECG to accurately differentiate systolic flow reversal in the hepatic vein (which should occur coincident with isovolumic contraction) from a prominent (*a*) wave can be

key to avoiding misinterpretation of quite different hemodynamic conditions.

Right Ventricle

In the absence of tricuspid stenosis, the right ventricular end-diastolic pressure should equal the RA pressure as estimated from the IVC measurement. If tricuspid regurgitation (TR) is present, the peak velocity (v_{TR}) measured at end-expiration can be used to estimate the pressure gradient between the right ventricle and right atrium during systole ($\Delta P = 4V_{TR}^2$) (Fig. 11.4a). This pressure gradient can be added to the RA pressure to estimate the right ventricular systolic pressure (RVSP = RA + $4V_{TR}^2$). A TR velocity greater than 2.8–2.9 cm/s, in the setting of a normal RA pressure (0–5 mmHg), corresponds roughly to an RVSP of 36 mmHg, which

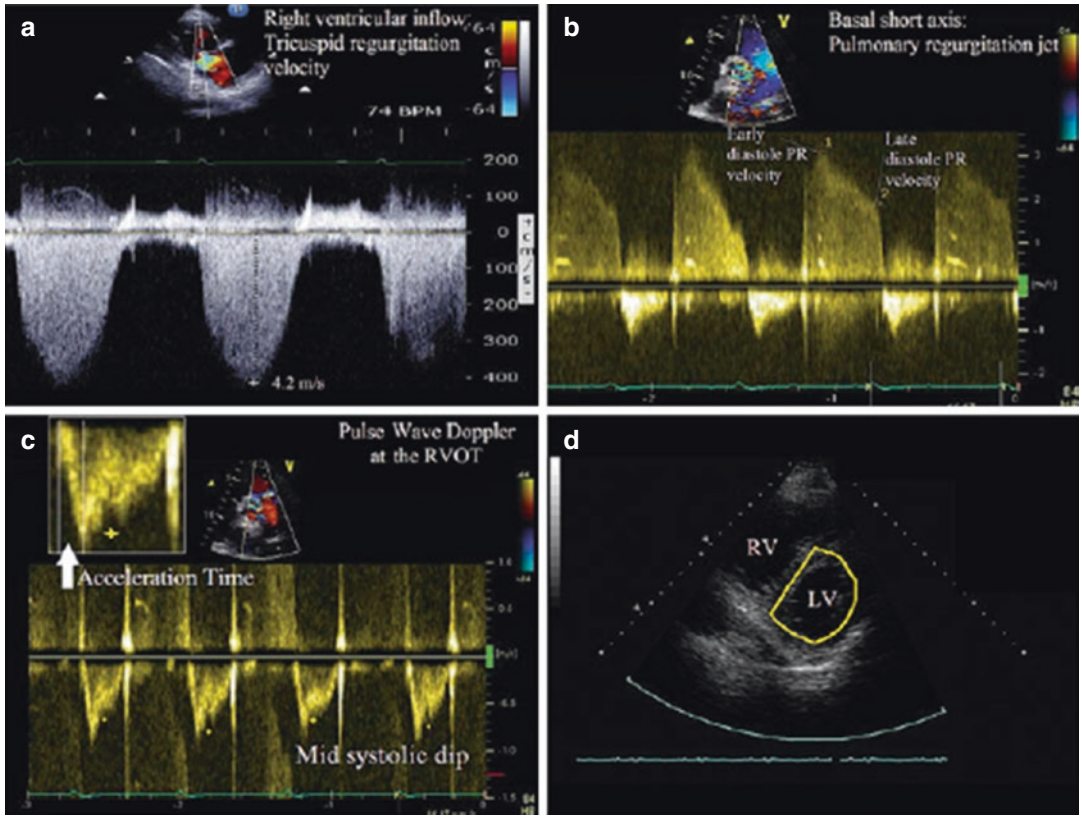

Fig. 11.4 Pulmonary pressures and signs of pulmonary hypertension. (**a**) The right ventricular systolic pressure can be estimated from the peak tricuspid regurgitation velocity obtained in the right ventricular inflow view (*see Question 1*). (**b**) The continuous wave (CW) Doppler profile of the pulmonary regurgitation jet. The early peak velocity can be used to determine the mean pulmonary artery (PA) pressure by the following formula: Mean PA Pressure = $4v_{EarlyDPR}^2$. In this case, early pulmonary regurgitation (PR) jet velocity is 3.9 m/s and the end-diastolic PR velocity is 1.9 m/s. Therefore, the mean PA pressure is roughly 39 mmHg. Also, the pulmonary artery end-diastolic pressure (PAEDP) can be determined from the end-diastolic velocity and estimated right atrial (RA) pressure: PAEDP = RA + $4v_{EDPR}^2$ (*see Question 2*). Note that in pulmonary hypertension, there is absence of the typical end-diastolic dip in the pulmonary regurgitation CW profile that normally corresponds to atrial systole. (**c**) The sample volume is in the RVOT, just below the pulmonic valve. In pulmonary hypertension, there is a steep slope in early systole (acceleration phase becomes shorter, *upper left corner*) and there can be a mid-systolic dip in the RVOT profile (*yellow stars*), due to high afterload. A simplified formula to calculate the mean pulmonary artery pressure (MPAP) is MPAP = 80 − 0.5 (acceleration time (ms)). Acceleration time is roughly 90 ms, yielding a MPAP of 35 mmHg. (**d**) Note the D-shaped septum during systole, suggestive of RV pressure overload

indicates the presence of mild pulmonary hypertension [4].

In cases of severe TR, in which the tricuspid valve is essentially "wide-open" during systole and there is no longer a fixed orifice with a significant pressure drop across the orifice, the RVSP may be underestimated. This is due to the fact that the flow acceleration (inertance) component of the Bernoulli equation is no longer negligible (a pressure drop must occur to overcome the inertance of the large volume of blood), while the convective flow component is less important (large orifice). Therefore, the simplified Bernoulli equation, which includes only the convective component, typically underestimates the RVSP in this scenario [4, 7].

If there is no RVOT obstruction or pulmonary stenosis, then the RVSP should be equal to the pulmonary artery systolic pressure (PASP). In the presence of pulmonary stenosis, because the peak gradient across the pulmonary valve during systole represents the pressure drop from the RV to the pulmonary artery (PA), the PASP can be derived from subtracting the peak gradient across the pulmonary valve during systole (obtained by CW) from the RVSP obtained from the TR jet [8].

Pulmonary Artery

As stated above, the PASP is equal to the right ventricular systolic pressure in the absence of RVOT obstruction. The end-diastolic pressure gradient between the pulmonary artery and the right ventricle is extrapolated from the end-diastolic velocity of the pulmonary regurgitation jet ($\Delta P = 4V_{\mathrm{PRed}}{}^2$) (Fig. 11.4b). Because this jet represents the difference between pulmonary artery end-diastolic pressure (PAEDP) and RVEDP (i.e., $\Delta P = 4V_{\mathrm{PRed}}{}^2 = \mathrm{PAEDP} - \mathrm{RVEDP}$), and RVEDP equals RA pressure in the absence of tricuspid stenosis, it follows by algebraic manipulation that $\mathrm{PAEDP} = \mathrm{RA} + 4V_{\mathrm{EDPR}}{}^2$ [9]. Also, the mean PA pressure can be estimated from the peak pulmonary regurgitation jet velocity (Mean PA Pressure = $4V_{\mathrm{EarlyDPR}}{}^2$) or the RVOT flow measured by PW Doppler using the formula $80 - 0.5 * (\text{pulmonic acceleration time(ms)})$ (Fig. 11.4c) [10]. These formulae can be useful when TR velocity signal is weak and unreliable. Estimation of pulmonary vascular resistance can be made by determining the ratio of the Peak TR velocity and the RVOT VTI (right ventricular outflow tract velocity time integral) in the following formula [11]:

$$\mathrm{PVR}\ (\text{Woods units}) = \frac{10 * (\text{peak TR velocity}(\mathrm{m/s})}{\text{RVOT VTI}(\mathrm{cm})) + 0.16}.$$

Echocardiographic signs of pulmonary hypertension include a D-shaped left ventricle, loss of the atrial systolic dip in the pulmonary regurgitation jet, and a mid-systolic decrease in the pulmonary outflow velocity (Fig. 11.4).

Pulmonary Capillary Wedge/Left Atrial Pressure

One method of estimating the left atrial (LA) pressure is to determine the peak mitral regurgitation velocity (V_{MR}), from which one can derive the pressure gradient between the left ventricle (LV) and LA (LV systolic pressure − LA pressure = $4V_{\mathrm{MR}}{}^2$) [12]. Because the LV systolic pressure equals the systolic blood pressure (SBP) in the absence of LVOT obstruction, the LA pressure = $\mathrm{SBP} - 4V_{\mathrm{MR}}{}^2$. A more common method of estimating the left atrial pressure is to determine the ratio of the mitral inflow *E* velocity to septal mitral annular velocity (*e′*), or *E/e′* [13]. *An E/e′ ratio of >15 is highly correlated with a pulmonary capillary wedge pressure (PCWP) >20, while an E/e′ ratio less than 8 corresponds to a normal PCWP* [13]. This method is valid for patients with

normal and abnormal systolic function. Tissue Doppler-derived estimates of PCWP can be used in patients with atrial fibrillation as well. However, in patients with constriction the exaggerated e' velocity, which corresponds to the rapid y descent on JVP waveform, yields a low E/e' ratio in spite of the fact that the left atrial pressures are elevated. This is the so-called *annulus paradoxus* [14].

Finally, in patients with aortic insufficiency, because the end-diastolic velocity of the aortic regurgitation jet ($4V_{AI}^2$) represents the pressure gradient between the aorta (diastolic blood pressure or DBP) and the LV end-diastolic blood pressure (LVEDP), one can estimate the LVEDP using the following formula: $\text{LVEDP} = \text{DBP} - 4V_{EDAI}^2$. Measurement error inherent with sphygmomanometric readings provides the primary limitation of this method. In the case of severe acute AI, where the end-diastolic velocity of the aortic insufficiency jet approaches zero, the LVEDP approaches the DBP.

Cardiac Output and System Vascular Resistance

The flow rate through a vessel is the product of the cross-sectional area of the vessel and the velocity of blood. However, because velocity varies over time throughout the cardiac cycle due to pulsatility, one cannot take an instantaneous velocity to measure overall flow rate. Rather, an integral of the velocities over time, called the VTI from the Doppler profile, is used to characterize integrated velocity in a given time period to determine flow (volume), rather than flow rate (volume/time) (Fig. 11.5a, b). VTI is essentially a measure of stroke distance. When the VTI (distance) is multiplied by the cross-sectional area (distance squared), the product is a volume (distance cubed). Therefore, stroke volume of the left ventricle can be estimated by multiplying the cross-sectional area of the LVOT ($\pi r^2 = \pi(D/2)^2 = \pi D^2/4 = D^2 * 0.785$, where r is radius and D is diameter) obtained in the parasternal long axis view and multiplying it by the VTI of the PW Doppler profile obtained in the apical long axis view (Fig. 11.5a). The PW cursor is typically placed about 0.5–1 cm below the valve to obtain a laminar flow curve. It is important to measure the PW Doppler profile at the same location as the measured cross-sectional area to maintain accuracy. This stroke volume can be multiplied by the heart rate to give an estimated cardiac output (in the absence of significant aortic regurgitation). If there is no regurgitation or intracardiac shunts, then the stroke volume through the tricuspid, pulmonary, mitral, and aortic valves should be equivalent, and therefore, the principle of multiplying the cross-sectional area of these valves by the VTI of flow across the valves can be applied throughout the heart. Practically speaking, however, stroke volume is typically measured in the LVOT.

If a left to right shunt is present (i.e., ASD or VSD), then it is clinically relevant to estimate the severity of the shunt by determining the ratio of pulmonary blood flow (Q_p) to systemic blood flow (Q_s). Figure 11.6 shows an example of a secundum ASD with left to right flow. Systemic stroke volume is measured by multiplying the LVOT area ($D^2*0.785$) by the LVOT VTI from the parasternal long axis views and the apical long axis views, respectively. The pulmonary stroke volume is measured by multiplying the RVOT Area by the RVOT VTI, measured in the basal short axis view across the pulmonary valve. The ratio of Q_p/Q_s, which equals [(RVOT VTI) (RVOT $D^2*0.785$)]/[(LVOT VTI) (LVOT $D^2*0.785$)], gives an estimate of the shunt fraction (Fig. 11.6). The term 0.785 cancels, and the ratio simplifies to (RVOT VTI) (RVOT D^2)/(LVOT VTI) (LVOT D^2). A ratio greater than 1.5 is considered a significant left to right shunt.

Just as pulmonary vascular resistance correlates with the TR velocity/RVOT VTI, systemic vascular resistance (SVR) correlates relatively well with *MR velocity/LVOT VTI*. A ratio of *MR velocity/LVOT VTI > 0.27* has a relatively high sensitivity and specificity for *SVR > 14 Woods units* [15].

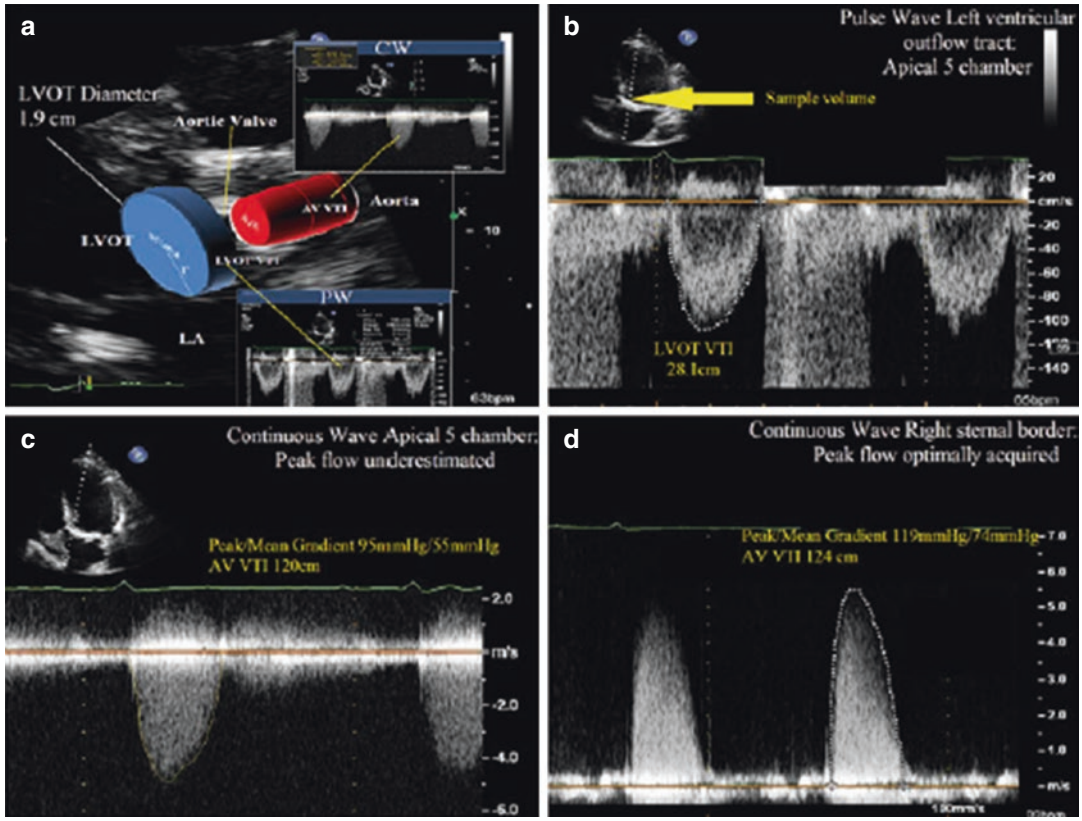

Fig. 11.5 Stroke volume and aortic valve area (AVA) calculation using the continuity equation. (**a**) Based on the continuity equation, the flow through the left ventricular outflow tract (LVOT), or the volume of the *blue cylinder*, must equal the flow through the aortic valve, or the volume of the *red cylinder*. The stroke volume (represented by the *blue cylinder*) is estimated by multiplying the LVOT area by the LVOT VTI. The LVOT area is obtained using the equation Area = πr^2 = (Diameter)^2∗0.785, with the diameter measured in the parasternal long axis view. Because the LVOT diameter in this case is 1.9 cm, the LVOT area is 2.84 cm^2. From the apical 5 chamber or apical long axis view, the LVOT VTI is obtained, which in this case is 28.1 cm (*bottom right* and (**b**)). Therefore, the stroke volume = 28.1 cm∗2.84 cm^2 = 79.8 cm^3. The product of the stroke volume and the heart rate (SV∗HR) can give an estimate of cardiac output. The volume of the *red cylinder* is the product of the AVA and the AV VTI (**c**, **d**). Because the volume of the *blue cylinder* (LVOT Area∗LVOT VTI) must equal the volume of the *red cylinder* (AVA∗AV VTI) to satisfy the continuity equation, it follows that AVA = [LVOT VTI ∗ (LVOT diameter)^2 ∗ 0.785]/[AV VTI] = Stroke volume/AV VTI (*see Question 3*). (**b**) Pulse wave Doppler Sample volume is placed just below the aortic valve in the 5 chamber view, and the LVOT VTI is traced. (**c**) Continuous wave Doppler measures the highest velocity along its path to estimate the peak and mean gradient across the aortic valve. The peak and mean gradients are 95/55 mmHg from the 5 chamber view, which is an underestimation of peak flow in this particular patient. Multiple views are necessary to obtain the highest, most representative jet velocity, as seen in (**d**). Right sternal border view obtains peak and mean gradients of 119/74 mmHg, higher than the peak gradient of 95 mmHg from the apical 5 chamber view

Valve Disease

It is important to recognize that an integrated approach using multiple echocardiographic methods of analysis and clinical context to determine severity of valve lesions is crucial, rather than relying on one specific measurement.

Aortic Stenosis

Echocardiography is currently the standard method to evaluate aortic valve stenosis. Application of the continuity equation is central to the calculation of aortic valve area (AVA). Based on the conservation of mass, the flow in

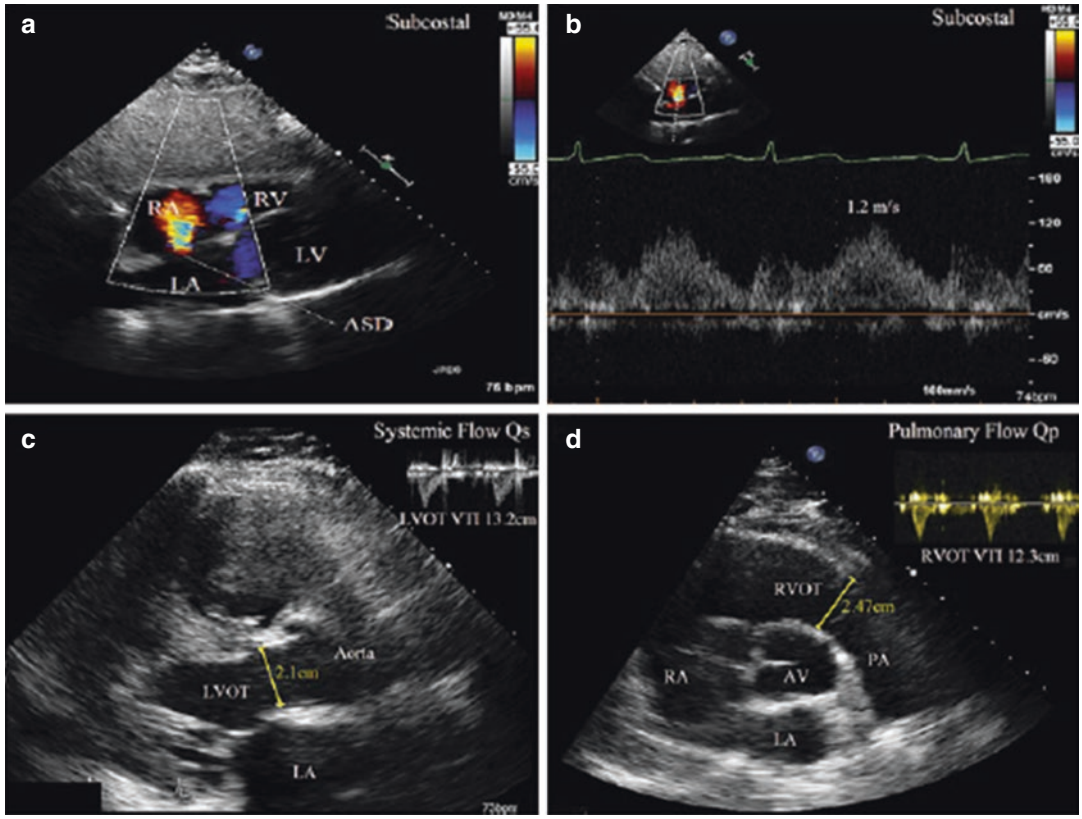

Fig. 11.6 Shunt calculation in a patient with a secundum atrial septal defect (ASD). (**a**) Color flow Doppler demonstrates left to right flow across the ASD in this subcostal view. (**b**) Pulse wave Doppler at the level of the ASD confirms that there is left to right continuous flow. During peak systole, based on the velocity of 1.2 m/s, the pressure gradient between the right atrium (RA) and the left atrium (LA) is $4v^2 = 4(1.2)^2 = 5.8$ mmHg. The RA pressure was estimated at 10 mmHg, so the LA pressure during systole is estimated at 15.8 mmHg (LA = RA + $4v^2$). (**c**) Measurement of systemic flow (Q_s) based on the LVOT area and LVOT VTI (pulse wave Doppler from the apical 5 chamber view, *right upper corner*). (**d**) Measurement of pulmonary flow (Q_p) based on the RVOT area and the RVOT VTI (pulse wave Doppler from the basal short axis view, *right upper corner*). The Q_p/Q_s or shunt fraction is 1.3:1 (*see Question 4 for calculation of Q_p, Q_s, and shunt fraction*)

the left ventricular outflow tract (LVOT) should be equal to the flow through the aortic valve orifice. First, one must determine the flow in the LVOT, or the stroke volume, by multiplying the cross-sectional area of the LVOT by the LVOT VTI determined by PW Doppler in the apical long axis or 5 chamber view (Fig. 11.5a, b). The PW sample volume should be located in the LVOT beneath the valve, and a crisp laminar Doppler signal with no contamination from the pre-stenotic flow acceleration should be sought. This is typically 0.5–1.0 cm from the aortic valve. The LVOT diameter should be measured from the septum to the anterior mitral leaflet in mid-systole, roughly 0.5–1.0 cm from the aortic valve in the parasternal long axis view to approximate the location where the PW was measured in the other echocardiographic view [16]. This flow should equal the product of the cross-sectional area of the aortic valve (AVA) and the AV VTI as determined by CW Doppler, typically the highest VTI obtained from a given view (suprasternal, apical, right parasternal) (Fig. 11.5c, d). The volume of blood in the cylinder in the LVOT (blue cylinder) must equal the volume of blood in the cylinder at the aortic valve (red cylinder) to not violate the law of mass conservation. The AV VTI obtained by CW Doppler is highly dependent on technique and the ability to obtain a good signal that is parallel to flow. Occasionally the right parasternal approach is used to obtain the highest gradient (Fig. 11.5d).

Based on the continuity equation:

$$\text{LVOT Cylinder Volume or Stroke Volume} = \text{AV Cylinder Volume}$$
$$\text{LVOT VTI} * \text{LVOT area} = \text{AV VTI} * \text{AVA}$$
$$\text{LVOT VTI} * (\text{LVOT diameter})^2 * 0.785 = \text{AV VTI} * \text{AVA}$$

Rearrangement yields [17] (Fig. 11.5):

$$\text{AVA} = \frac{\left[\text{LVOT VTI} * (\text{LVOT diameter})^2 * 0.785\right]}{\left[\text{AV VTI}\right]}$$

This equation gives a reliable estimate of the AVA; less than 1.0 cm^2 is considered severe aortic stenosis [16, 18]. Because the LVOT diameter is squared and measurements can vary, this is the greatest source of error in the formula.

The AVA is just one method among many to assess severity of aortic stenosis. Other methods include identifying the peak and mean gradient across the aortic valve, peak velocity across the aortic valve, and dimensionless index [17]. The peak velocity across the aortic valve is obtained from the CW Doppler profile, from which the peak gradient is calculated (from the peak velocity using $\Delta P = 4V^2$), and the mean gradient is calculated by averaging the instantaneous gradients during the ejection period [17]. A mean gradient >40 mmHg is considered severe. Echocardiographic assessment of peak gradient provides the instantaneous gradient between the LV and the aorta, which is different from cardiac catheterization in which often a peak to peak gradient is reported, a less physiologic value. Importantly, the mean gradient on cardiac catheterization correlates well with the Doppler-derived mean gradient. Table 11.1 shows the stages of severity of aortic stenosis based on the AHA/ACC 2014 Valve Guideline Update [16].

Although the peak velocity and estimated AVA are usually concordant (i.e., either velocity >4 m/s and AVA <1.0 cm^2 or velocity <4 m/s and AVA >1.0 cm^2), there may be scenarios in which the jet velocity and AVA may be discordant. In the case of velocity >4 m/s and AVA >1.0 cm^2, possibilities include a high stroke volume, concomitant moderate-to-severe aortic regurgitation, and a large body size. In the case of velocity <4 m/s and AVA <1.0 cm^2, possibilities include low stroke volume, severe concomitant mitral regurgitation, and small body size [16]. In either situation, the peak velocity is the better predictor of clinical outcome, and it is suggested that it be used to determine valve stenosis severity [16].

In patients who have left ventricular dysfunction (LVEF <40%) with concomitant aortic stenosis, the calculated AVA may be severe (<1.0 cm^2), but the mean gradient may not be severe (<30–40 mmHg). It is important to then determine if the aortic stenosis is truly severe and causing left ventricular dysfunction, which would imply improved left ventricular function with valve replacement, or if the aortic stenosis is only moderate in the presence of LV dysfunction from another cause (i.e., coronary disease, nonvalvular cardiomyopathy, etc.), in which the perceived small AVA is related to the inability of the left ventricle to generate the necessary valve opening forces (pseudostenosis). In the latter scenario, valve replacement would not be expected to improve left ventricular dysfunction. Low-dose dobutamine stress protocols (described in detail elsewhere [16]) can distinguish the two clinical scenarios. Recall from the continuity equation that the AVA is proportional to the *LVOT VTI/AV VTI*. If the patient truly has severe aortic stenosis, with the administration of dobutamine, the LVOT VTI and AV VTI should increase proportionally due to increased flow across a fixed,

Table 11.1 Aortic stenosis stages based on the recent AHA/ACC 2014 valve guidelines update [16]

Stage	Definition	Valve anatomy	Valve hemodynamics	Hemodynamic consequences	Symptoms
A	At risk of AS	Bicuspid aortic valve, aortic valve sclerosis, or other congenital anomaly	Aortic V_{max} <2 m/s	None	None
B	Progressive AS	Mild-to-moderate leaflet calcification with some reduced systolic motion or rheumatic commissural fusion	Mild AS: Aortic V_{max} 2.0–2.9 m/s or mean ΔP < 20 mmHg Moderate AS: Aortic V_{max} 3.0–3.9 m/s or mean ΔP 20 - 39 mmHg	Early LV dysfunction may be present but LVEF is preserved	None
C1	Asymptomatic severe AS	Severe leaflet calcification or congenital stenosis with severely reduced leaflet motion	Aortic $V_{max} \geq 4$ m/s Mean $\Delta P \geq 40$ mmHg AVA ≤ 1.0 cm^2 Very severe AS is an aortic $V_{max} \geq 5$ m/s or Mean $\Delta P \geq 60$ mmHg	LV diastolic dysfunction Mild LV hypertrophy Normal LVEF	None: exercise testing is reasonable to confirm symptom status
C2	Asymptomatic severe AS with LV dysfunction	Severe leaflet calcification or congenital stenosis with severely reduced leaflet motion	Aortic $V_{max} \geq 4$ m/s Mean $\Delta P \geq 40$ mmHg AVA ≤ 1.0 cm^2	LVEF <50%	None
D1	Symptomatic severe high gradient AS	Severe leaflet calcification or congenital stenosis with severely reduced leaflet motion	Aortic $V_{max} \geq 4$ m/s Mean $\Delta P \geq 40$ mmHg AVA ≤ 1.0 cm^2	LV diastolic dysfunction, LVH, pulmonary HTN may be present	Exertional dyspnea, angina, or reduced exercise tolerance, syncope or presyncope
D2	Symptomatic severe low-flow/low-gradient AS with reduced LVEF	Severe leaflet calcification with severely reduced leaflet motion	AVA ≤ 1.0 cm^2 with resting aortic $V_{max} < 4$ m/s or mean $\Delta P < 40$ mmHg Dobutamine stress echo shows AVA ≤ 1.0 cm^2 with $V_{max} \geq 4$ m/s at any flow rates	LV diastolic dysfunction, LVH, LVEF <50%	HF, angina, syncope or presyncope
D3	Symptomatic severe low-gradient AS with normal LVEF or paradoxical low-flow severe AS	Severe leaflet calcification with severely reduced leaflet motion	AVA ≤ 1.0 cm^2 with aortic V_{max} <4 m//s or mean ΔP < 40 mmHg Indexes AVA ≤ 0.6 cm^2/m^2 *Stroke volume index <35 mL/m^s* *Measured when patient is normotensive*	Increased relative wall thickness with preserved ejection fraction Small LV chamber with low stroke volume Restrictive diastolic filling	HF, angina, syncope, or presyncope

stenotic orifice, so the AVA should remain relatively unchanged. However, if the aortic stenosis only appears severe because of concomitant left ventricular dysfunction, dobutamine infusion will increase the LVOT VTI without a concomitant increase in AV VTI because of improved valve opening, thereby resulting in an increased calculated AVA. It follows that if the AVA increases above 1.0 cm^2 with dobutamine infusion, it is not likely to be severe aortic stenosis. Severe AS is suggested by a peak jet velocity >4.0 m/s provided that the valve area does not increase to >1.0 cm^2 [16]. In addition, the presence of contractile reserve (increase in EF or

SV ≥ 20%) during dobutamine stress predicts a lower mortality rate (<10%) with AVR than if contractile reserve is absent (>30%) [19].

The velocity ratio, also known as the dimensionless index, which is flow independent, is the ratio of the LVOT peak velocity and the AV peak velocity (can also use VTI ratio). A velocity index <0.25 is considered severe. This is used to compare aortic stenosis severity over time in patients who may have different loading conditions.

Accurate estimation of aortic stenosis severity depends on meticulous technique to obtain both an accurate LVOT diameter assessment, as well as the highest velocity jet which may require multiple echocardiographic views. In general, inaccuracies in measuring gradients by echocardiography typically err on the side of underestimation. However, there are two situations in which echocardiography may overestimate severity of stenosis. First, as stated earlier, the peak gradient estimated by the simplified Bernoulli equation ignores the velocity in the LVOT (V_1) as it is usually very small (<1 m/s). Scenarios in which the proximal velocity is >1.5 m/s or the peak velocity is <3 m/s, the flow velocity and gradient may be overestimated since the V_1 is ignored. Therefore, a more accurate estimate of peak gradient across the valve is $\Delta P = 4\left(V_2^2 - V_1^2\right)$ [16]. Another scenario in which the stenosis severity may be overestimated is the pressure recovery phenomenon. This occurs when some of the potential energy which was converted to kinetic energy at the level of the aortic stenosis is converted back to potential energy as flow decelerates (i.e., increasing pressure distal to the valve in the aorta). This pressure recovery is typically negligible, except in the case of small aortas with gradual widening after the stenosis (typically less than 3 cm in diameter). With larger aortas, much of the kinetic energy is converted to heat due to turbulence and viscous friction, so pressure recovery is not an issue [16]. Pressure recovery can be quantitatively calculated as $\Delta P = 4V^2 * 2(\text{AVA/aorta area}) * (1 - \text{AVA/Aorta area})$. As can be seen by the equation, if the AVA is small, and the aorta area is large, the AVA/aorta area ratio is small, and pressure recovery is minimal [16].

One collateral method to confirm the pressure gradient across the LVOT or aortic valve is to assess the peak mitral regurgitation velocity. As described previously, LV systolic pressure − LA pressure = $4V_{MR}^2$. If the LA pressure is estimated to be between 10 and 20 mmHg, then the LV systolic pressure can be estimated by 10–20 mmHg + $4V_{MR}^2$. If the SBP is known, then the difference between the estimated LV systolic pressure and SBP approximates the peak pressure gradient across the LVOT or aortic valve.

Mitral Stenosis

The most common cause of mitral stenosis (MS) is commissural fusion as a result of rheumatic fever. Several echocardiographically derived measurements can be used to assess mitral stenosis, including pressure gradient, pressure half-time, continuity equation, proximal isovelocity surface area (PISA) method, and planimetry. Although planimetry may well provide the most accurate measurement of the mitral valve area (MVA) provided that the images are acquired at leaflet tip level and are a true on-axis view, this section will focus on the pressure gradient, pressure half-time, and continuity equation to assess the valve area. PISA method and planimetry are discussed in detail in another reference [16]. Peak and mean pressure gradients across the mitral valve in diastole are measured by CW from the apical 4 chamber view (Fig. 11.7). It is essential to interrogate the mitral valve during a regular rhythm and normal heart rate (60–80 bpm). If the patient is in atrial fibrillation, then several cardiac cycles (6–8) should be averaged. Mean gradient is preferred to the peak gradient, since the peak gradient may be influenced by mitral regurgitation, atrial compliance, and left ventricular diastology. One cause of a very high peak gradient out of proportion to the mean gradient, for example, is severe mitral regurgitation. While pressure gradients are important parameters in the assessment of mitral stenosis severity, they are highly influenced by heart rate, cardiac output, and mitral regurgitation [16]. Mean pressure gradients supportive of mild, moderate, and

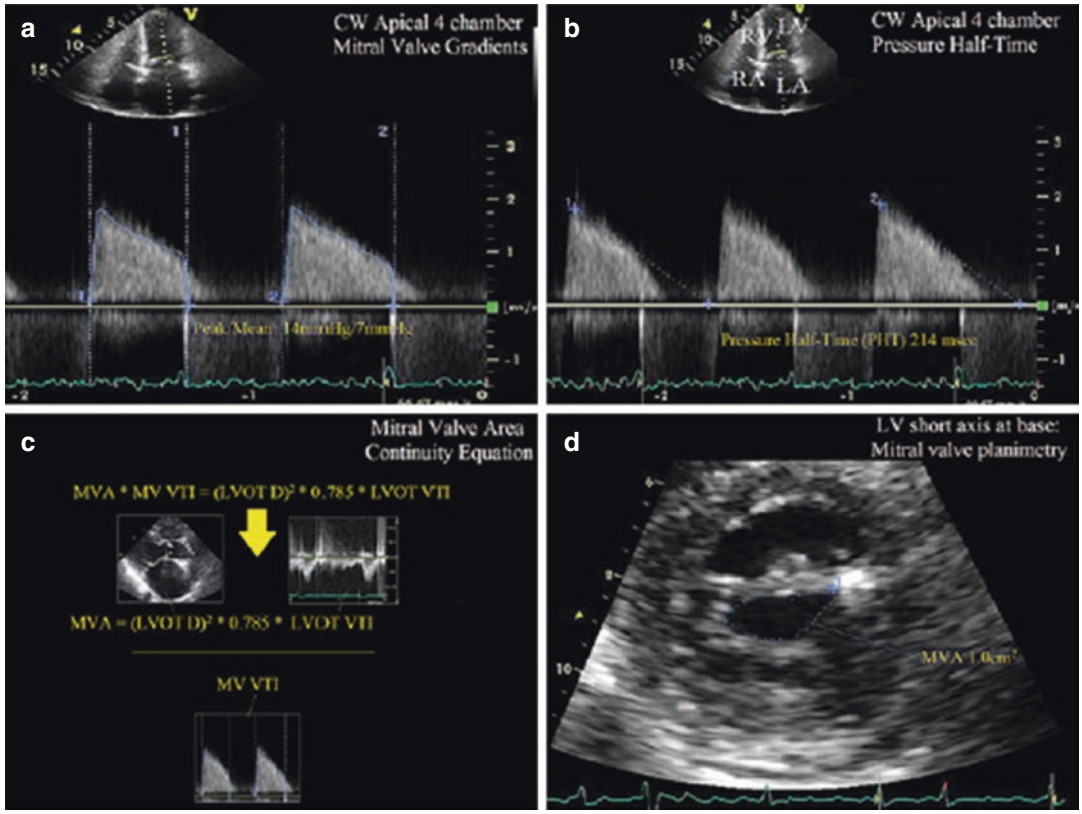

Fig. 11.7 Assessment of mitral stenosis. (**a**) Continuous wave Doppler across the mitral valve yields the peak and mean gradient (14/7 mmHg). Given the irregular heart rhythm, 6–8 beats are measured and averaged to obtain the peak and mean gradient. (**b**) The pressure half-time (PHT) is the time for the pressure gradient to decrease by 50%, and is equal to 0.29∗Deceleration time. Again, multiple beats are averaged (6–8) to obtain the PHT of 214 ms. The mitral valve area (MVA) is estimated by the following empiric equation: MVA = 220/PHT, giving a MVA of 220/214, or 1.0 cm^2, by the PHT method. (**c**) Calculation of MVA using the continuity equation. The flow across the mitral valve must equal the flow across the aortic valve, and therefore, MVA ∗ MV VTI = LVOT a ∗ LVOT VTI. In this case, the LVOT diameter is 1.9 cm, the LVOT VTI is 20 cm, and the MV VTI is 56.4 cm. Therefore, the calculated MV area is 1.0 cm^2. Note that the MV VTI is measured using CW and the LVOT VTI is measured using PW in this situation. (**d**) Planimetry is another method of estimating the MVA. Note the commissural fusion and "fish-mouth" appearance of the mitral opening, characteristic of rheumatic mitral valve disease. In this example, planimetry yields a MVA of 1.0 cm^2, concordant with the PHT and continuity methods

severe MS are <5 mmHg, 5–10 mmHg, and >10 mmHg, respectively [20].

Pressure half-time (PHT) is the time (in ms) it takes for the peak pressure gradient across the mitral valve in diastole to decrease by 50%. Based on the relationship between pressure and velocity, it is also the time in ms it takes for the peak velocity to decrease by 29%. This measurement is obtained by tracing the slope of the *E* wave during early diastole (Fig. 11.7b). It has been found that there is an inverse relationship between PHT and MVA by the following equation: MVA (cm^2) = 220/PHT [21]. In addition, the MVA (cm^2) = 759/Deceleration Time (ms). See Table 11.2 for measurements and valve stenosis severity.

Pressure half-time may be low even in severe MS if atrial compliance is low. In severe aortic insufficiency, due to the increase in the LVEDP during diastole as a result of regurgitation, the pressure between the LV and LA will equilibrate sooner, so the PHT will be reduced and the MVA estimate using the PHT will be inaccurate.

Table 11.2 Stage of mitral stenosis

Stage	Definition	Valve anatomy	Valve hemodynamics	Hemodynamic consequences	Symptoms
A	At risk of MS	Mild valve doming during diastole	Normal transmitral flow velocity	None	None
B	Progressive MS	Rheumatic valve changes with commissural fusion and diastolic doming of the mitral valve leaflets, MVA > 1.5 cm^2	Increased transmitral flow velocities MVA > 1.5 cm^2 Diastolic pressure half-time <150 msec		None
C	Asymptomatic severe MS	Rheumatic valve changes with commissural fusion and diastolic doming of the mitral valve leaflets Planimetered MVA ≤ 1.5 cm^2 MVA ≤ 1.0 cm^2 with very severe MS	MVA ≤ 1.5 cm^2 MVA ≤ 1.0 cm^2 with very severe MS Diastolic pressure half-time >150 ms, or >220 ms with very severe MS	Severe LA enlargement Elevated PASP>30 mmHg	None
D	Symptomatic severe MS	Rheumatic valve changes with commissural fusion and diastolic doming of the mitral valve leaflets Planimetered MVA ≤ 1.5 cm^2	MVA ≤ 1.5 cm^2 MVA ≤ 1.0 cm^2 with very severe MS Diastolic pressure half-time > 150 ms, or ≥220 ms with very severe MS	Severe LA enlargement Elevated PASP>30 mmHg	Decreased exercise tolerance Exertional dyspnea

MVA mitral valve area, *PASP* pulmonary artery systolic pressure

The continuity equation estimates the MVA if there is no aortic insufficiency or mitral regurgitation. The flow through the mitral valve should equal the flow through the LVOT by conservation of mass. The formula for flow through the LVOT (i.e., stroke volume), as described previously, is LVOT VTI ∗ (LVOT diameter)^2 ∗ 0.785. Again, this can be thought of as a cylinder, in which the base of the cylinder is the area of the LVOT and the height is the LVOT VTI. The flow through the mitral valve equals the product of the cross-sectional area of the mitral orifice (base of the cylinder) multiplied by the MV VTI (height of the cylinder). The MV VTI is determined by the computer package from the tracing of the CW mitral inflow from the 4 chamber view (Fig. 11.7c).

$$\text{LVOT Cylinder Volume or Flow} \quad \text{MV Cylinder Volume or Flow}$$

$$\text{LVOT VTI} * \text{LVOT area} = \text{MV VTI} * \text{MVA}$$

$$\text{LVOT VTI} * \left(\text{LVOT diameter}\right)^2 * 0.785 = \text{MV VTI} * \text{MVA}$$

$$\text{MVA} = \frac{\left[\text{LVOT VTI} * \left(\text{LVOT diameter}\right)^2 * 0.785\right]}{\left(\text{MV VTI}\right)}$$

Because MS elevates LA pressures, pulmonary hypertension may result. In general, the more severe the MS is, the more severe the pulmonary hypertension becomes. Pulmonary artery (PA) pressures can be assessed using the estimated RVSP, assuming there is no RVOT obstruction or pulmonic stenosis. A resting PASP > 50 mmHg or exercise-induced pulmo-

Table 11.3 Mitral regurgitation severity [16]

Grade	Definition	Valve anatomy	Valve hemodynamics	Hemodynamic consequences	Symptoms
A	At risk of MR	Mild mitral valve prolapse Mild valve thickening and leaflet restriction	No MR jet or small central jet <20% LA on Doppler Small vena contracta <0.3 cm	None	None
B	Progressive MR	Severe mitral valve prolapse with normal coaptation Rheumatic valve changes with leaflet restriction and loss of central coaptation Prior infective endocarditis(IE)	Central jet MR 20–40% LA or late systolic eccentric jet MR Vena contracta <0.7 cm Regurgitant volume <60 mL Regurgitant fraction <50% ERO <0.40 cm^2 Angiographic grade 1–2+	Mild LA enlargement No LV enlargement Normal pulmonary pressure	None
C	Asymptomatic severe MR	Severe mitral valve prolapse with loss of copatation or flail leaflet Rheumatic valve changes with leaflet restriction and loss of central coaptation Prior IE Thickening of leaflets with radiation heart disease	Central jet MR >40% LA or holosystolic eccentric jet MR Vena contracta ≥0.7 cm Regurgitant volume ≥60 mL Regurgitant fraction ≥50% ERO ≥0.40 cm^2 Angiographic grade 3–4+	Moderate or severe LA enlargement LV enlargement Pulmonary hypertension may be present at rest or with exercise C1 LVEF >60% and LVESD <40 mm C2 LVEF ≤60% and LVESD ≥40 mm	None
D	Symptomatic severe MR	Severe mitral valve prolapse with loss of coaptation or flail leaflet Rheumatic valve changes with leaflet restriction and loss of central coaptation Prior IE Thickening of leaflets with radiation heart disease	Central jet MR >40% LA or holosystolic eccentric jet MR Vena contracta ≥0.7 cm Regurgitant volume ≥60 mL Regurgitant fraction ≥50% ERO ≥0.40 cm^2 Angiographic grade 3–4+	Moderate or severe LA enlargement LV enlargement Pulmonary hypertension present	Decreaesd exercise tolerance Exertional dyspnea

nary hypertension (PASP > 60 mmHg) in the absence of other causes implies hemodynamically significant mitral stenosis [22].

Mitral Regurgitation

Echocardiographic assessment of mitral regurgitation severity relies on a "weighted average" of the information obtained from multiple modalities (Table 11.3). Color Doppler is the most readily apparent and visualized method of assessing mitral regurgitation. The jet area in the atrium on color Doppler is highly dependent on PRF and color scale. Typically, a large jet area spanning more than 40% of the atrium is considered severe MR. However, there are many caveats to using jet area. The appearance of the color is highly

technique-dependent, and can be affected by hemodynamic changes and atrial size. In addition, a very eccentric jet may "hug" the wall and appear to be smaller than a more central jet, giving the false impression that the eccentric MR is not severe. In addition, in the case of acute, severe mitral regurgitation, the jet duration may be very short given the acute rise in LA pressure, and technical factors such as insufficient color resolution may lead to underestimation [23]. Given its many limitations, jet area should not be the sole method used for quantification of mitral regurgitation.

Another method of MR assessment is the flow convergence or PISA method, which is an extension of the continuity principle and has been shown to correlate well with angiographically determined severity [24]. As flow converges toward a regurgitant orifice, the flow organizes into several concentric hemispheres, each with a specific velocity (Fig. 11.8a). As blood approaches the regurgitant orifice, the radius of the hemisphere decreases, while the velocity of blood at the surface of the hemisphere increases. Since the surface area (cm^2) of the hemisphere can be derived from the radius (surface area of hemisphere = $2\pi r^2$), and the velocity of the blood cells (cm/s) at the surface of the hemisphere (aliasing velocity, V_a) can be obtained from the color scale, the product of these two values (in units of cm^3/s) gives the flow rate proximal to the orifice (Fig. 11.8a). The flow rate distal to the orifice, which must equal the flow rate proximal to the orifice, can be calculated from the effective regurgitant orifice area (EROA) multiplied by the peak mitral regurgitant velocity, obtained from the CW Doppler in the 4 chamber view (Fig. 11.8c). To determine the velocity of the hemisphere of the proximal flow convergence, the color baseline or Nyquist limit are shifted downward toward the direction of flow (Fig. 11.8a). As shown in the figure, this maneuver increases the radius of the hemisphere, allowing easy visualization of color transition from blue to yellow, which is the location where the velocity is equal to the aliasing velocity. By having a larger radius and a lower aliasing velocity, propagation of error in radius measurement is reduced.

It follows that:

$$\text{Flow rate proximal to orifice} = \text{Flow rate distal to the orifice}$$

$$\text{Hemisphere surface area} * V_a = \text{EROA} * \text{peak mitral velocity}$$

$$2\pi r^2 * V_a = \text{EROA} * V_{MR}$$

$$\text{EROA} = \frac{\left(6.28 r^2 * V_a\right)}{V_{MR}}$$

This, of course, assumes that the hemisphere radius is measured at the time that the peak MR velocity occurs, so attempts must be made and standardizing the timing of measurement (i.e., mid-systole). As seen in Table 11.2, ERO > 0.4 is severe MR, and <0.2 is mild MR. The PISA method is not very accurate in situations of very eccentric MR jets (may overestimate severity) and noncircular orifices. A geometric correction factor for eccentric jets that create a wedge of a hemisphere instead of a full hemisphere has been described [25]. The angle created by the wedge (α) is divided by 180° and multiplied by the EROA to obtain the geometrically corrected EROA. Therefore, Geometrically corrected ER OA = $(\alpha/180) * (6.28r^2 * V_a)/V_{MR}$. Furthermore, flow velocity calculated by the PISA method represents an instantaneous flow rate. For instance, in mitral valve prolapse, the instantaneous EROA may be large but if the regurgitation only occurs in mid to late systole, the total regurgitant volume may not be very large. So perhaps a more accurate measurement of MR severity in this situation would be regurgitant volume.

To determine the regurgitant volume (RV), the EROA is multiplied by the MV VTI.

$$\text{RV} = \text{EROA} * \text{MV VTI}$$

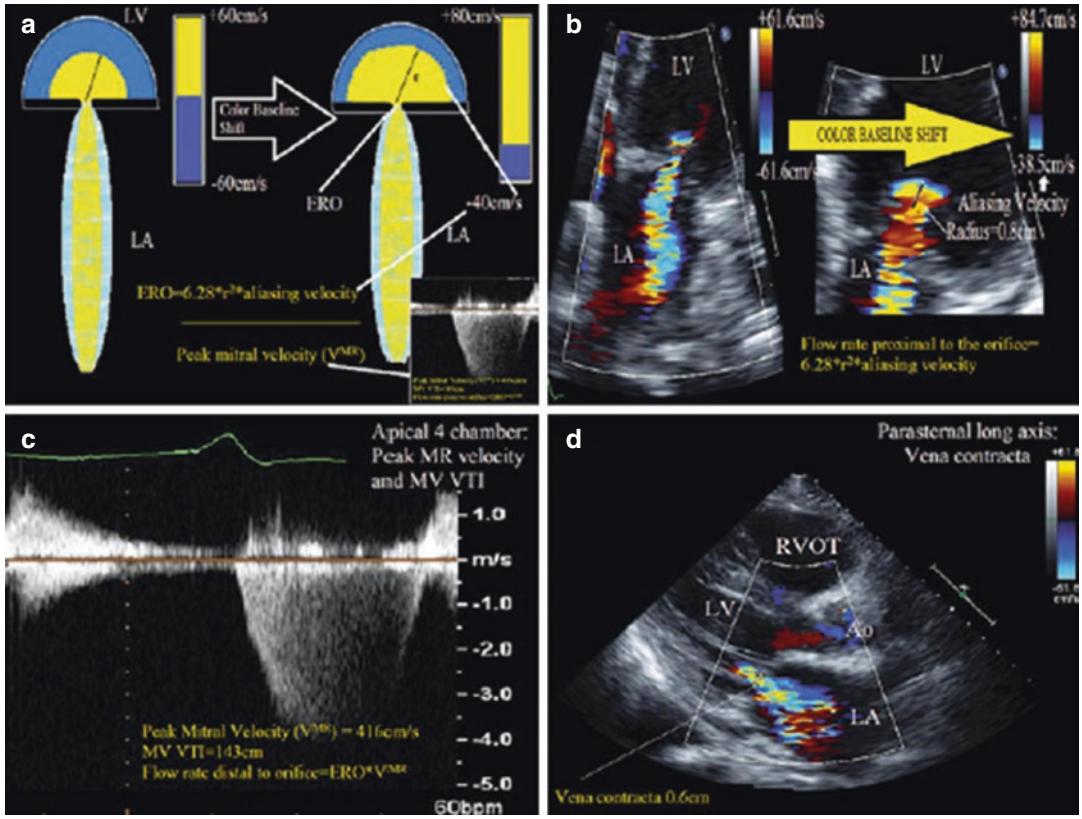

Fig. 11.8 PISA (proximal isovelocity surface area) method for mitral regurgitation and vena contracta. (**a**) Artistic rendition of the PISA concept. As flow converges during systole toward the regurgitant orifice, it accelerates and forms concentric hemispheres of increasing velocity and decreasing radius. For example, the velocity at the edge of the *yellow hemisphere* is higher than the velocity at the edge of the *blue hemisphere*. First the image should be optimized and zoomed. Next, the color baseline is shifted downward toward the direction of flow, from −65 to −40 cm/s, creating the *larger yellow hemisphere* with a lower velocity on the right. The velocity at the boundary between the *yellow* and *blue hemisphere* is the aliasing velocity (V_a = −40 cm/s). The flow proximal to the orifice equals the product of the hemisphere surface area ($2\pi r^2$) and the aliasing velocity (V_a). This proximal flow should equal the flow distal to the orifice, which is the product of the regurgitant orifice area (EROA) and peak MR velocity (V_{MR}). Therefore, EROA = $(2\pi r^2 * V_a)/V_{MR}$. (**b**) Similar to *panel A*, after creating a zoomed-in image, the color baseline is shifted toward the direction of flow, and a larger hemisphere with a known radius (0.8 cm) and aliasing velocity (V_a = 38.5 cm/s) is created. Based on the above equation, the proximal flow rate is 154.7 cm^3/s. (**c**) Continuous wave Doppler across the mitral valve to obtain the peak mitral regurgitant velocity (V_{MR}) = 416 cm/s and MV VTI. The distal flow rate is V_{MR}*EROA. The EROA, which is equal to $(2\pi r^2 * V_a)/V_{MR}$, is 0.37 cm^2, consistent with moderately-severe MR. Regurgitant volume can be calculated with the information in this figure (*see Question 5*). Using the simplified PISA formula, $r^2/2$, estimated EROA is 0.32 cm^2, likely slightly underestimated because the aliasing velocity is 38.5 cm/s, not the 40 cm/s assumed in the simplified formula. (**d**) The vena contracta, the narrowest jet width at the orifice, measured in the parasternal long axis view, is 0.6 cm, consistent with moderately-severe MR

EROA calculation using the PISA may be cumbersome, which can discourage its routine use. A simplified formula can be used if certain assumptions are made [26]. First, one assumes a pressure gradient between the LV and LA of 100 mmHg, which yields a mitral velocity (V_{MR}) of 5 m/s or 500 cm/s (from the Bernoulli equation, LV systolic pressure − LA pressure = $4V_{MR}^2$). If aliasing velocity (V_a) is set to 40 cm/s, then plugging these into the equation:

$$\text{EROA} = \frac{\left(6.28r^2 * V_a\right)c}{V_{MR}}$$

$$\text{EROA} = \frac{\left(6.28r^2 * 40\ \text{cm/s}\right)}{500\ \text{cm/s}}$$

$$\text{EROA} \oplus \frac{r^2}{2}$$

The vena contracta is the narrowest color flow at or upstream of the valve orifice [16]. For mitral regurgitation, it is typically assessed in the parasternal long axis view, and is considered to be independent of flow and pressure for a fixed orifice, even for eccentric jets (Fig. 11.8d). A vena contracta width of <0.3 cm is considered mild MR, and >0.7 cm is considered severe [16]. This parameter, when measurable, should always be considered a key component to the integrated approach to determining mitral regurgitation severity.

Other signs of severe MR are a triangular shape in the CW profile of the mitral regurgitant (early peaking) rather than a smooth parabolic profile, which implies rapid equilibration of LV and LA pressure from severe MR [16]. In addition, in the mitral inflow PW profile, severe MR is typically associated with a tall *E* wave >120 cm/s. Stage 1 diastolic dysfunction pattern on mitral inflow virtually excludes severe MR. In severe MR, the elevated LA pressures during systole decrease the gradient between the LA and the pulmonary veins, so the pulmonary vein *s* wave may be blunted or even reversed.

Aortic Insufficiency

In the parasternal long axis view, the percentage of the LVOT width that the regurgitant jet occupies has been correlated with aortic insufficiency (AI) severity [16]. If the jet width in diastole occupies more than 65% of the LVOT diameter, then it is considered severe. However, just as with jet area in MR, jet width in AI is not valid for eccentric jets in which severity may be underestimated (Fig. 11.9a) [27]. The vena contracta is the narrowest neck of the jet at the level of the valve. The width of the vena contracta correlates with regurgitant orifice area and is unaffected by jet eccentricity [28]. To accurately measure the vena contracta width, a zoomed-in parasternal long axis view should be obtained that shows the flow convergence zone, the vena contracta, as well as the regurgitant jet in the LVOT. A vena contracta width ≥6 mm suggests severe AI (Table 11.4). The utility of this method is limited if there are multiple jets [16]. The PISA method has been applied for the calculation of the aortic regurgitant EROA. This measurement should be made in the apical 5 chamber or apical long axis view in early diastole but is technically more difficult to obtain than the PISA for MR. The same principle applies as with MR, in that the flow rate proximal to the orifice (aorta) which is the product of the hemisphere area and the aliasing velocity ($2\pi r^2 * V_a$) equals the flow rate distal to the orifice in the LVOT (EROA∗peak aortic regurgitant velocity). However, the color baseline is shifted up rather than down, as this is toward the direction of flow. EROA ≥0.3 cm^2 correlates with severe AI (Table 11.4). The simplified PISA method used for MR ($r^2/2$) does not apply to AI.

Pulse wave Doppler in the upper descending thoracic aorta from the suprasternal view can both qualitatively and quantitatively assess aortic regurgitation severity [27]. Holodiastolic flow reversal in the proximal descending aorta is specific for at least moderately-severe aortic insufficiency, and is considered to be the echocardiographic equivalent of the *Duroziez's sign* [16] (Fig. 11.9b). This is a much more specific finding if there is flow reversal is present when sampling in the abdominal aorta. The ratio of the reverse flow (diastolic VTI∗cross-sectional area of the aorta in diastole) to the forward flow (systolic VTI∗cross-sectional area of the aorta in systole) is proportional to the regurgitant fraction [29].

PHT of the aortic regurgitation jet reflects the rate of equalization between the aortic and LV pressures (Fig. 11.9c). Therefore, this PHT is not only influenced by the severity of aortic insufficiency but also by LV pressure, LV compliance, and afterload conditions. Hence, it may be the least reliable method for assessing regurgitation

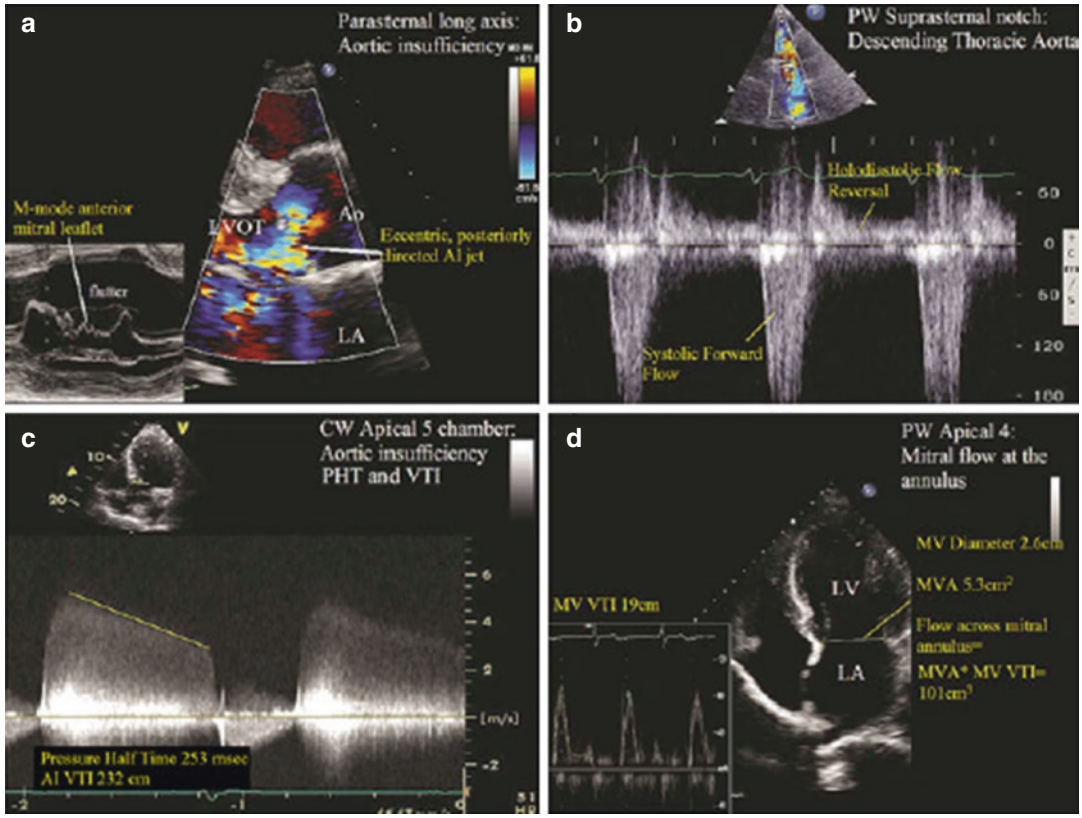

Fig. 11.9 Severe aortic insufficiency (AI). (**a**) Parasternal long axis view color Doppler demonstrates a very severe, eccentric, and posterior directed jet. Note that the M-Mode across the mitral leaflet shows fluttering of the anterior leaflet due to the aortic insufficiency jet (*lower left corner inset*). Given the eccentricity, one cannot use the LVOT jet area to assess severity. (**b**) Pulse wave Doppler with sample volume in the upper descending thoracic aorta, demonstrating holodiastolic flow reversal, a sign of severe AI. (**c**) Continuous wave Doppler across the aortic valve in the apical 5 chamber view. The PHT is 253 ms, consistent with severe AI. The aortic insufficiency VTI is 232 cm based on the CW profile. (**d**) Application of the continuity equation allows for the calculation of the regurgitant AI volume. Flow across the mitral valve plus the regurgitant volume should equal the flow across the aortic valve (Stroke volume). The MVA is determined by measuring the mitral valve diameter, and this area (5.3 cm^2) is multiplied by the MV VTI at the annulus (19 cm) to yield a flow of 101 cm^3. Flow across the aortic valve is determined by the product of the LVOT VTI and LVOT area, which yields a volume of 169 cm^3, calculation not shown. Therefore, the aortic insufficiency regurgitant volume is 169 cm^3 − 101 cm^3 = 68 cm^3, consistent with severe AI. The regurgitant orifice area (EROA) of the aortic valve is calculated by dividing the regurgitant volume (68 cm^3) by the AI VTI (232 cm), which equals 0.3 cm^2, also consistent with severe AI

severity [16]. A PHT <200 ms is supportive of severe aortic insufficiency, and a pressure half-time greater than 400 ms is unlikely to represent more than moderate AR. However, even in severe AI, if the LV has dilated as a chronic adaptation to the increased preload and afterload, then the pressure half-time could be normal since the LV and aorta pressures would not rapidly equilibrate. If vasodilators are given or LV pressures increase for a given degree of AI, the PHT would decrease.

The continuity equation can also be applied to aortic insufficiency if there is no more than mild mitral insufficiency. Think of the flow across the aortic valve as gross income, the regurgitant volume as the tax, and the flow across the mitral valve as the net income. The difference between the flow across the aortic valve ("gross" systolic stroke volume) and the flow across the mitral valve ("net" forward stroke volume) is equal to the "tax" or regurgitant volume per beat. The "gross"

Table 11.4 Stages of aortic insufficiency [16]

Stage	Definition	Valve anatomy	Valve hemodynamics	Hemodynamic consequences	Symptoms
A	At risk for AR	Bicuspid aortic valve (or other congenital valve anomaly) Aortic valve sclerosis Diseases of the aortic sinuses or ascending aorta History of rheumatic fever or known rheumatic heart disease IE(infective endocarditis)	AR severity: none to trace	None	None
B	Progressive AR	Mild-to-moderate calcification Dilated aortic sinuses Rheumatic valve changes Previous IE	Mild AR: jet width <25% of LVOT; vena contracta <0.3 cm; RVol <30 mL/beat; RF <30%; ERO <0.10 cm^2; angiography grade 1+ Moderate AR: Jet width 25–64% of LVOT; vena contracta 0.3–0.6 cm; RVol 30–59 mL/beat; RF 30–49%; ERO0.10–0.20 cm^2;angiography grade 2 + _	Normal LV systolic function Normal LV volume or mild LV dilation	-None
C	Asymptomatic severe AR	Calcific aortic valve disease Bicuspid valve Dilated aortic sinuses or ascending aorta Rheumatic valve changes IE with abnormal leaflet closure or perforation	Severe AR: Jet width ≥65% of the LVOT Vena contract>0.6 cm Holodiastolic flow reversal in the proximal abdominal aorta RVol ≥60 mL/beat RF ≥50% ERO ≥0.3 cm^2 Angiography grade 3–4+ LV dilation	C1: Normal LVEF ≥50% and mild-to-moderate LV dilation (LVESD ≤ 50 mm) C2: Abnormal LV systolic function with depressed LVEF (<50%) or severe LV dilatation(LVESD > 50 mm or indexed LVESD > 25 $mm.m^2$)	None, exercise testing is reasonable to confirm symptom status
D	Symptomatic Severe AR	Calcific aortic valve disease Bicuspid valve Dilated aortic sinuses or ascending aorta Rheumatic valve changes IE with abnormal leaflet closure or perforation	Severe AR: Jet width ≥65% of the LVOT Vena contract > 0.6 cm Holodiastolic flow reversal in the proximal abdominal aorta RVol ≥60 mL/beat RF ≥50% ERO ≥0.3 cm^2 Angiography grade 3–4+ LV dilation	Symptomatic severe AR may occur with normal systolic function (LVEF ≥50%), mild-to-moderate LV dysfunction(LVEF 40–50%), or severe LV dysfunction(LVEF <40); Moderate-to-severe LV dilation is present	Exertional dyspnea or angina or more severe HF symptoms

EROA effective regurgitant orifice area, *RV* regurgitant volume, *RF* regurgitant fraction, *DA* descending aorta, *LV* left ventricle

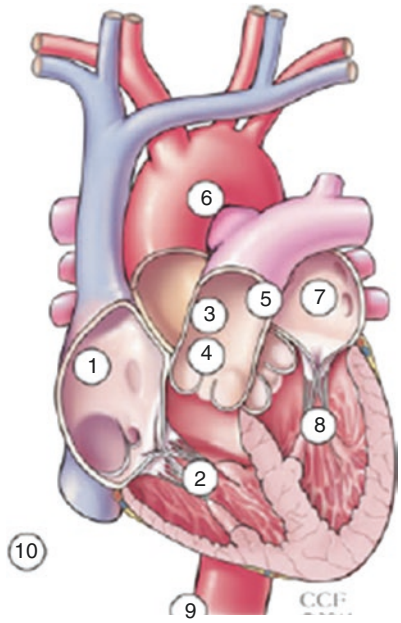
stroke volume can be obtained either from the LVOT VTI method or from the difference between the LV volumes in systole and diastole. To calculate "net" forward flow across the mitral valve, it is important to use PW and place the sample volume at the annulus of the mitral valve to measure and accurate flow across the mitral valve during diastole (Fig. 11.9d).

$$\text{Regurgitant volume}(\text{RV}) = \text{Stroke volume across aortic valve} - \text{Flow across mitral valve annulus}$$

$$\text{RV} = (\text{LVOT VTI} * \text{LVOT area}) - (\text{MV VTI}(\text{diastole}) * \text{MV annulus area})$$

$$\text{RV} = \left[\text{LVOT VTI} * (\text{LVOT diameter})^2 * 0.785\right] - [\text{MV VTI} * (\text{MV diameter})^2 * 0.785]$$

Once the regurgitant stroke volume is obtained, it can be divided by the regurgitant jet VTI obtained from CW in diastole to calculate the EROA [16]. If the EROA is in the severe range but the RV is not, it may be because in acute AI, the rapid increase in the LVEDP shortens the time for regurgitation, so the regurgitant volume may not be as large as expected from the EROA (Fig. 11.10).



1. RA=(0-5 mmHg) if IVC ≤ 2.1 cm and collapses > 50%
   RA=(10-20 mmHg) if IVC>2.1 cm and collapses <50%

3D Echocardiography

The advent of 3D echocardiography has provided clinicians with more anatomic detail regarding valve structure and function. One arena in particular in which 3D echo provided value is the assessment of valves during valve interventions, either surgical or in the catheterization lab. For instance, 3D echo assists the operator in the transcatheter placement of the Mitra-clip for the treatment of mitral regurgitation. Beyond informing the clinical regarding anatomic structure and function, 3D echo has some limited clinical applications in the assessment of valve hemodynamics. In mitral stenosis, 3D echo can be used for measuring valve area. In addition, in the same way that a PISA is calculated using 2D echo, 3D Doppler can be used to assess the radius of the proximal isovelocity surface area. The 2D PISA assumes a hemispheric shape of the PISA, which may not be true in all regurgitant lesions, and, for example, in functional mitral regurgitation, the geometry may be more ellipsoid. By applying the hemi-ellipsoid formula for instance, the mitral regurgitation severity can be more accurately measured [30, 31]. *Although its current clinical application in valve hemodynamics is somewhat limited, with time this method will likely receive wider adoption.*

Review Questions

1. What is the estimated right ventricular systolic pressure (RVSP) in the patient in Fig. 11.4a if the inferior vena cava (IVC) measures 2.5 cm and there is no collapse with sniff?
   A. 60 mmHg
   B. 70 mmHg
   C. 30 mmHg
   D. 85 mmHg
2. What is the estimated end-diastolic pulmonary artery pressure in Fig. 11.4b?
   A. 14.4 mmHg
   B. 14.4 mmHg + RA pressure
   C. 38.5 mmHg
   D. 38.5 mmHg + RA pressure
3. Based on the continuity equation, what is the estimated aortic valve area (AVA) in Fig. 11.5? Is this severe AS or moderate AS?
   A. 1.2 cm^2, moderate AS
   B. 1.2 cm^2, severe AS
   C. 0.6 cm^2, severe AS
   D. 0.6 cm^2, moderate AS
4. The patient in Fig. 11.6 has a known secundum atrial septal defect, and as shown in panel (a), there is left to right flow across the atrial septal defect. The echocardiogram was performed to estimate the shunt fraction. Based on the information provided in Fig. 11.6, what is the estimated Q_p/Q_s ratio?
   A. 1:1
   B. 1.3:1
   C. 0.5:1
   D. 2:1
5. In Fig. 11.8, the regurgitant orifice area is 0.37 cm^2. Based on the information in panel (c), what is the estimated regurgitant volume per beat?
   A. 143 mL/beat
   B. 416 mL/beat
   C. 53 mL/beat
   D. 100 cc/beat

Answers

1. The peak TR velocity is 420 cm/s, or 4.2 m/s. Based on the simplified Bernoulli equation, the difference between the RV and RA pressure is $4V_{TR}^2$, or $4*(4.2)^2 = 70.56$ mmHg, roughly 70 mmHg. The RA pressure is estimated at 15 mmHg based on the dilated IVC that does not collapse greater than 50% with the sniff. Therefore, because the RVSP is equal to RA pressure plus the $4V_{TR}^2$, RVSP = 70 mmHg + 15 mmHg = 85 mmHg, compatible with severe pulmonary hypertension.
2. In Fig. 11.4b, the spectral Doppler shows the CW across the RVOT and pulmonic valve. From the pulmonary regurgitation jet, the late diastolic pulmonary regurgitation velocity represents the pressure difference between the pulmonary artery and the right ventricle at end diastole (note the timing just at the onset of the QRS). Therefore, the $4v_{PRed}^2$ = RVEDP − PAEDP. It

follows that PAEDP = RVEDP + $4v_{PRed}^2$. Because the RVEDP is equal to RA pressure, PAEDP = RA + $4v_{PRed}^2$. Here the end-diastolic velocity is 1.9 m/s. Therefore, PAEDP = RA + $4(1.9)^2$ = 14.4 mmHg + RA pressure.

3. Based on the continuity equation, AVA = [LVOT VTI ∗ (LVOT diameter)^2 ∗ 0.785]/[AV VTI]. The LVOT VTI from Fig. 11.5b is 28.1 cm, and the LVOT diameter from Fig. 11.5a is 1.9 cm. The highest AV VTI was obtained from the right sternal border view, which is 124 cm. Note that this corresponded to a peak and mean gradient of 119/74 mmHg, severe aortic stenosis (AS) by gradients. Using the continuity equation, AVA = [28.1 ∗ $(1.9)^2$ ∗ 0.785]/[124] = 0.6 cm^2, also compatible with severe AS.
4. The ratio of pulmonary blood flow to systemic blood flow is the Q_p/Q_s, or shunt fraction. The systemic blood flow (Q_s) is estimated by multiplying the LVOT area, (LVOT D)^2∗0.785, by the LVOT VTI. As shown in Fig. 11.6c, the LVOT diameter is 2.1 cm and the LVOT VTI is 13.2 cm. Therefore, the systemic flow is $(2.1)^2$ ∗ 0.78 5 ∗ 13.2 = 45.7 cm^3. The pulmonary blood flow (Q_p) is estimated by multiplying the RVOT area, (RVOT D)^2∗0.785, by the RVOT VTI. As shown in Fig. 11.6d, the RVOT diameter is 2.47 cm and the RVOT VTI is 12.3 cm. Therefore, the pulmonary blood flow is $(2.47)^2$ ∗ 0.785 ∗ 12.3 = 58.9 cm^3. The Q_p/Q_s ratio is 45.7/58.9 = 1.3:1. Note that because the 0.785 constant is present in both the numerator and denominator, the Q_p/Q_s calculation can be simplified to [(RVOT D)^2 ∗ (RVOT VTI)]/[(LVOT D)^2 ∗ (LVOT VTI)].
5. The regurgitant volume is equal to the product of the regurgitant orifice area (EROA, cm^2) and the MV VTI (cm). In this case, the product of the EROA (0.37 cm^2) and the MV VTI (143 cm) gives a regurgitant volume of 53 mL/beat, which is consistent with moderately-severe MR.

CT and MRI Cardiovascular Hemodynamics

12

Andrew O. Zurick

Introduction

Noninvasive cardiac imaging has experienced dynamic improvements over the past several decades. Multiple, complementary technologies, including magnetic resonance imaging (MRI), computed tomography (CT), echocardiography, nuclear scintigraphy, fluoroscopy, and angiography, are now capable of directly or indirectly providing information on cardiac and great vessel anatomy, volumes and function, myocardial perfusion, valvular morphology and function, coronary artery blood flow, and presence or absence of myocardial fibrosis or scar. Further, several of these technologies now are capable of providing a noninvasive hemodynamic assessment, which has otherwise primarily in the past been the domain and strength of echocardiography and invasive catheterization. Both CT and MRI have been proven to be accurate and reproducible, with each now capable of providing noninvasive hemodynamic information which is capable of enhancing clinical decision-making and impacting patient care. However, the use of this information must be based on a thorough knowledge of the strengths and weaknesses of the various noninvasive methods of hemodynamic assessment. Understanding the applications and limitations of these modalities will permit their effective and efficient usage in the future (Table 12.1).

General Overview of MR and CT Physics and Techniques

Physics Overview

MRI is based on the resonance, or increased amplitude of oscillation of a system exposed to a periodic force, of atomic nuclei. Following the application of radio waves, MRI measures the electromagnetic signals that are emitted from atomic nuclei. Hydrogen is the most simple and abundant element in the human body, consisting of a single proton and electron, and therefore, it represents an ideal substrate for clinical MRI. There exists a unique relationship between electricity and magnetism, namely moving electrical charges are capable of generating a magnetic field, and a time-varying magnetic field can create electric fields that can promote the flow of electrical charges. Atomic nuclei of several atoms behave as small magnets with angular momentum, and when placed within a magnetic field, they have a tendency to align with the direction of an electric field applied, and process, or rotate, about their own axis, as would a top.

Most current clinical MRI involves superconducting magnets, where a magnetic field is

Table 12.1 CT and MRI advantages and disadvantages

	Advantages	Disadvantages
Computed tomography	Rapid image acquisition	Radiation exposure
	Excellent spatial resolution (<1 mm)	Potential need for iodinated contrast dye
	3D dataset acquisition for ability for post-processing/reconstruction	Limited temporal resolution (best temporal resolution with current generation scanners on order of 75 ms)
	Typically well tolerated by patients	Limited hemodynamic assessment options currently
	Not contraindicated in patients with ferromagnetic/metallic implants	
Magnetic resonance imaging	Tissue characterization	Increased image acquisition time
		Potential for patient claustrophobia
	Excellent spatial resolution (1–2 mm)	Possibility, although rare, for NSF following gadolinium contrast administration
	Temporal resolution better than CT (typically 25–50 ms)	Inability to image patients with absolute contraindications including those with ferromagnetic implants (i.e., pacemakers, ICDs, intracerebral vascular coils, etc.)
	Unlimited imaging plane orientation and ability to acquire 3D datasets	
	No need for contrast (i.e., can be performed on patients with decreased GFR)	
	Increased ability to assess cardiovascular hemodynamics noninvasively via volumetric and phase-contrast analysis	

generated perpendicular to an electrical current flowing along a cylindrical coiled wire. The creation of MR images involves the excitation of protons, within a magnetic field, using pulses of radiofrequency energy, which can be specifically applied to body parts of interest through the concurrent application of magnetic field gradients. Following excitation of a tissue, a signal is created within a "receive" coil, which subsequently undergoes analog-to-digital conversion (ADC), which is then processed by the MRI computer as raw data into "k-space." The "Fourier transform" of the raw data ultimately generates 2D or 3D MR images that can be viewed for interpretation. MR imaging of the heart must contend with both cardiac and respiratory motion, conflicting requirements for both high temporal and spatial resolution, and do all of this both accurately and reproducibly in the clinical setting, in a timely fashion.

As with CMR, the small dimensions of the coronary arteries and rapid motion of cardiac structures pose significant challenges to effective imaging with cardiac computed tomography (CT). Current generation multirow detector CT (MDCT) scanners involve a rotating X-ray source, which emit photons, which pass through a patient, as they are moved through the machine gantry. Due to continued improvements in gantry rotation times, and the development of dual-source CT, temporal resolution has improved. Slice collimation, or thickness, has also continued to improve, resulting in greater spatial resolution. Increased X-ray tube strength has also resulted in decreased image noise and recent generation scanners have continued to improve simultaneous slice acquisition, now up to as many as 320 slices per rotation, which allows one to cover a larger volume per rotation, decrease overall data acquisition time, and reduce duration of required breath hold. Through the simultaneous registration of the ECG, it is possible to synchronize image reconstruction with the relative cardiac phase. Ongoing developments in tube-current modulation, prospective ECG-gated scanning, and improved table pitch (speed with which the patient table is advanced through the scanner) continue to lower patient radiation exposure (effective dose).

MRI Techniques

Phase-Contrast Imaging

Phase-contrast imaging (PCI) is an MRI technique for quantifying velocity and blood flow in the heart, across valves, and through great vessels. By measuring the phase shift, or change in precessional frequency, of protons in blood as they move through a magnetic field with a bipolar gradient, velocity, direction, and volume of blood flow can be determined. The amount of relative phase difference is proportional to the velocity of the moving spin, and these phase shifts are measured in degrees within a range of ±180°. Similar to aliasing velocity in Doppler echocardiography, the encoding velocity (VENC) chosen for this technique should optimally be chosen to correspond to a phase shift of 180°. If the phase shift exceeds 180°, then the spins will be interpreted as having a different orientation, which would therefore result in abnormal velocity interpretation. Ultimately, phase-contrast MR imaging produces velocity-encoded images where signal intensity is proportional to the velocity of blood moving through or within the slice plane. Unlike echocardiography, which is constrained by acoustic windows, PCI, utilizing a single imaging plane that is most commonly perpendicular to the direction of blood flow, generates a velocity-encoded image of multiple phases of the heart cycle either with or without breath-holding. No intravenous contrast is necessary to generate these images. Quantification of blood flow is subsequently determined by various software applications that require the user to manually outline the vessel of interest for each cardiac phase, which then produces time-velocity and time-flow curves (Fig. 12.1a,b). Many studies have now demonstrated the reliability of PCI with CMR; however it must be noted that the accuracy of the technique can be significantly affected by the presence of eddy currents [1].

Myocardial Tagging

Myocardial tagging is a series of techniques that impose a saturation grid or series of saturation lines across the myocardium [1]. Deformation of these lines due to myocardial contraction and relaxation are then monitored and can be used to assess myocardial function by tracking the motion of the myocardium during the various phases of the cardiac cycle [2] (Fig. 12.2). When combined with cine imaging, myocardial tagging can provide complementary information regarding myocardial contraction, performance, and can be used to measure myocardial strain in three dimensions. In clinical practice, myocardial tag lines are typically evaluated subjectively to differentiate normal and hypokinetic myocardial segments. While predominantly used as a supplementary technique to cine imaging to evaluate cardiac wall motion, the research applications of myocardial tagging are continuing to evolve, particularly with recent advances in image acquisition speed and improved signal-to-noise ratios.

Volumetric and Functional Assessment

Through continued improvement in hardware and software, MRI has evolved into the "gold standard" for ventricular volumetric and function assessment owing to its excellent accuracy and reproducibility. With manual or automated contours of multiphase, ECG-gated epi- and endocardial contours, ventricular volumes, function, and mass can be determined. In addition, while Doppler echocardiography has typically been considered the reference standard for assessment of diastolic dysfunction, recent studies have also demonstrated the utility and reproducibility of CMR techniques for flow and phase-contrast data analysis to extract velocity-related diastolic parameters [3]. The degree of myocardial fibrosis is related to the degree of left ventricular stiffness. Malaty et al. evaluated 50 patients with dilated cardiomyopathy (DCM) with Doppler echocardiography and breath-hold segmented inversion recovery sequence imaging following intravenous gadolinium administration to determine amount of left ventricular scar burden. Hyperenhancement (HE) was present in 31 patients with a mean scar burden of 4 ± 7.6%, and patients with DCM without HE had significantly higher septal E/E' ratio than patients with scar ($p = 0.05$) suggesting that factors other than scar burden likely contribute to LV stiffness to a greater extent than replacement fibrosis in this

Fig. 12.1 (**a**) Cardiac amyloidosis. Flow curves in *upper left panel* demonstrate systolic blunting consistent with diastolic dysfunction. Images at *bottom* demonstrate tissue characterization of myocardium in cardiac amyloidosis, with associated circumferential pericardial effusion, through multiple different cardiac MRI pulse sequences. (**b**) Hypertrophic cardiomyopathy with severe systolic anterior motion of the mitral valve (SAM). Representative phase-contrast image (*top*) demonstrating manual contouring of the left ventricular outflow tract. Contours are propagated to images from multiple cardiac phases. Image at *bottom left* represents single cardiac-phase magnitude gradient echo image at end-systole. Peak left ventricular outflow tract velocity can be measured and converted to pressure gradient through utilization of modified Bernoulli equation

b

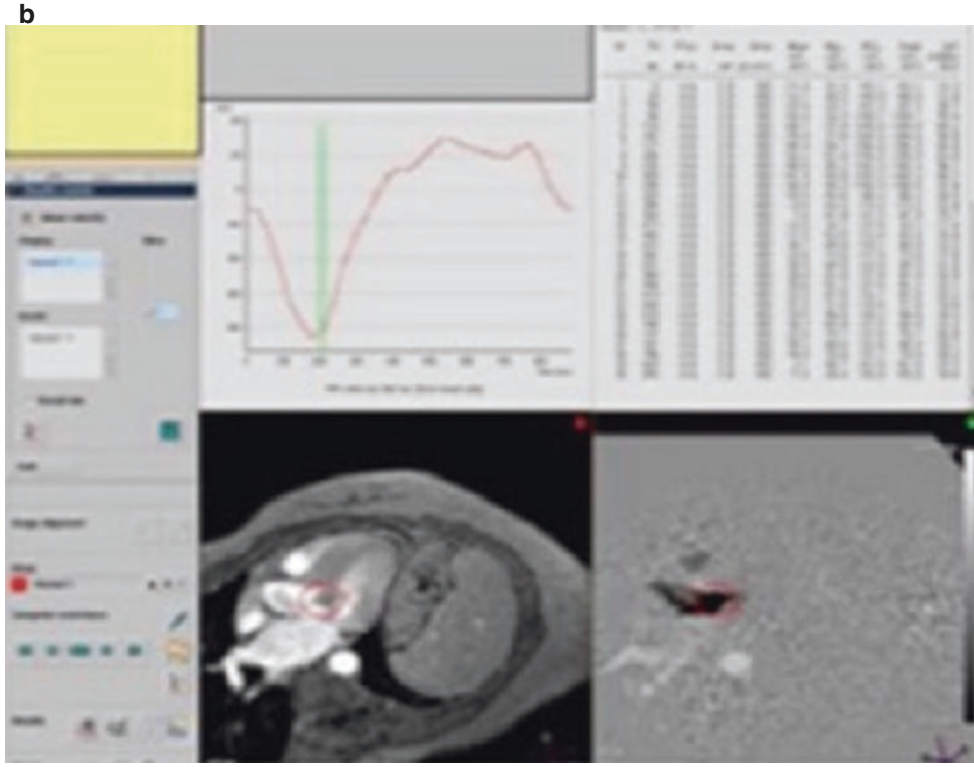

Fig. 12.1 (continued)

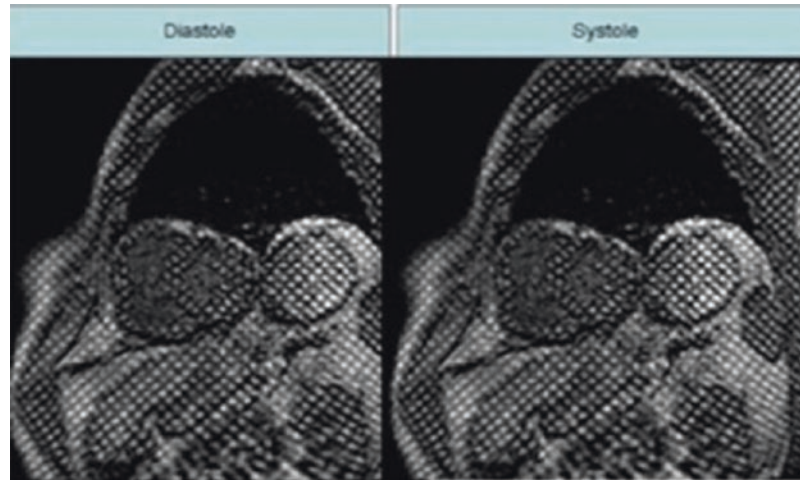

Fig. 12.2 Myocardial tagged image (short axis orientation) with saturation lines depicted across the myocardium in both systole (*right*) and diastole (*left*)

patient population [4]. However, other groups have also shown that cardiac fibrosis correlates with impaired LV diastolic function and functional capacity, elevated NT-pro BNP, and adverse cardiac remodeling in patients with non-ischemic DCM [5]. Other groups have utilized CMR phase-contrast velocity mapping (i.e., tissue phase mapping) to evaluate regional wall motion patterns and longitudinally and circumferentially directed movements of the left ventricle [6]. The complex pattern of ventricular twisting and longitudinal motion in the normal

human heart can be better understood through applications such as these, ultimately helping to provide a better understanding of the complex mechanics of the normal heart.

Stress cardiac MRI has continued to evolve and is capable of providing a multiparametric examination of cardiac function, perfusion, and valvular function and assessing for interstitial fibrosis or myocardial scar. Lipinksi M et al. performed a meta-analysis to understand the role that stress cardiovascular MRI plays in the assessment of patients with known or suspected coronary artery disease [7]. A total of 11,636 patients were evaluated, and those with ischemia were noted to have a higher rate of myocardial infarction or cardiovascular death compared with patients that had a non-ischemic study.

The combined outcome annualized events rates were 4.9% for a positive versus 0.8% for a negative stress CMR ($p < 0.0001$), 2.8% versus 0.3% for cardiovascular death ($p < 0.0001$), and 2.6% versus 0.4% for MI ($p < 0.0005$). The presence of late gadolinium enhancement was significantly associated with a worse prognosis. More recently, Liu A et al. published the first prospective validation of stress T1 mapping against invasive coronary measurements for detecting obstructive coronary artery disease [8]. Sixty patients with angina and 30 normal patients were imaged with CMR adenosine stress/rest T1-mapping. Ischemic viable myocardium downstream from obstructive CAD showed nearly abolished T1 reactivity, while myocardium downstream from non-obstructive coronary artery disease with microvascular dysfunction showed a lesser degree of blunting of T1 reactivity. This method of evaluating patients with coronary artery disease for ischemia may prove to obviate the need for routine intravenous gadolinium contrast administration.

Delayed Enhancement Imaging

The intensity of voxels in an MR image is a direct result of the amount of signal that can be measured by a receiver coil. MR intravenous contrast agents are useful for depicting anatomy and physiology, evaluating vascular supply to both normal and pathologic tissues, and assessing myocardial viability. Most MR contrast agents work by shortening T1 relaxation times, which results in increased signal intensity. The most commonly used MR contrast agents are chelates of gadolinium (Gd3+), a lanthanide heavy metal ion.

Inversion recovery imaging is capable of selectively suppressing signal from certain tissues based on their T1 recovery times and is useful for assessing myocardial infarction and viability. Following gadolinium administration, infarcted myocardium demonstrates a delayed pattern of gadolinium washout, and through the use of inversion recovery techniques, normal myocardium is "nulled" so that infarcted myocardium appears bright by comparison.

Tissue Characterization (T1- and T2-Weighted Imaging)

One of the unique features of cardiac MRI is the ability to characterize normal and pathologic tissues through the use of various pulse sequences. In addition to fat suppression and gadolinium contrast enhancement, T1- and T2-weighted imaging are the most widely utilized techniques. Tissues that tend to appear brighter on T1-weighted images include lipid, hemorrhagic products, proteinaceous fluid, and gadolinium. T2-weighted images of the heart help to characterize tissues with longer T2-times and are typically performed with concurrent blood nulling.

CT Techniques

ECG-Triggering

Through the simultaneous registration of the ECG, it is possible to synchronize CT image reconstruction with the relative cardiac phase. Due to cardiac and respiratory movements, motion artifacts can significantly affect cardiovascular CT images. Appropriate collimation size and image acquisition speed are important to obtain images free from artifacts. Currently, the collimation size for coronary artery calcium screening and angiography is 0.6–3 mm and acquisition speed ranges from 50 to 250 ms. Currently, two ECG-trigger techniques are utilized in cardiac CT

imaging, retrospective and prospective triggering. Prospective triggering can be performed with R wave triggering, end-systolic triggering, and both end-systolic and end-diastolic combined triggering. Alternatively, retrospective triggering is widely used and synchronized to an ECG signal that is recorded simultaneously with images. Changes in heart rate or rhythm can induce misregistration artifact in both prospective and retrospective triggered images.

Contrast Media

The primary purpose of contrast media injection is to increase contrast between the structure of interest and surrounding tissues by increasing the CT Hounsfield units. Care must be taken regarding circulation time for contrast media, the time interval that it takes blood to move from the point of venous access, the structure/region of interest, with several factors having influence, including cardiac output, injection rate, and venous anatomy. Circulation time can be measured using a small contrast bolus injection with serial scanning of a single image slice to obtain peak enhancement time through the time density curve. Alternatively, automatic bolus triggering utilizes a monitoring scan obtained 10–12 s following the start of contrast injection, and when the Hounsfield unit (HU) reaches a pre-specified threshold (typically 120 HU), imaging is initiated.

Clinical Applications

Shunts

Cardiac MRI has become a valuable tool in the evaluation of both cardiac anatomy and quantification of physiologic function. CMR can detect, provide morphologic information about, and quantify both intra- and extra-cardiac shunts. Shunt volume can be calculated through the use of volumetric cine MR imaging or PCI. Provided that there is absence of concurrent valvular regurgitation, total forward flow through the proximal ascending aorta and main pulmonary artery can be utilized to determine shunt fraction (Shunt fraction % (Q_p/Q_s) = total PCI pulmonary artery volume flow (mL)/total PCI ascending aortic volume flow (mL)). Alternatively, shunt severity can be calculated by comparing the ratio of right ventricular to left ventricular stroke volumes (Q_p/Q_s), again provided that there is not significant simultaneous valvular regurgitation. In addition, MR angiography can provide excellent 3D anatomic examination of vessels including the presence of anomalous pulmonary veins.

Cardiac CT is a useful adjunctive imaging modality in the assessment of intra- and extracardiac shunts. It is typically reserved for patients with contraindications for CMR or when there are issues associated with severe claustrophobia. Excellent spatial resolution provides the ability to visualize interatrial and interventricular septal defects (VSDs) [9]. Cardiac CT permits detailed imaging the heart, but also affords additional assessment of several noncardiac structures including mediastinum, lungs, pulmonary artery system, aorta, esophagus, chest wall, and airways [10]. Previous studies have shown that cine CT, through evaluation of indicator dilution curves, provides a precise, noninvasive technique for measuring shunt lesions in congenital and acquired heart diseases [11].

Atrial Septal Defect

Atrial septal defect (ASD) is the most common shunt lesion detected de novo in adulthood [12]. Sinus venosus, septum secundum, and primum defects can clearly be identified with MR imaging in the transverse plane or along the short axis. Further, spin-echo MR imaging has been found to have a greater than 90% sensitivity and specificity for identification of atrial septal defects [13]. PCI enables more precise evaluation of both size and shape of atrial septal defects and permits more accurate quantification of the degree of shunting present [14, 15]. In addition, cardiac CT has been also shown to detect and characterize ASDs with high sensitivity (66–100%) and specificity (86–100%) [16] (Fig. 12.3).

Ventricular Septal Defect

VSD is the second most common congenital defect of the heart, accounting for nearly 20% of

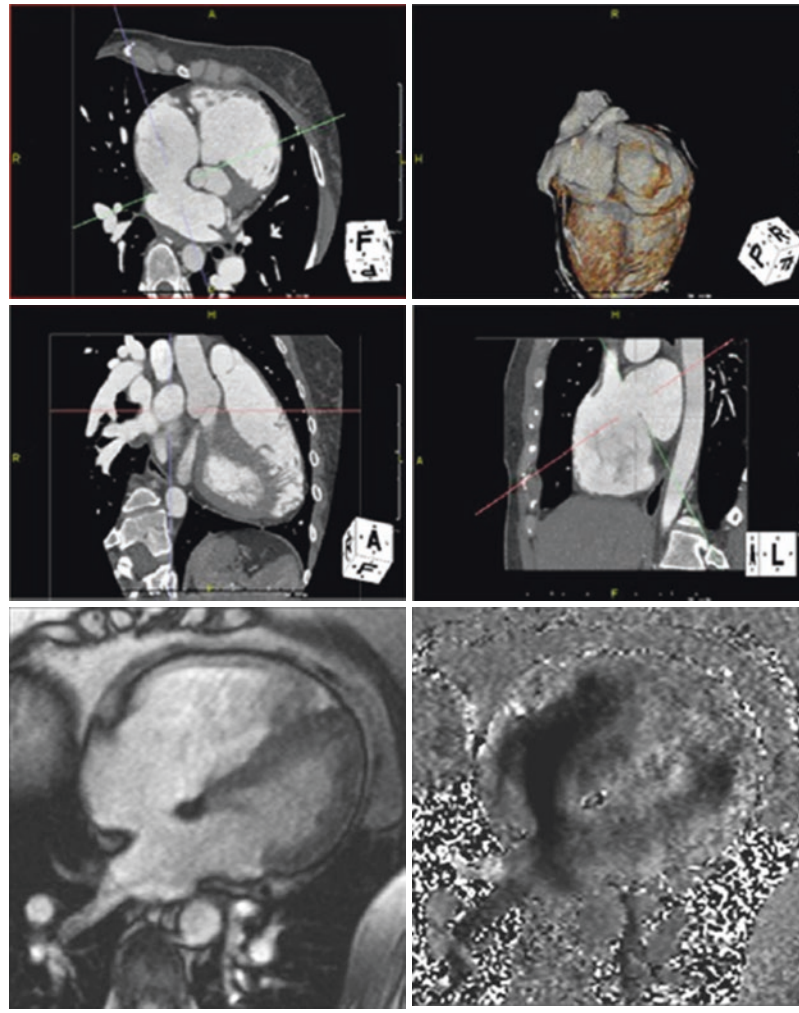

Fig. 12.3 ECG-gated cardiac computed tomography with iodinated contrast axial image demonstrating atrial septal defect (ASD), ostium secundum type (*top*). Cardiac MRI (*bottom*) steady-state free precession 4-chamber image demonstrating ASD, ostium secundum type (*right*), and phase-contrast image demonstrating left to right shunt across ASD (*left*)

all cardiac malformations [12]. VSD can be further categorized into four groups based on location and margin: outlet, membranous, trabecular, and inlet [17]. Membranous is the most common. MR imaging possesses greater than 90% sensitivity for the detection of VSD [18].

Atrioventricular Septal Defect

Atrioventricular septal defects present as a common atrioventricular valve with abnormal arrangement of the valvular leaflets, and variable defects in the primum atrial septum and ventricular inlet septum [19]. In the most severe form of atrioventricular septal defect, there exists bidirectional shunting, where all four chambers of the heart communicate. CMR is a particularly valuable tool in the evaluation of atrioventricular septal defects to delineate anatomical features which are important for surgical planning, cardiac chamber dimension, and presence and size of ventricular component of defects.

Patent Ductus Arteriosus

Before birth, the ductus arteriosus allows blood to bypass the baby's lungs by connecting the pulmonary arteries with the aorta. Patent ductus arteriosus (PDA) is a congenital disorder within the great vessels wherein a neonate's ductus arteriosus fails to close after birth. PDA accounts for 10–12% of all congenital heart disease [12].

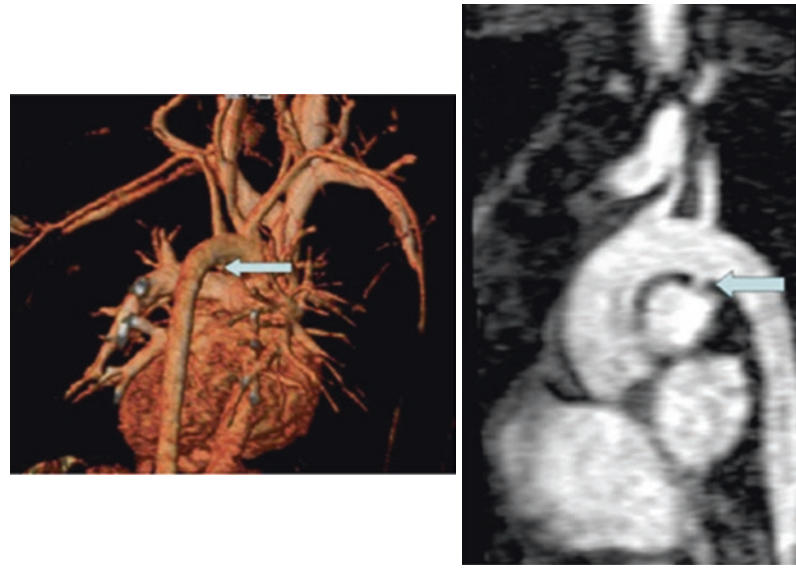

Fig. 12.4 Patent ductus arteriosus. Image at right is 3D, volume rendered MR image of PDA (*arrow*). Image at *left* is MR angiography sagittal image demonstrating PDA in an alternate orientation (*arrow*)

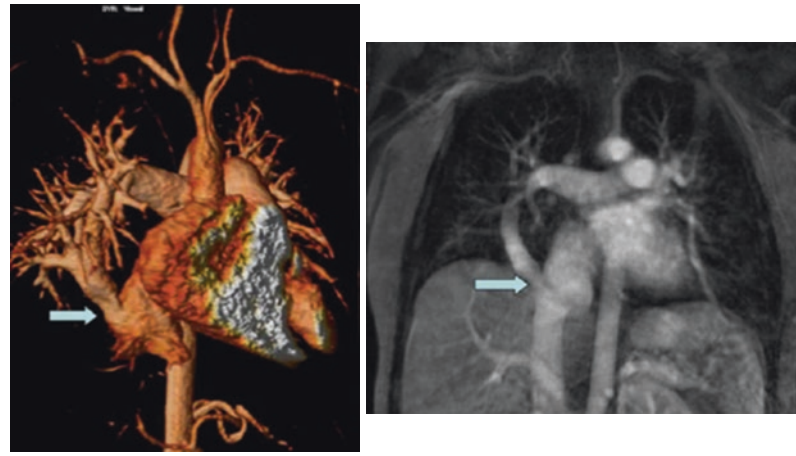

Fig. 12.5 Scimitar syndrome patient (partial anomalous pulmonary venous drainage). Image at *left* demonstrates 3D volume-rendered MR image of anomalous pulmonary venous return with right inferior pulmonary vein draining via antrum on inferior vena cava. Image at right is coronal MR maximum intensity projection (MIP) depicting same

CMR is capable of clearly demonstrating the persistent communication between the aorta and pulmonary artery; however due to the often small size of these defects (<3 mm), echocardiography remains the primary diagnostic tool for their identification and evaluation (Fig. 12.4).

Partial Anomalous Pulmonary Venous Return

Partial anomalous pulmonary venous return (PAPVR) involves one or more pulmonary veins returning aberrantly to the superior or inferior vena cava, right atrium, or coronary sinus. PAPVR is present in 10–15% of patients with secundum-type atrial septal defects and 100% of patients with sinus venosus-type defects [19]. Children with PAPVR are typically asymptomatic, whereas adults with the condition will typically present with dyspnea and palpitations. CMR is a particularly attractive imaging modality for identifying PAPVR as it provides a large field of view and can be performed without ionizing radiation or contrast material. CMR has been reported to have greater sensitivity (95%) for identification of PAPVR compared with echocardiography and angiography [20] (Fig. 12.5).

Diastology

CMR is now playing an increasing role in understanding the physiology of diastolic function. CMR is capable of evaluating myocardium in both active and passive phases, providing insight into relaxation and compliance characteristics. Further, CMR through PCI can assess inflow and myocardial velocities. Previous studies comparing CMR to TTE in the assessment of diastolic function have shown that velocities of mitral valve flow (E and A wave) measured by CMR correlated well with TTE ($r = 0.81$; $p < 0.001$), but also demonstrated systematic underestimation by CMR compared to TTE [21, 22]. Myocardial tagging with CMR can provide complementary information regarding myocardial contraction performance and can be used to measure myocardial strain in three dimensions.

While not typically thought of as a reliable source for assessment of diastolic function, recent studies have demonstrated that CT is capable of providing information regarding cardiac diastolic function. Boogers et al. evaluated 70 patients who had undergone CT and 2D echocardiography with TDI. Good correlations were observed between cardiac CT and 2D echocardiography for assessment of E ($r = 0.73$; $p < 0.01$), E/A ($r = 0.87$; $p < 0.01$), E_a ($r = 0.82$; $p < 0.01$), and E/E_a ($r = 0.81$; $p < 0.01$). In addition, a good diagnostic accuracy (79%) was found for detection of diastolic dysfunction using cardiac CT [23]. Other groups have evaluated the arterial enhancement of the aortic-root lumen on contrast-enhanced CT and plotted its change over time to determine the time-enhancement curve. Nakahara et al. evaluated 30 patients with suspected coronary artery disease who underwent MDCT and echocardiography. On univariate analysis, the slope of the time-enhancement curve was found to correlate with the e' ($r = 0.686$; $P = 0.000$) and E/e' ($r = -0.482$; $P = 0.007$) ([24]).

Valvular Heart Disease

While echocardiography remains the primary first-line imaging modality for the assessment of valvular heart disease, over the past several years, complementary uses of cardiovascular MRI and CT for the assessment of valvular heart disease have been demonstrated. MRI and CT can provide a comprehensive assessment of cardiac valvular anatomy and function. MRI offers the additional capability of assessing blood flow through a variety of imaging sequences.

The unlimited imaging planes offered by cardiac MRI are advantageous for assessment of the complex mitral valve anatomy. The primary benefit of MRI for the assessment of mitral regurgitation is the ability to quantitate regurgitant volume in conjunction with ventricular volumes and function. The primary method for quantification of mitral regurgitation involves subtracting aortic forward flow (calculated from aortic phase-contrast imaging) from the left ventricular stroke volume. Quantification of mitral regurgitation with MRI correlates only modestly with echocardiography but offers lower inter- and intra-observer variability [25]. More recently however, some data has demonstrated discrepancy between mitral regurgitation severity calculated by echocardiography compared with MRI [26]. Some have argued that since LV volume reductions following mitral valve surgery were more closely related to regurgitant volumes measured by MRI rather than echocardiography, that MRI should be the preferred method of mitral regurgitation assessment [26].

Multi-slice computed tomography (MSCT), while not able to provide information of blood flow like MRI, can provide additional or complementary information on the assessment of mitral valve anatomy. Delgado V et al. evaluated 151 patients with MSCT to assess the anatomy of the mitral valve subvalvular apparatus, mitral valve tenting height, and leaflet tethering [27]. The anatomy of the subvalvular apparatus was noted to be highly variable, particularly the posterior papillary muscle, involving multiple heads and insertion sites. Mitral valve tenting height at the central level and mitral valve sphericity index were the strongest determinants of FMR severity. With the continued growth in structural heart transcatheter therapies, MSCT will certainly play an increasing role in the pre-procedural planning of these complex cases over the coming years.

Further, MRI PCI has been demonstrated to help in the stratification of aortic regurgitant (AR) severity. Holodiastolic reversal in the mid-descending thoracic aorta using PCI has been shown to indicate severe AR and can be used with quantified regurgitant values obtained from PCI to further stratify AR severity [28].

One measure of severity of a valvular stenosis involves the peak transvalvular pressure gradient that is generated across the area of narrowing. For stenotic valvular lesions, PCI can be positioned through-plane or in-plane to estimate the maximum transvalvular velocity (V_{max}). As is seen with spectral Doppler echocardiography, if the imaging slice does not pass through the area of maximum velocity, then the pressure gradient, estimated using the modified Bernoulli equation (pressure gradient (mmHg) = $4 \times V_{max2}$), will be underestimated. Aliasing will have a similar appearance as in Doppler echocardiography, and if this is seen at the time of image acquisition, this sequence must be repeated using an alternate phase encoding velocity (V_{enc}). Additionally, PCI can also evaluate volume flow rates by measuring the mean velocity of blood across its lumen (V_{mean}) and multiplying by the cross-sectional area of the vessel lumen (volume flow (mL/s) = V_{mean} (cm/s) × area (cm^2)).

Aortic valve stenosis continues to be one of the most common valvular disorders in older adults with a prevalence of 8% at age 85 [29]. Open surgical aortic valve replacement is the only treatment that has been demonstrated to improve symptoms, survival, and functional status [30]. However, certain patient subsets are deemed high-risk for surgical repair, which lead to the development of transcatheter aortic valve replacement (TAVR). CT now plays a vital role in assessing patients prior to percutaneous aortic valve implantation. 3D reconstructed multi-planar images allow assessment of the aortic valve in multiple phases of the cardiac cycle and permit direct valve and annular area planimetry (Fig. 12.6). These measurements tend to be slightly larger than what is reported by 3D transesophageal echocardiography. Additionally, cardiac CT permits estimation of optimal valve implantation angles via fluoroscopy in the catheterization laboratory. Further, ECG-gated imaging of the thoracic aortic permits accurate assessment of aortic anatomy and morphology. Contrasted imaging of the abdominal aorta and peripheral arteries is also very important for determining whether the peripheral arteries are large enough to accommodate the large diameter of the delivery catheters. The results of the PARTNER trial have shown that at 1 year, the rate of death from any cause was 30.7% with TAVR, compared to 50.7% with standard therapy. However, at 30 days, TAVR as compared to standard therapy was associated with a high incidence

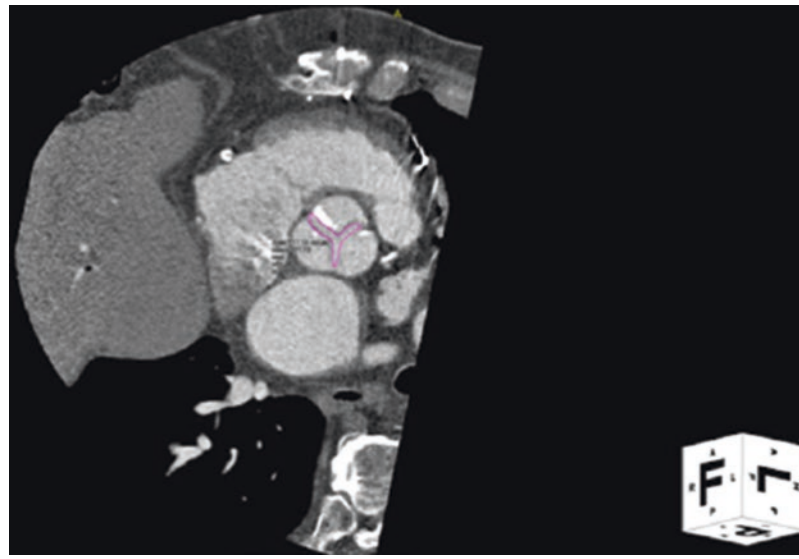

Fig. 12.6 Aortic stenosis. Cardiac CT 3D reconstructed multi-planar image of the aortic valve in short axis at end-systole with planimetry of aortic valve area

of major strokes (5 vs. 1.1%, $p = 0.06$) and major vascular complications (16.2 vs. 1.1%, $p < 0.001$) [31]. With the continued expansion of structural and valvular heart disease therapies in the coming years, CT will continue to play a larger role in pre-procedural planning.

CT is also capable of assessing ventricular volumes on multiphase-gated images to help in the determination of ventricular dilatation with regurgitant valvular lesions. Further, in patients with mechanical valves, CT provides a rapid, low-radiation exposure technique to image the valve in multiple phases of the cardiac cycle to determine opening and closure angles.

Cardiomyopathies

CMR provides excellent qualitative as well as quantitative assessment of ventricular function. When compared with Doppler echocardiography, phase-contrast measurements correspond well, and show fair correspondence when compared with invasive techniques utilizing the Fick principle, indicator-ink method, or thermodilution [32, 33]. Volumetric and functional assessment of the ventricles typically involves retrospectively gated steady-state free precession imaging of the chambers either in short- or long-axis orientations. Utilizing post-processing software, contours of the epi- and endocardium are typically drawn manually for each imaging slice, though more recently with progressive developments in artificial intelligence (AI), contouring can now more commonly be done automatically and edited by a reviewer for accuracy. Post-processing software generates quantitative data regarding cardiac function (ejection fraction, stroke volume, cardiac output), mass, and volumes. Alternatively, determination of cardiac output can be performed with phase-contrast imaging. By comparing cardiac output of the left ventricle in the ascending aorta with the cardiac output of the right ventricle in the main pulmonary artery, there is an internal control of these measurements, with gross differences typically indicating either unknown intra- or extra-cardiac shunt or more commonly, error in the initial prescription of the phase-contrast technique with either incorrectly selected imaging plane or phase encoding velocity.

CMR is now evolving as an important imaging modality in the assessment of patients with hypertrophic cardiomyopathy [34]. Cine imaging provides anatomic and morphologic assessment, allowing for measurement of myocardial wall thickness, papillary muscle anatomy, and left ventricular outflow tract obstruction. Phase-contrast imaging has proven useful in the assessment of gradients in patients with hypertrophic obstructive cardiomyopathy [35]. In patients with left ventricular outflow tract obstruction, PCI (both in plane and through plane) is useful to determine the peak velocity in a manner similar to Doppler echocardiography [34]. Post-gadolinium contrast delayed enhancement imaging also permits assessment of myocardium for scar. CMR also has proven useful in the evaluation of myocardial sarcoidosis [36], amyloidosis [37–39], and hemochromatosis [39, 40].

Through the simultaneous registration of the ECG, it is possible to synchronize image reconstruction with the relative cardiac phase with cardiac CT imaging. In patients with suspected or documented heart disease, precise, accurate quantification of cardiac function is vital for diagnosis, risk stratification, treatment, and prognosis. The same data that is acquired for coronary arterial evaluation, as part of coronary CT angiography, can also be used for evaluation of cardiac function. Previous studies have demonstrated that multiphase, gated cardiac CT demonstrates good correlation when compared with 2D surface echocardiography [41, 42].

Pericardial Disease

CMR is an excellent modality for assessing pericardial disease. CMR can accurately demonstrate pericardial thickness, effusion, pericardial cysts and through various pulse sequences, also demonstrate pericardial edema and/or inflammation. Real-time gradient-echo CMR in a single imaging slice can evaluate ventricular function with simultaneous respiration visualization and assess for

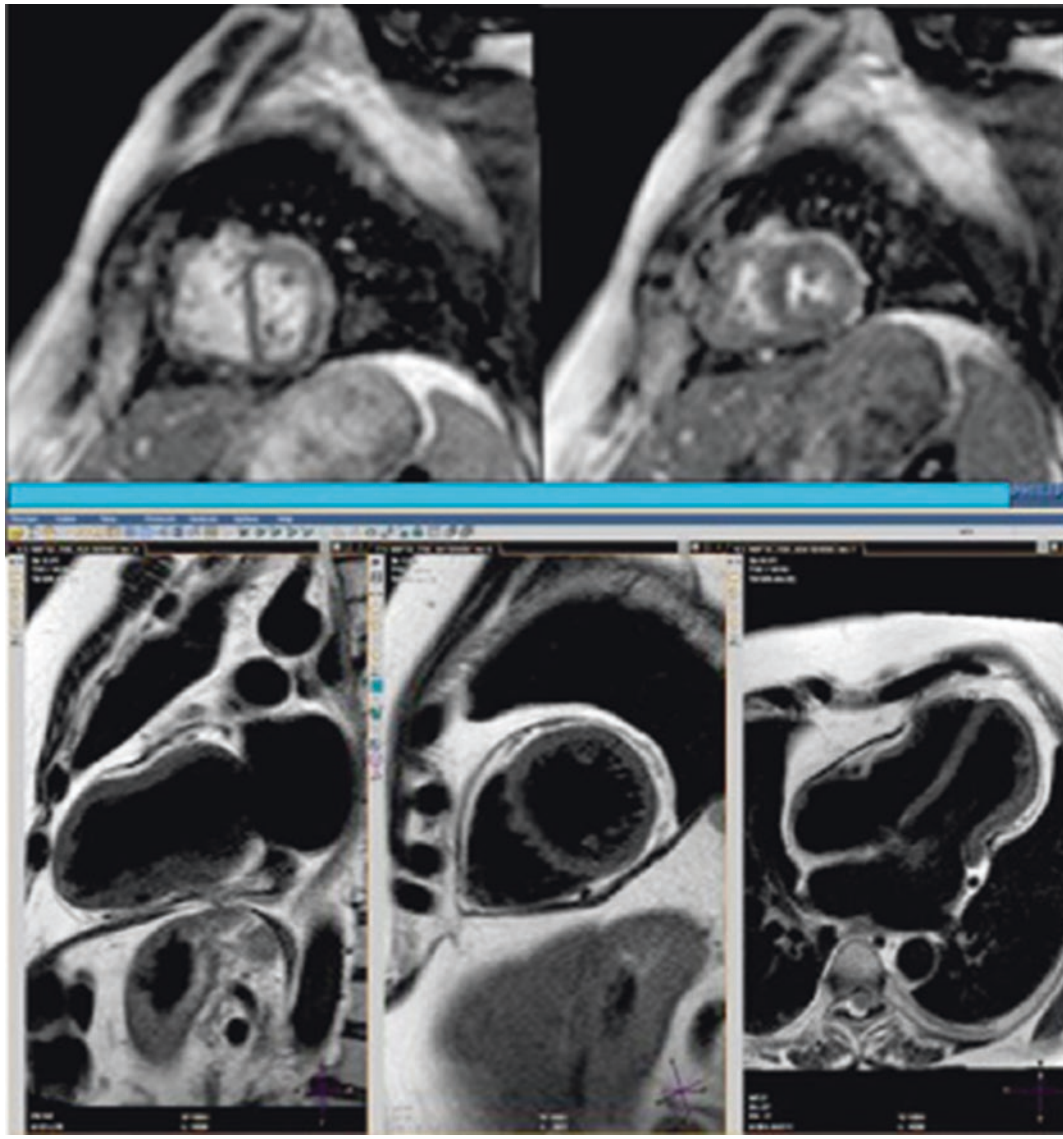

Fig. 12.7 Constrictive pericarditis cardiac MRI. Images at *top* demonstrate real-time free-breathing gradient echo short axis image of the left ventricle demonstrating ventricular interdependence in patient with constrictive pericarditis. Images at *bottom* are spin-echo "dark-blood" images in multiple orientations demonstrating pericardial thickening

ventricular interdependence that might suggest tamponade or constrictive physiology (Fig. 12.7). One area where CMR has significant limitations is in the assessment of pericardial calcification. Pericardial calcium causes significant susceptibility artifact on bright-blood cine MRI sequences.

Cardiac CT provides the ability, whether gated or non-gated, with iodinate contrast or without, to visualize the pericardium and assess and quantify pericardial thickening, calcification, or effusion. Multiphase, retrospectively ECG-gated cardiac CT imaging with iodinated contrast also allows for a functional assessment of interventricular septal motion and ventricular interdependence, although with a somewhat lesser temporal resolution (Fig. 12.9).

Vascular Hemodynamics

Vascular anatomy and pathology can be imaged using CMR with or without gadolinium-based contrast. Black-blood imaging provides excellent vascular anatomic detail with nulling of the blood pool. Alternatively, cine bright-blood CMR imaging provides additional information about vascular wall pathology and flow dynamics. First pass gadolinium-enhanced magnetic resonance angiography (MRA) can now be performed on nearly any MR scanner and produces high-spatial resolution images with broad anatomic coverage (Fig. 12.8). Artifacts with MRA may occasionally result in misdiagnosis of pseudostenosis in a vessel due to metal artifacts, susceptibility artifact from concentrated gadolinium, and volume averaging.

Phase-contrast imaging has also proven useful in the assessment of gradients across aortic coarctation [5]. With aortic coarctation, collateral flow can be assessed by measuring blood flow within 2 cm of the coarctation and above the diaphragm. In patients with significant coarctation, the flow within the coarctation increases toward the diaphragm due to retrograde perfusion of the dilated intercostal arteries, which are providing collateral circulation [43]. Additionally, measurements within the coarctation can help determine peak velocity and therefore pressure gradient within the stenosis. Pressure gradients greater than 20 mmHg measured during cardiac catheterization have been previously considered an indication for intervention [44].

Alternatively, CT angiography can also provide excellent spatial resolution when imaging arterial phase vascular images. Typically, vascular imaging with CT angiography does not necessitate ECG-gating, unless there is specific concern regarding the aortic root, which will typically be affected by cardiac motion artifact on non-ECG-gated images.

Fig. 12.8 3D volume rendered MR angiography image of aortic coarctation (*arrow*) with significant collateral vessels

Coronary Angiography

Through the simultaneous administration of intravenous iodinated contrast material, oral and intravenous beta-blockers to lower the heart rate, and sublingual nitroglycerin for coronary vasodilation, imaging of the coronary arteries has become increasingly feasible (Fig. 12.9). Several multicenter clinical studies have now shown the high diagnostic yield with coronary CT angiography, with sensitivities reported between 83% and 99% and specificities ranging from 93% to 98% [45]. Further, due to very high negative predictive values (95–100%), modern CCTA can be used to reliably rule out the presence of significant coronary artery stenoses.

While the strength of coronary CT is its excellent spatial resolution and anatomic definition, its most commonly cited weakness had been its inability to provide hemodynamic data. Coronary artery stenosis severity does not always correlate well with lesion functional severity at time of invasive FFR. Several studies have now been performed with coronary CT angiography that not only assess anatomy and morphology, but also provide functional physiologic information on coronary flow. New methods have been developed that utilize the anatomic data provided by CCTA in conjunction with computational fluid dynamic modeling that can calculate coronary fractional flow reserve (CT-FFR) from resting CCTA datasets [46], under estimated hyperemic flow conditions (Figs. 12.10 and 12.11). This provides for lesion-specific decreases in FFR, noninvasively. HeartFlow CT-FFR analysis uses an off-site, supercomputer, three-dimensional modeling technique and has now been validated against invasive FFR measurements and was approved by US Food and Drug Administration (FDA) for clinical use in 2014. Siemens Healthcare has also developed a one-dimensional analysis (cFFR) that can be performed at on-site workstations, but this technology is not yet commercially available as of the time of this writing.

During the past several years, multiple studies have been published that evaluated the diagnostic performance of CT-FFR and cFFR compared with invasive FFR as the reference standard [47–53]. Compared with CCTA anatomic assessment of stenosis severity alone, cFFR and CT-FFR

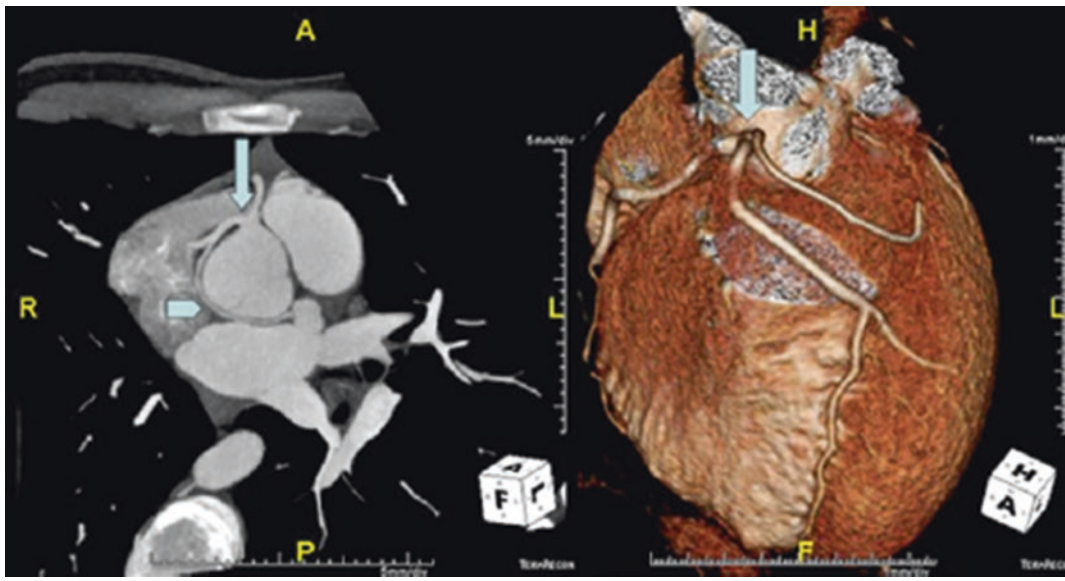

Fig. 12.9 Anomalous origin of the coronary arteries. Image at left demonstrates a maximum intensity projection (MIP) image of a common origin of both the left and right coronary arteries from a single, common ostium with the circumflex coronary artery passing retro-aortic (*arrowhead*). Image at left is a 3D volume-rendered image depicting same (*arrow*)

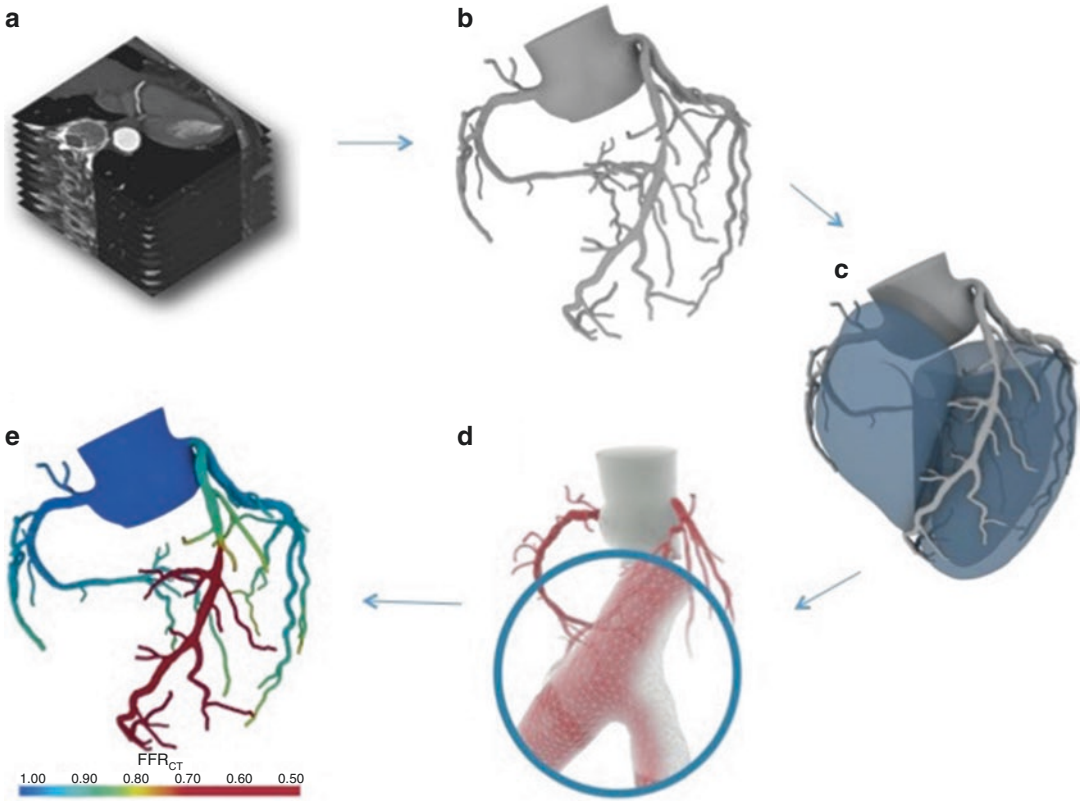

Fig. 12.10 (**a**) Coronary CT angiography image dataset, acquired using standard imaging protocol. (**b**) Image segmentation produces an anatomic model of the root of aorta and epicardial coronary arteries including all second and third order branchings to approximately 1 mm in diameter. (**c**) Physiologic model of coronary flow with specified inflow and outflow boundary conditions is created. Resting coronary flow is based on left ventricular myocardial volume extracted from CT image data and the microcirculation model is based on epicardial vessel size. (**d**) Computational fluid dynamics methods are used to simulate coronary blood flow under maximal hyperemia with simultaneous computation of coronary pressure and flow at millions of discrete points throughout the coronary tree. (**e**) Three-dimensional display of FFR_{CT} values in each coronary artery and its branches with color coding of numerical FFR_{CT} values as shown on the scale. Fig. 12.11 CT-FFR. Case example. CCTA demonstrates heavily calcified LAD lesion with >70% stenosis. HeartFlow FFR_{CT} analysis shows functionally significant proximal LAD stenosis with FFR_{CT} 0.68. Coronary angiogram confirms 70% LAD stenosis with measured FFR 0.71. (Images courtesy of Dr. Christopher Zarins, HeartFlow)

both demonstrated improved test specificity. Good correlations with both cFFR and CT-FFR compared to invasive FFR were reported, ranging from 0.63 to 0.82. Certainly, overall image quality plays a vital role in overall CCTA imaging, and prior studies evaluating cFFR and CT-FFR have demonstrated that 10–13% of cases could not be utilized due to suboptimal image quality. In a sub-analysis of the NXT trial, among patients with CAC score 400, the accuracy, sensitivity, and specificity of FFR_{CT} for the determination of lesion-causing pressure drop were 75% (95% CI, 62%–84%), 88% (95% CI, 64%–97%), and 69% (95% CI, 54%–81%), which were higher than those of CCTA with 44% (95% CI, 31%–56%), 94% (95% CI, 79%–100%), and 23% (95% CI, 11%–37%), respectively [50].

Several groups have now started to look at the potential role of stress and rest myocardial perfusion imaging with CT [54–56]. Pontone G et al. evaluated 100 consecutive symptomatic patients scheduled for invasive coronary angiography with resting coronary CCTA and stress static computed tomography myocardial perfusion (CTP). Patients were evaluated for overall diagnostic accuracy and overall effective dose compared with those of invasive coronary angiography and FFR. Coronary CTA alone demonstrated a per-vessel and per-patient sensitivity, specificity, negative predictive value, positive predictive value, and accuracy of 98%, 76%, 99%, 63%, and 83% and of 98%, 54%, 96%, 68%, and 76%, respectively. Combining coronary CTA with stress CTP, per-vessel and per-patient sensitivity, specificity, negative predictive value, positive predictive value, and accuracy were 91%, 94%, 96%, 86%, and 93% and 98%, 83%, 98%, 86%, and 91%, with a significant improvement in specificity, positive predictive value, and accuracy in both models. The mean effective dose for coronary CTA and stress CTP were 2.8± 1.4 mSv and 2.5± 1.1 mSv [53].

Coronary artery disease remains the leading cause of morbidity and mortality in the industrialized world. While conventional coronary angiography remains the "gold standard" for evaluation of coronary arterial disease, it does possess limitations, namely its invasive nature, cost, and need for radiation and iodinated contrast exposure. Due to these limitations, alternative noninvasive imaging modalities have evolved for the evaluation of coronary artery disease that can avoid some of these undesirable attributes. While CT coronary angiography provides excellent spatial and temporal resolution, its use still requires patient breath-holding, exposure to radiation, and use of iodinated contrast agents. MR imaging of the coronary arteries does not require radiation exposure, can be performed either with or without administration of contrast material, and is capable of being accomplished with or without patient breath-hold. Similar to other noninvasive modalities, MR imaging of the coronary arteries is limited by both cardiac and respiratory motion. In addition, the small size and tortuosity of the coronary vessels, coupled with rapid spatial displacement and increased distance from the body or surface coils, present challenges for accurate imaging.

Initial studies with coronary MRA demonstrated that this technique was capable of accurate diagnosis of left main coronary artery and three-vessel disease [57]. With the continued development and improvement in MRI software and hardware, improvements in spatial resolution and image quality have been possible. Additional studies have now reported that contrast-enhanced MRA (CE-MRA) at 3.0 T is able to depict significant coronary artery stenoses with high sensitivity (94.6%), and negative predictive values of 98.5% and 97.7% on a per-segment and per-vessel basis respectively [58]. Additional studies have compared the visual and quantitative analysis high-spatial resolution CMR perfusion at 3.0 T against invasively determined fractional flow reserve (FFR) [59]. At an FFR threshold <0.75 to define hemodynamically significant lesions, visual CMR analysis reported sensitivity and specificity of 0.82 and 0.94 ($p < 0.0001$), respectively.

Further developments in coronary artery imaging have come through the use of ECG and respiratory triggered, segmented, 3D data acquisition. During free-breathing, monitoring of diaphragmatic motion is performed by a unique navigator echo, and the decision to accept or

reject image data are made based on the position of the diaphragm [60]. In addition, stress-induced myocardial ischemia can now be assessed noninvasively with the use of blood oxygen level-dependent (BOLD) CMR [59]. Perfusion CMR imaging has been compared with quantitative coronary angiography (QCA) and fractional flow reserve (FFR). Futamatsu et al. evaluated 37 patients with perfusion CMR imaging, quantitative coronary angiography, and FFR. Myocardial perfusion reserve (MPR) using a cutoff of 2.06 was found to have sensitivity and specificity for identification of hemodynamically significant CAD (defined as FFR ≤0.75) of 92.9 and 56.7% respectively. Sensitivity and specificity of anatomically significant CAD (>50% diameter stenosis) were 87.2% and 49.2% respectively [61].

Future Directions

The future of cardiac imaging is dynamic. With ever-increasing advances in both hardware and software, cardiac MRI and CT will continue to evolve and improve. Increasing magnetic field strength coupled with multiphased array coils promises to improve CMR spatial resolution. Continued improvements in gantry rotation times, table pitch, X-ray tube strength, and improved simultaneous slice acquisition are all promising areas of improvement in cardiac CT technology at present. Additionally, the coming decade will likely see continued advancements in artificial intelligence and software processing algorithms. With these continued advancements, cardiac CT and MRI will continue to play an ever-increasing role in the noninvasive hemodynamic evaluation of our patients.

Review Questions

1. A 47-year-old female has developed increasing shortness of breath over the preceding 6 months. Transthoracic echocardiogram has demonstrated severe ventricular hypertrophy. Subsequent cardiac MRI is performed to assess LVOT gradients and papillary muscle morphology.

   Among the following, CMR can best evaluate diastolic dysfunction via:

   A. Phase-sensitive inversion recovery imaging (PSIR) post-gadolinium contrast.
   B. Phase-contrast imaging.
   C. Non-breath-hold T2-weighted axial images of the myocardium.
   D. Magnetic resonance angiography.

   Answer B: Phase-contrast imaging (PCI) is capable of assessing both inflow and myocardial velocities, and plotting flow curves relative to the various phases of the cardiac cycle. This modality can provide insight into both myocardial relaxation and compliance characteristics. PCI has been shown to correlate well with TTE in the assessment of diastolic function; however, it tends to underestimate velocities of mitral valve flow (*E* and *A* waves) compared to TTE.

2. A 69-year-old African American male previously underwent coronary artery bypass graft surgery and mitral valve repair 10 years ago. Over the past 9 months, he has developed increasing shortness of breath, lower extremity edema, and abdominal fullness. Transthoracic echocardiogram demonstrates septal bounce and tubular shaped left ventricle with atrial tethering. Subsequent cardiac MRI is performed to evaluate for constrictive pericarditis.

   Among the following, which method is most useful for evaluating for ventricular interdependence?

   A. Real-time gradient echo CMR.
   B. Breath-hold, four-chamber steady-state free precession cine imaging.
   C. Short-axis, breath-hold delayed-hyperenhancement imaging post-gadolinium contrast.
   D. Short-tau inversion recovery imaging (STIR).

   Answer A: Real-time gradient echo CMR typically provides a single image slice, the short axis left ventricle is most often chosen. Through simultaneous evaluation of both ventricular function with respiration, it is possible to assess for ventricular interdependence. Breath-hold, four-chamber steady-state free precession cine imaging is a good method for assessing ventricular function. Short-axis, breath-hold delayed-hyperenhancement

imaging post-gadolinium contrast has been shown to be an effective method for evaluating for active pericardial inflammation; however, this in and of itself does not necessarily reflect evidence of constriction. Short-tau inversion recovery imaging (STIR) is an effective method for evaluating for myocardial and/or pericardial inflammation.

3. With cardiac CT, it is possible to synchronize image reconstruction with the relative cardiac phases via:
   A. Iterative reconstruction.
   B. ECG-triggering.
   C. Filtered back-projection.
   D. Myocardial tagging.

   Answer B: ECG-triggering, through the simultaneous registration of the ECG at the time of image acquisition, can allow for image reconstruction that is synchronized to the relative cardiac phase. ECG-triggering can be performed both prospectively and retrospectively. Iterative reconstruction is a method or group of algorithms used in 2D and 3D image sets. Filtered back-projection is also a reconstruction technique used for CT that applies a filter to the raw data collected during CT and attenuation information is simultaneously collected that are then utilized in image creation. Myocardial tagging is a cardiac MRI technique that applies saturation grid lines to the myocardium, and their subsequent deformation can be used to assess myocardial contraction and relaxation.
4. Shunt volume and shunt fraction (Q_p/Q_s) using MRI can be calculated through use of:
   A. Volumetric cine MRI.
   B. Phase-contrast imaging (PCI).
   C. Neither.
   D. Both A and B.

   Answer D: Both volumetric cine MRI and PCI can be used to calculate shunt volume and shunt fraction (Q_p/Q_s) provided that there is no significant concurrent valvular regurgitation. Specifically, total forward flow through the proximal ascending aorta and main pulmonary artery can be used to determine shunt fraction (Shunt fraction % (Q_p/Q_s) = total PCI pulmonary artery volume flow (mL)/total PCI ascending aortic volume flow (mL)) Alternatively, by using the ratios of the right ventricular to left ventricular stroke volumes, acquired by use of volumetric cine MRI, the shunt fraction can be calculated—provided there is again no significant simultaneous valvular regurgitation.
5. A 17-year-old girl is found to have bicuspid aortic valve by echocardiography. What imaging modality, among those listed below, would be best suited to assess for a common associated cardiovascular anomaly with this condition?
   A. CT.
   B. Chest X-ray.
   C. PET.
   D. MRI.

   Answer D: Patients with bicuspid aortic valve often have other congenital aortic and cardiac abnormalities [62]. The most common association is with coarctation of the aorta, which in autopsy series has been reported to be found in 6% of cases. Alternatively, 30–40% of patients with coarctation are subsequently found to have a bicuspid aortic valve. MRI not only is an excellent modality for assessing the aortic valve morphology and function, but also provides excellent spatial resolution and a large field of view (see Fig. 12.7) to evaluate noncardiac thoracic anatomy. While CT also is a versatile modality with excellent spatial resolution and broad field-of-view, the radiation exposure in this young patient is less than desirable. Chest X-ray is an indirect method of assessing for additional complications associated with coarctation such as notching noted along the ribs. PET has no significant role in imaging coarctation.

13 Objective Evaluation of Hemodynamics in the Outpatient Setting

Gbolahan Ogunbayo and Ahmed Abdel-Latif

Introduction

Noninvasive hemodynamic (HD) monitoring offers a safer and relatively accurate means of monitoring patients' hemodynamics when performed appropriately. Beyond the potential benefit of determining volume status, noninvasive HD monitoring can be of value in evaluating the adequacy of cardiac perfusion and indirect assessment of cardiac index. Some of these HD parameters have been shown to predict or reduce heart failure admissions [1–6]. It can further reduce the complications associated with invasive hemodynamic monitoring [7, 8]. In the outpatient setting, noninvasive hemodynamic assessment helps to optimize medical therapy, titrate mediations, and identify heart failure patients who will require more aggressive therapies and mechanical support. Accordingly, the current American College of Cardiology Foundation/American Heart Association (ACC/AHA) guidelines for the diagnosis and management of patients with heart failure designates hemodynamic assessment in patients with heart failure a Class I indication [9].

Ambulatory hemodynamic monitoring can be done remotely or in an outpatient setting. Continuous remote monitoring usually requires implantation of a device and external equipment for remote (home) monitoring and transmission or on-site (office) measurement. Instantaneous monitoring can be done in an ambulatory (office) setting. Compared to standard scheduled office visits/audible device alerts, remote monitoring has been shown to reduce emergency department or unplanned/urgent office visits by allowing early and rapid detection of events requiring attention and action [10, 11].

History and Physical Examination

Assessment of volume status is an integral part of management and begins with a thorough and systematic history and physical examination. History focuses on severity and changes in symptoms, response to therapy and inquisition about possible etiologies. Although the cardinal symptom of left ventricular failure is shortness of breath (SOB), a patient may present with a myriad of other symptoms in isolation or combination with SOB including cardiac symptoms such as chest discomfort, palpitations, progressive/worsening dyspnea on exertion or at rest, orthopnea, or paroxysmal nocturnal dyspnea. Exertional dyspnea may not be

evident in sedentary patients. A (usually productive) cough is not uncommon due to pulmonary edema and irritation. Downstream effects of congestion include symptoms related to hepatic congestion such as jaundice and other features of resultant hepatic dysfunction as well as pedal edema and resultant symptoms including skin changes. Additional presentations/complaints of cardiac decompensation include weakness, fatigue, symptoms of cerebral hypoperfusion including mental status changes, weight loss (cardiac cachexia), nausea, anorexia, bloating, and early satiety.

Physical findings of volume overload may be subtle or overwhelming depending on the degree of volume overload. Vitals may reveal low blood pressure and even low body temperature from reduced cardiac output. Decompensated patients may have a fast and thread-like pulse. Cardiac signs may include inability to lay flat even during the examination, displaced apical impulse that suggests cardiomegaly, elevated jugular venous pressure (JVP), S3 gallop, pulsus alternans, murmurs, or mitral and tricuspid regurgitation from ventricular enlargement. Pulmonary signs include wheezing, rhonchi, reduced air entry, and crackles. Patient with severe heart failure may exhibit signs of reduced cerebral perfusion and include SOB with use of accessory muscles, anxiety, somnolence or confusion. Other signs on physical examination are cachexia with evidence of malnutrition, cyanosis, distended neck veins, exophthalmos jaundice, ascites, and hepatomegaly that may be tender and pedal edema.

Chest X-Ray

Chest X-ray is a quick and noninvasive tool to assess for pulmonary edema in patients with heart failure. The classic signs of pulmonary edema on a chest X-ray include pulmonary vascular congestion and pleural effusion. However, it is important to note that patients with advanced heart failure may not exhibit the classic signs of pulmonary congestion on chest X-ray despite elevated pulmonary capillary wedge pressure. Thus, chest X-ray is not always a sensitive tool in assessing heart failure and could lag behind other methods such as invasive assessment and physical examination.

Echocardiography

Echocardiography is another noninvasive and quick methods to assess cardiac function and estimate hemodynamics in patients. Classical findings of elevated left ventricular filling pressure include high E/e' ratio (the ratio between the velocity of blood inflow through mitral valve and the tissue Doppler velocity at the mitral valve annulus). This concept has been challenged in new studies and the consensus is to avoid complete reliance on this finding specially in patients with advanced heart failure [12]. Dilated inferior vena cava (IVC) on echocardiography has the highest predictive value for decompensated heart failure and elevated PCWP compared to clinical congestion, elevated JVP, and elevated biomarkers. The addition of echo to the clinical and laboratory tests has an extremely high correlation with invasive PCWP assessment [13].

Biomarkers

Natriuretic peptides are a group of plasma peptides that have been measured routinely in clinical practice to guide the diagnosis and management of patients with heart failure. This family includes B-type natriuretic peptide (BNP) and the N-terminal portion of the pro-brain natriuretic peptide (NT-proBNP). NT-proBNP is the biological inert byproduct of the degradation of pre-proBNP. NT-proBNP has been established as a biological marker in the diagnosis and staging of heart failure and has been recommended as a diagnostic tool by the American College of Cardiology/American Heart Association guidelines [14]. Additionally, BNP and NT-proBNP are important prognostic markers in patients with chronic heart failure [15]. Functionally, NT-proBNP hormone acts to promote natriuresis, diuresis and induce vasodilation [15]. The clearance of NT-proBNP occurs primarily in the

kidneys and the plasma levels are therefore affected by renal dysfunction. Careful consideration should be taken when using NT-proBNP levels for hemodynamic assessment in obese patients in which NT-proBNP levels tend to be low. On the other hand, NT-proBNP levels should be evaluated within the clinical context in patients with other conditions that could elevate their levels such as pulmonary disease. Nonetheless, the addition of NT-proBNP level to careful physical examination and history taking increases the clinical accuracy in diagnosing and managing patients with heart failure [15].

As detailed above, none of these methods provide ideal sensitivity and specificity for hemodynamic assessment in patients with heart failure. Therefore, multiple investigators and clinicians have utilized composite scores combining some or all of the above parameters to achieve better clinical decisions when treating heart failure patients. These scores have been shown to be highly predictive of mortality in heart failure patients and improve the specificity of clinical assessment [16, 17].

Continuous Pulmonary Vascular Pressure Monitoring

Continuous monitoring devices include pulmonary artery measurement, right ventricular (RV) pressure monitoring, left atrial (LA) pressure measurements and measurement of thoracic or cardiac (electrical) impedance via intracardiac device leads. Instantaneous hemodynamics may be obtained in the ambulatory/outpatient setting by thoracic bioimpedance, bioreactance, partial carbon dioxide rebreathing technique, portable Doppler flow measurement, and photoelectric plethysmography.

Implantable (Continuous) Sensors/ Monitoring Devices

Pulmonary Artery Monitoring

Changes in pulmonary artery pressure are good predictors of adverse clinical outcomes and hospital readmission in patients with heart failure [3, 18, 19]. In the absence of mitral valve stenosis, PCWP reflects the left ventricular filling pressure. Chronic pulmonary artery pressure monitoring can be achieved using the CardioMEMS™ HF System (CardioMEMS, Inc./St Jude Medical, Inc., USA) implanted in the pulmonary artery connected to a monitoring device by acoustic ultrasonic signals [20]. Multipe reports have confirmed the feasibility, ease of use, accuracy, and predictive ability in long- and short-term large-scale outcome studies [3, 18, 21–25]. This led to FDA approval of wireless implantable hemodynamic monitors for use in patients with New York heart association II–IV symptoms with a recent hospital admission. The goal of these devices in heart failure patients is to reduce heart failure admissions. This system consists of a sensor, an antenna, and interrogating devices (Fig. 13.1). The sensor is made of a coil and a pressure-sensitive capacitor, which both form a pressure-sensitive electric circuit that resonates at a specific frequency. Pressure applied to this unit causes a deflection that shifts the device's frequency which is electromagnetically coupled through an antenna held against the patient's body either with a wand for outpatient pressure measurement or through a pillow for ambulatory or home use [26].

Pulmonary artery pressure tracings from this system can be used as a marker of volume status to monitor and treat patients. Patients with heart failure and dilated left ventricles function at the end of the pressure-volume curve. Therefore, smaller increases in volume are more likely to cause significant and measurable increase in left ventricular end-diastolic and pulmonary pressures, leading to pulmonary edema. Similarly, heart failure patients with preserved ejection fraction and noncompliant ventricles respond to volume changes as described above, although through a different mechanism. Pulmonary artery pressure measurements can detect these small changes days before the onset of heart failure symptoms and need for heart failure admission. Implantation of the CardioMEMS™ device is safe and requires the initial use of dual

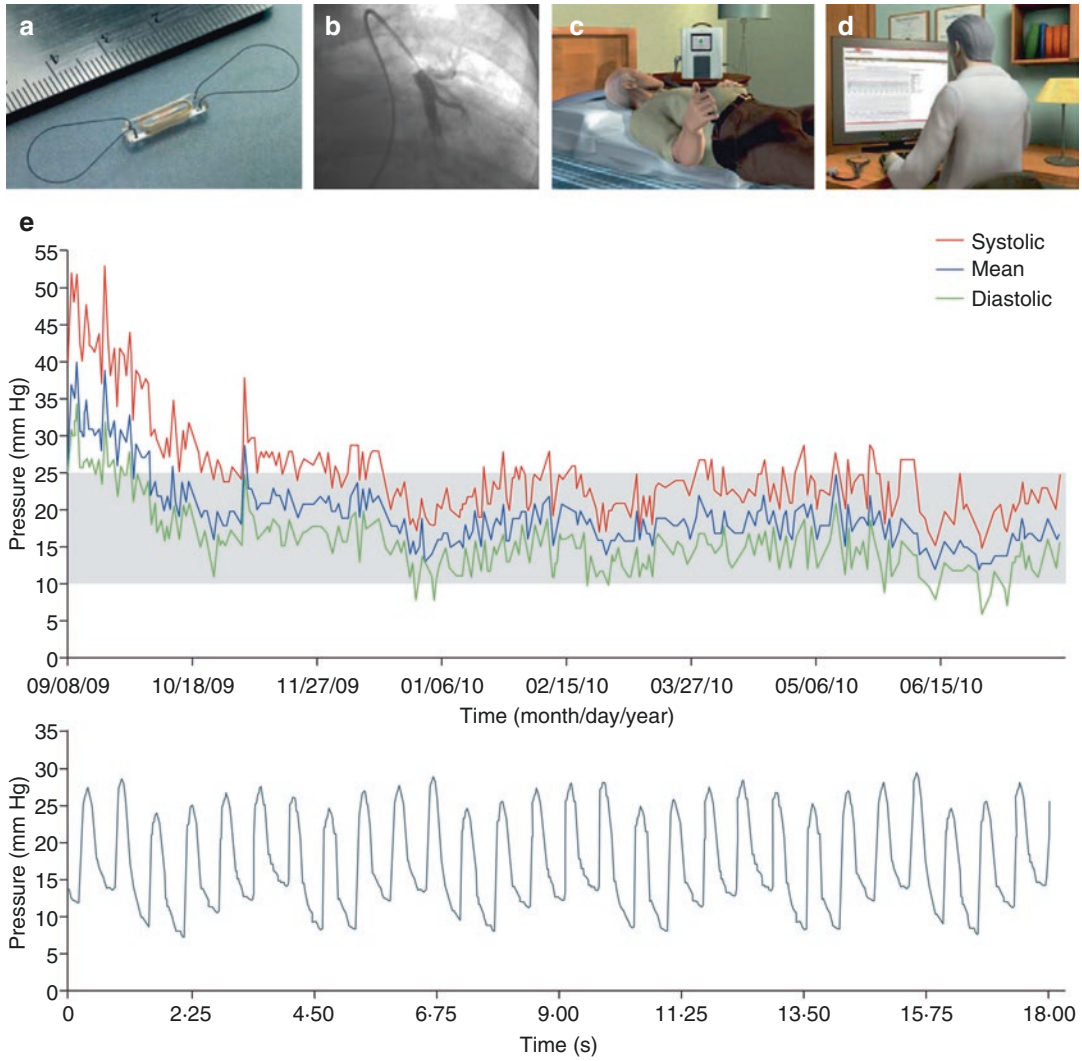

Fig. 13.1 The CardioMEMS™ HF implantable hemodynamic monitoring system. (**a**) CardioMEMS sensor or transmitter; (**b**) transcatheter implantation of the device into a distal branch of the descending pulmonary artery; (**c**) patient is instructed to take daily pressure readings from home using the home monitoring unit; (**d**) information transmitted from the monitoring system to the database is immediately available to treating physicians for review; (**e**) transmitted information consists of pressure trend information and individual pulmonary artery pressure waveforms and are available on the online portal for healthcare providers. (Adapted from Abraham et al. [3])

antiplatelet therapy for 1 month followed by lifelong aspirin use [27–29].

Advantages of this system include accuracy, reproducibility, ease of use, and the relative safe insertion and operation. The sensor does not require a battery and does not need to be replaced or refitted with a battery. Patient compliance with monitoring and medication adhesion are essential to achieve the proposed benefit.

Intracardiac Sensors/Monitoring Devices

Right Ventricular Pressure Sensors

There is no stand-alone right ventricular (RV) sensor device approved by the Food and Drug Administration (FDA). A trial of an implantable monitoring system, the Chronicle® ICD and

Chronicle® implantable hemodynamic monitor (Medtronic, Inc., USA) to measure RV hemodynamics and other parameters showed no clinical effectiveness and therefore it was not approved by the FDA [22].

Left Atrial Pressure Sensors

As with stand-alone RV sensors, there is no FDA-approved left atrial (LA) pressure sensor. An outcomes trial of an investigational LA pressure monitoring device, the HeartPod® (St Jude Medical, Inc., USA) showed feasibility and favorable short- and long-term performance. However, enrollment stopped early because of an excess of implant-related complications [30–32]. These studies, however, show that LA pressure monitoring devices have some promise in the ambulatory and remote management of patients with heart failure.

Intrathoracic Impedance to Measure Volume Status

Intrathoracic impedance is inversely related with volume status and pulmonary capillary wedge pressure. Aortic blood flow is the major determinant of thoracic impedance and therefore, impedance can be used to non-invasively assess cardiac stroke volume and cardiac output/index. These measurements correlate with invasive cardiac output/index [33]. Changes in intrathoracic impedance are noted days or weeks before the onset of symptoms or hospital admission in patients with heart failure [34]. The inverse relationship between intrathoracic impedance and volume accumulation is due to the increased electrical conductance through fluid medium. Feasibility of measuring thoracic congestion by thoracic impedance with the use of an implantable system was almost simultaneously described in human and canine models (Figs. 13.2 and 13.3) [34, 35].

Pacemakers and implantable cardioverter defibrillators (ICDs) are able to measure intrathoracic impedance in humans using the RV bipolar electrode, the LV lead, or ICD electrode. This is done

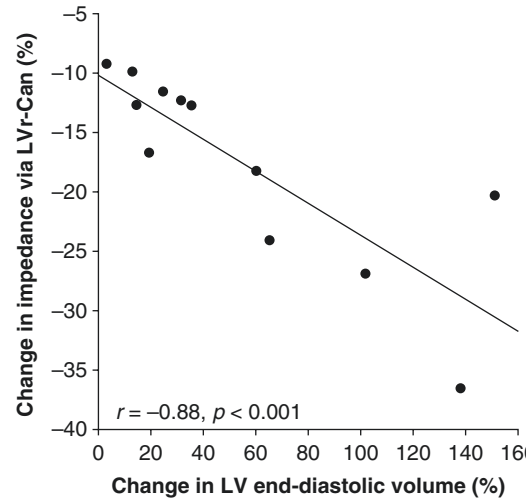

Fig. 13.2 Relationship between LVEDP and impedance. Data shown are for impedance recorded by left ventricular (LV) r–Can in 12 dogs. Correlation coefficient is calculated using Spearman rank order. (Adapted from Khoury et al. [36])

by injecting low-voltage, non-stimulating currents between the device casing and the electrodes. The LV lead has been shown to be the most sensitive to impedance changes in left atrium and left ventricular end-diastolic pressures (LVEDP) [36]. Different devices have patented software that monitor changes in impedance by establishing a baseline using sampling obtained over a period of time. Some programs are able to alert a patient and/or care provider when a predetermined or preset volume threshold is met. Monitoring this parameter has been shown to reduce hospital admissions in patient with heart failure [4, 23, 37, 38]. A 12-week period is required from implantation to impedance measurement. Shorter periods are required for replaced devices.

Advantages of intrathoracic impedance monitoring include the ease of use and the simplicity of the device without the need for additional equipment. When used appropriately and integrated in the clinical management of patients with heart failure, intrathoracic impedance can help reduce hospital admissions due to heart failure (Fig 13.6) [34]. It gives the patient and caregiver the opportunity to be proactive about alteration of hemodynamics and fluid status. Currently, with advances in battery technology,

the impact of impedance monitoring on battery life is small. Instantaneous (ambulatory) impedance measurement is usually inaccurate in settings where there are sources of electrical noise and body motion. Additionally, the system is very sensitive to positioning of the electrodes, body size, humidity, and temperature.

Impedance can also be measured in the ambulatory setting by placing electrodes/sensors on either side of the neck and thorax, two on either side (Fig 13.4). A pair of electrodes inject/transmit alternating electric current while the other pair senses and determines the thoracic impedance. There are two components of impedance: base impedance, which is based on tissue and air in the thoracic cavity and dynamic impedance, which is determined by changing blood volume and velocity in the thoracic aorta. All these parameters have different electrical properties, causing variations in electrical conductance. Ventricular function causes blood flow through the compliant arteries to be pulsatile, thus causing changes in blood volume in the aorta and the thoracic arterial system that results in changes in electrical conductance and impedance.

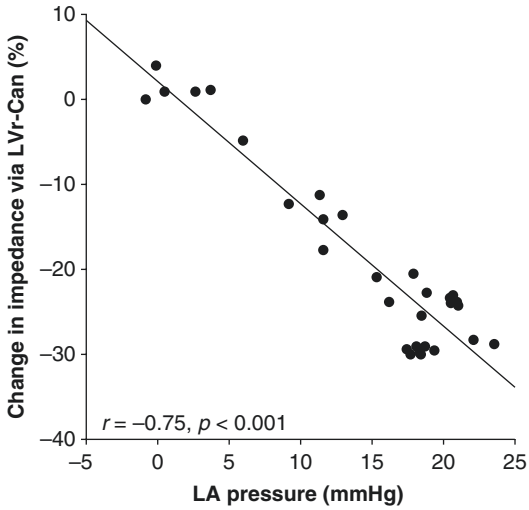

Fig. 13.3 Relationship between LA pressure and Impedance. Data shown are for impedance recorded by left ventricular (LV) r–Can in 1 dog at different time points of the experiment. Correlation coefficient is calculated using Spearman rank order. (Adapted from Khoury et al. [36])

These dynamic, beat-to-beat changes in electric conductance and impedance are used to calculate the stroke volume and other hemodynamic parameters (Fig 13.5). Parameters that can be measured include the stroke volume (SV), cardiac output (CO), central fluid volume, cardiac time intervals, contractility/ejection fraction (EF), acceleration index, total peripheral resistance, aortic compliance, pulmonary capillary wedge pressures (PCWP), and total fluid index (Table 13.1) [40].

The concept of impedance is based on Ohm's Law:

$$\left(I = \frac{E}{R} \right)$$

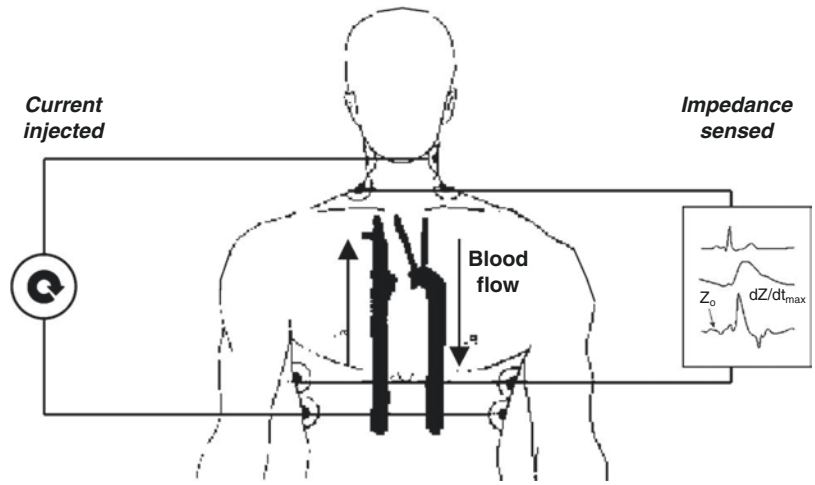

Fig. 13.4 Tetrapolar system of electrodes, separating the current pathway from the sensing pathway. After transmitting electricity by way of the outer electrodes, the impedance to flow of the current through the thorax along the path of least resistance (i.e., the great vessels) is sensed by way of the inner electrodes. (Adapted from Summers et al. [39])

where I is the flow of electric current, E is the voltage drop between the two ends of a circuit, and R is the resistance or impedance [41]. Given a constant current in the circuit, the relationship of changes in voltage across the circuit will be inversely proportional to the impedance. Impedance is related to the resistivity ($_{\varrho}$) (measured in Ωcm), length (L), and cross-sectional area of the conducting medium/material:

$$Z = {}_{\varrho}\left(\frac{L}{A}\right).$$

Since volume is equal to the product of cross-sectional area and length, impedance can be related to changes in the volume according to the following equation [39, 41]:

$$Z = {}_{\varrho}\left(\frac{L^2}{V}\right).$$

In 1940, Nyboer examined the changes in blood volume and flow in the extremities by impedance plethysmography and related the change in impedance (ΔZ) to the change in volume (ΔV) [39, 42]:

$$\Delta V = {}_{\varrho}\left(\frac{L^2}{Z_0^2}\right)\Delta Z$$

With regard to time (t), the equation can be simplified by:

$$\Delta V(t) = {}_{\varrho}\left(\frac{L^2}{Z^2}\right)\Delta Z(t)$$

Changes in impedance in a conductor (thorax) will reflect changes in the volume within the great vessels of the thorax since current will flow through the path of least resistance (resistivity of plasma 65 Ωcm; whole blood 300 Ωcm and muscle, fat, bone and air 200–5000 Ωcm). Using these formulas, the stroke volume can be estimated using a derivative of the impedance waveform $(\delta Z/\delta t)_{max}$, the peak volume change during peak current flow (PF), and the ventricular ejection time (VET) [39, 41, 42]:

$$\mathrm{PF} = {}_{\varrho}\left(\frac{L^2}{Z_0^2}\right)\left(\frac{\delta Z}{\delta t}\right)_{\max}$$

where Z_0 is the baseline impedance of all thoracic tissue, fluid, and air, about 25 Ω for the average adult.

$$\Delta V = \mathrm{SV} = \mathrm{PF} \times \mathrm{VET}$$

$$\Delta V = \mathrm{SV} = {}_{\varrho}\left(\frac{L^2}{Z_0^2}\right)\left(\frac{\delta Z}{\delta t}\right)_{\max} \mathrm{VET}$$

${}_{\varrho}\left(L^2 / Z_0^2\right)$ can be represented by a constant of proportionality, C. Therefore,

$$\Delta V = \mathrm{SV} = \mathrm{C} \times \left(\frac{\delta Z}{\delta t}\right)_{\max} \times \mathrm{VET}$$

The basic assumption of this method is that the change in thoracic impedance is primarily due to increases in the aortic volume. Because the electrical field distribution in the thorax is actually closer to a cone than a cylinder, the initial model was changed from a cylinder to a cone, and therefore the formula was revised [39, 43, 44]:

$$\Delta V = \mathrm{SV} = {}_{\varrho}\left(\frac{L^3}{4.2}\right)\left(\frac{\delta Z}{\delta t}\right)_{\max} \frac{\mathrm{VET}}{Z_0}$$

To avoid the length measurements, the average distance of the thorax (L) is determined to be 17% of the total body height (H); therefore, the equation is revised to:

$$\Delta V = \mathrm{SV} = \left(\frac{(0.17\mathrm{H})^3}{4.2}\right)\left(\frac{\delta Z}{\delta t}\right)_{\max} \frac{\mathrm{VET}}{Z_0},$$

where $(0.17\mathrm{H})^3/4.2$ is defined as the volume of electrically participating thoracic tissue (VEPT).

Finally, when this equation is normalized to an ideal body weight by a factor, δ, the equation would become [39, 44, 45]:

$$\mathrm{SV} = \delta(\mathrm{VEPT})\left(\frac{\delta Z}{\delta t}\right)_{\max} \frac{\mathrm{VET}}{Z_0}$$

Although very sensitive, other changes and pathologies like changes in blood viscosity from anemia and lung pathologies such as pleural effusion or pneumothorax can significantly alter impedance, therefore increasing false positives and reducing its specificity [39, 46]. A study reported that in order to achieve a low false-positive rate, FDA-approved intrathoracic impedance models resorted to algorithms with lower sensitivity for predicting heart failure exacerbation. This may limit the use of thoracic impedance for the prediction/detection of heart failure episodes [47]. More recently, intrathoracic impedance has been used to monitor intravascular volume, aiming to apply knowledge of this method to guide volume therapy in patients with heart failure (Fig. 13.6). Optimal determination of stroke volume by impedance requires patient weight between 67 and 341 pounds and a height of 4–7 feet. Impedance may not be accurate in patients with sepsis, severe aortic regurgitation, and tachycardia (HR > 250 bpm) or patients on intra-aortic balloon pumps [40]. Table 13.2 summarizes the correlation coefficients of different impedance measurements compared to the standard for normal variants and pathologic states.

Intracardiac Impedance Monitoring

Intracardiac impedance has been discussed as an alternative, or a complimentary tool, to other hemodynamic parameters and surrogates in patients with heart failure [46, 48, 49]. It has been used to measure the volume status in patients with cardiac resynchronization therapy (CRT) devices. Intracardiac impedance is a reflection of volume changes in the LV during the entirety of the cardiac cycle. It reduces the false positives encountered with intrathoracic

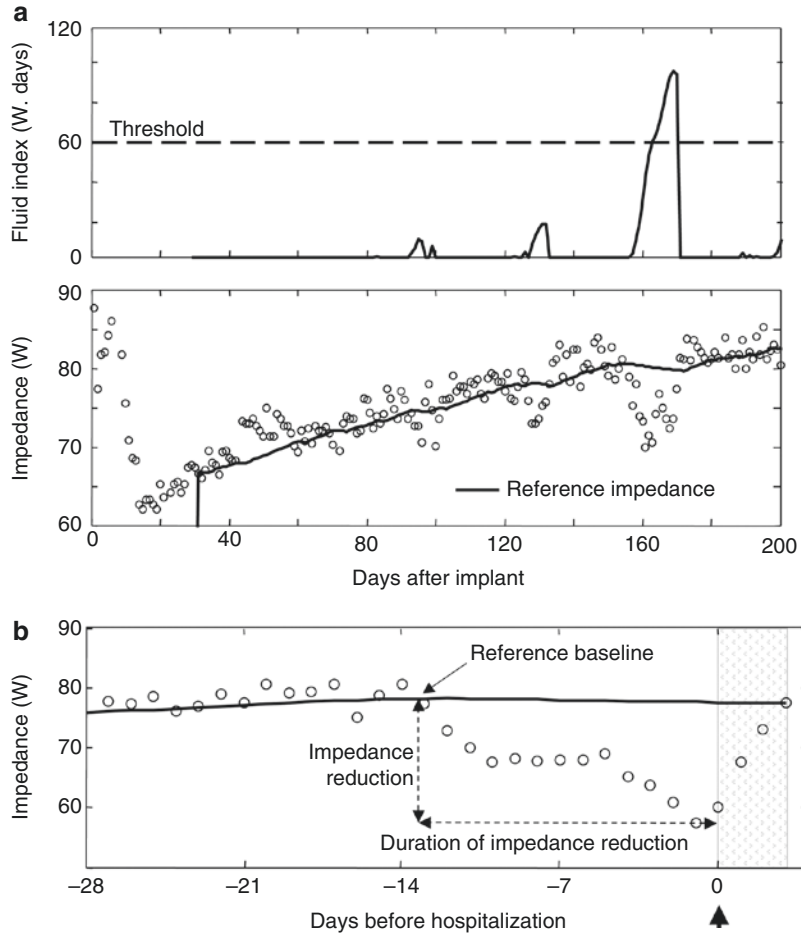

Fig. 13.6 Operational algorithm for detecting changes in impedance over time. (**a**) Differences between measured impedance (bottom; o) and reference impedance (solid line) are accumulated over time to produce fluid index (top). Threshold is then applied to fluid index to detect sustained decreases in impedance. (**b**) Example of impedance reduction before heart failure hospitalization (arrow) for fluid overload and impedance increase during intensive diuresis during hospitalization. Label indicates reference baseline (initial reference impedance value when daily impedance value consistently falls below the reference impedance line before admission). Magnitude and duration of impedance reduction are also shown. Days in hospital are shaded. (Adapted from Yu et al. [34])

impedance measurements associated with other thoracic pathologies. Other theoretical advantages over intrathoracic impedance measurements include reduced delay needed for device pocket maturation and the potentially earlier detection of volume overload as changes in the LVEDP typically occur before pulmonary edema. It can however only be used in patients with CRT devices and these measurements are dependent on lead position which renders them relative rather than absolute values. Additionally, adjustments are needed for postural and diurnal changes commonly encountered with intracardiac impedance measurements.

A combination of multiple parameters that can be recorded from intracardiac devices to form a diagnostic algorithm have been described. These algorithms include various parameters and surrogate markers and have been used to predict heart failure admissions [50, 51]. A list of the devices described above and their proprietary names are summarized in Table 13.3.

Table 13.2 Cumulative correlation coefficients of different impedance measurements compared to a standard for normal variants and pathologic states: How they could affect accurate estimation of cardiac output

Patient	Average correlation	Possible issues with CO estimation
Heathy	0.81 (0.50–0.98)	Hyperdynamic/overestimates
Animals	0.86 (0.41–0.98)	Anatomic landmarks/underestimates
CAD/AMI	0.79 (0.22–0.95)	Weak pulse/underestimates
Chest tubes	0.35	Noise/variable estimates
CHF	0.83 (0.63–0.99)	Lung edema/underestimates
COPD	0.92	Conduction/overestimates
Elderly	0.95	Atherosclerosis/underestimates
Gunshot wound	0.72	Noise/variable estimates
Hemorrhagic shock	0.88 (0.84–0.98)	Low flow/underestimates
Intubated	0.84 (0.1–0.98)	Noise/variable estimates
Obesity	0.76 (0.58–0.94)	Conduction/underestimates
Obstetric patients	0.81 (0.28–0.97)	Anatomic landmarks/underestimates
Pediatric/neonatal patients	0.83 (0.28–0.97)	Lower current/underestimates
Sepsis	0.56 (0.36–0.75)	Runoff/underestimates

Modified from Summers et al. [39]

Table 13.3 Overview of intracardiac impedance monitoring devices

Device	Primary indication	FDA status	Primary measured variable(s)	Implant location	Pertinent contraindications or restrictions
OptiVol® fluid status monitoring system (Medtronic, Inc., USA)	Ambulatory HF surveillance in patients who also meet indication for ICD therapy	Approved Nov 2004	Intrathoracic impedance and heart rate variability	Pectoral muscle region	Patients without an indication for ICD therapy or limited thoracic venous access
Chronicle® ICD and Chronicle® implantable hemodynamic monitor (Medtronic, Inc., USA)	Ambulatory HF surveillance in patients who also meet indication for ICD therapy	Not approved	RV systolic pressure, RV diastolic pressure (an estimate of PADP), maximum change in pressure over time (dP/dt and −dP/dt)	Right ventricle	Patients without an indication for ICD therapy or limited thoracic venous access
HeartPod® (St Jude Medical, Inc., USA)	Ambulatory HF surveillance	Not approved	Mean left atrial pressure	Left atrium	Patients unable to perform Valsalva maneuvers and maintain an airway pressure >39 mmHg for 8 s (required for periodic device calibration)
CardioMEMS™ HF system (CardioMEMS, Inc./St Jude medical, Inc., USA)	Ambulatory surveillance in HF patients with NYHA III symptoms who have preserved EF or reduced EF on OMT, who have had a HF hospitalization in the previous year	Approved May 28, 2014	Systolic, diastolic, and mean pulmonary artery pressure	Left pulmonary artery (ideally, basal segmental branch)	Based on CHAMPION trial criteria (REF), patient should not have any of the following: History of recurrent (>1) pulmonary embolism or deep vein thrombosis inability to tolerate a right heart catheterization recent major cardiovascular event (e.g., myocardial infarction, stroke) within 2 months of monitoring

RT cardiac resynchronization therapy, dP/dT rate of rise of left ventricular pressure (mmHg/sec), *EF* left ventricular ejection fraction, *eGFR* estimated glomerular filtration rate, *HF* heart failure, *ICD* implantable cardioverter defibrillator, *NYHA* New York Heart Association functional class, *OMT* optimal medical therapy, *PADP* pulmonary artery diastolic pressure, *RV* right ventricle

Bioreactance

Bioreactance is another noninvasive method of measuring cardiac hemodynamics, much like impedance cardiography, but unlike impedance, uses change in signal amplitude of blood flow (Fig. 13.7). Accordingly, bioreactance measures relative phase shifts of the received signals (alternating currents) in comparison to transmitted signals (ΔΦ). These phase shifts are categorized by changes in capacitive and inductive properties of changes in blood flow and intrathoracic volume. This system is less susceptible to noise, and theoretically can be more widely used with fewer limitations compared to impedance cardiography. Also, Unlike hemodynamic measurements by impedance cardiography, bioreactance neither needs static impedance nor utilizes the distance between electrodes for calculation of SV and CO, making hemodynamic calculation less prone to uncertainty [52]. This method has been shown to be accurate and show close overall correlation with hemodynamic measurements obtained using the thermodilution method [53].

Despite the advantages of bioreactance and its improvements over bioimpedance, both methods have similar underlying concepts and hence similar limitations. Changes in aortic dynamics including diseases of the aorta and aortic valve would affect the accuracy of readings. Arrhythmias and heart rates above 150 beats per minute, as well as shunts, edema, abdominal/thoracic pathologies that involve rapid volume shifts between intravascular and extravascular spaces could also make recordings inaccurate.

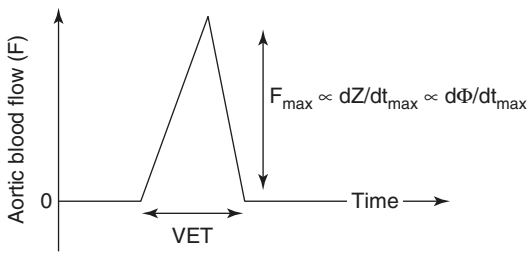

Fig. 13.7 Overview of aortic flow as a function of time and its use to measure cardiac hemodynamics. The basic principle of stroke volume (SV) estimation from changes in the bioimpedance ($\delta Z/\delta t$) or phase shift ($\delta\Phi/\delta t$)

Similar to the cardiac impedance underlying method of measurement, bioreactance is governed by the following physics equation:

$$\Delta V = \mathrm{SV} = {}_{\varrho}\left(\frac{L^2}{Z_0^2}\right)\left(\frac{\delta Z}{\delta t}\right)_{\max} \mathrm{VET}$$

given the tight correlation between rate of blood flow and change in phase shifts, ($\delta\Phi/\delta t$), therefore [52]:

Using a constant of proportionality (C):

$$\Delta V = \mathrm{SV} = \mathrm{C} \times \left(\frac{\delta\Phi}{\delta t}\right)_{\max} \times \mathrm{VET}$$

Partial Carbon Dioxide Rebreathing Technique

This method of hemodynamic measurement uses the carbon dioxide method of the Fick principle which is based on mass conservation [54]:

$$Q = \frac{\mathrm{VCO_2}}{\left(\mathrm{CvCO_2} - \mathrm{CaCO_2}\right)},$$

where Q = cardiac output; VCO_2 = CO_2 elimination (ml/min); $CvCO_2$ = venous CO_2 content (ml/ml of blood); and $CaCO_2$ = arterial CO_2 content (ml/ml of blood). This calculations assume that CO_2 concentrations remain relatively constant.

Since only the pulmonary capillary (nonshunted) blood flow (PCBF) is used in this calculation, accurate measurement of cardiac output requires adding the estimated amount of blood flow not passing through the lungs. In the CO_2 rebreathing method, subjects rebreathe air from a bag, allowing CO_2 to accumulate such that the mixed venous partial pressure is calculated. In the partial rebreathing method, however, in addition to measurements during the rebreathing, measurements are obtained during a non-rebreathing period. These measurements are applied to the Fick equation to obtain cardiac outputs [54].

$$Q_{PCBF} = \frac{VCO_{2NR} - VCO_{2R}}{\left(CvCO_{2NR} - CaCO_{2NR}\right) - \left(CvCO_{2R} - CaCO_{2R}\right)},$$

where NR = non-rebreathing phase and R = rebreathing phase.

Since it is assumed that CO_2 concentrations remain relatively constant during both phases,

$$Q_{PCBF} = \frac{VCO_{2NR} - VCO_{2R}}{CaCO_{2NR} - CaCO_{2R}} \text{ or :}$$

$$Q_{PCBF} = \frac{\Delta VCO_2}{\Delta CaCO_2}$$

Several systems exist for this method of cardiac output calculation. Each one consist of CO_2 measurements, processing of CO_2 signals and several hardware modifications to increase accuracy.

Generally, the first phase is non-rebreathing when baseline measurements are obtained. This lasts about a minute and is followed by a rebreathing phase which lasts for about another minute. During this period, there is repeated inhalation of expired CO_2. The amount of CO_2 inhaled is regulated by a valve attached to the mouthpiece. CO_2 in the rebreathing phase of the test is stored from the preceding exhalation period by the valve system in the mouthpiece, therefore making sure that the inhaled CO_2 is actually from the patient. Repeated inhalation of CO_2 during the rebreathing period increases alveolar CO_2 concentration, arterial CO_2 content and reduces alveolar diffusion of CO_2 and CO_2 clearance from the lungs. In the third and final phase, there is restoration of the patient's CO_2 stores, called the stabilization phase. This also lasts approximately 1 min and restores CO_2 parameters to normal [54].

Although this method is noninvasive, safe, convenient, and applicable in an ambulatory/outpatient setting, it assumes constant cardiac output, partial pressure of mixed venous oxygen, and shunt fraction. Changes during measurements of any of these parameters can significantly change the test results. Also, It is assumed that subjects' hemoglobin concentration is 11 g/dl. A drop of 3 mg/dl can change the estimated cardiac output by about 10%. It may also be inaccurate in patients with lung disease and resultant abnormalities of gas exchange or in patients with a $PaCO_2$ greater than 30 mmHg. Additionally, this method will be technically difficult to use in patients who cannot tolerate the rebreathing phase [7, 54, 55].

Conclusion

Noninvasive cardiac hemodynamic assessment and long-term monitoring have proven beneficial in patients with heart failure. Advances in monitoring devices and technology is allowing accurate and reliable remote monitoring of patients with heart failure. This concept is helping clinicians to manage patients and reduce unnecessary hospital admissions.

14 Cardiac Catheterization: Right- and Left-Heart Catheterization

Michael D. Faulx and Khaled M. Ziada

Introduction

Myocardial performance is determined by the combined effects of preload, afterload, and contractility [1]. *In vivo,* myocardial performance is represented by the cardiac output, while loading conditions are defined by the interplay between volume, pressure, and vascular resistance within the cardiac chambers and great vessels. Catheterization remains the gold standard for cardiovascular hemodynamic assessment because it provides direct, "real-time" hemodynamic information. Catheterization plays a major role in the diagnosis and management of conditions such as valvular heart disease, complex congenital heart disease, acutely decompensated heart failure, shock, and pulmonary hypertension.

Cardiac catheterization is widely available, and in most centers these procedures are performed quite safely. However, one must always respect the fact invasive procedures are inherently risky. In most cases invasive hemodynamic assessment should be pursued only after noninvasive modalities have failed to furnish the desired results.

Invasive Hemodynamic Assessment: Fundamental Concepts

The goal of invasive hemodynamic assessment is to accurately replicate real cardiovascular physiology. The accuracy of the data depends on the means through which it is obtained. A basic understanding of how hemodynamic information is acquired in the laboratory is essential to its correct interpretation.

Pressure Measurements

Complex pressure waves generated by the heart and great vessels are periodic, meaning that each cycle repeats itself at a fundamental frequency determined by the heart rate (expressed as cycles/second or Hertz, Hz). The French physicist Jean Baptiste Fourier (1786–1830) demonstrated that complex periodic waves can be expressed as the sum of any number of simpler sinusoidal waves, each with its own frequency and amplitude. These are referred to as *harmonics* and the frequency of each harmonic is an integral multiple of the fundamental frequency (Fig. 14.1). Fourier's theorem is important because the physical properties of a monitoring system must be configured to accurately reproduce pressures across a broad range of harmonic frequencies.

The challenge of constructing a practical hemodynamic monitoring system was tackled by the

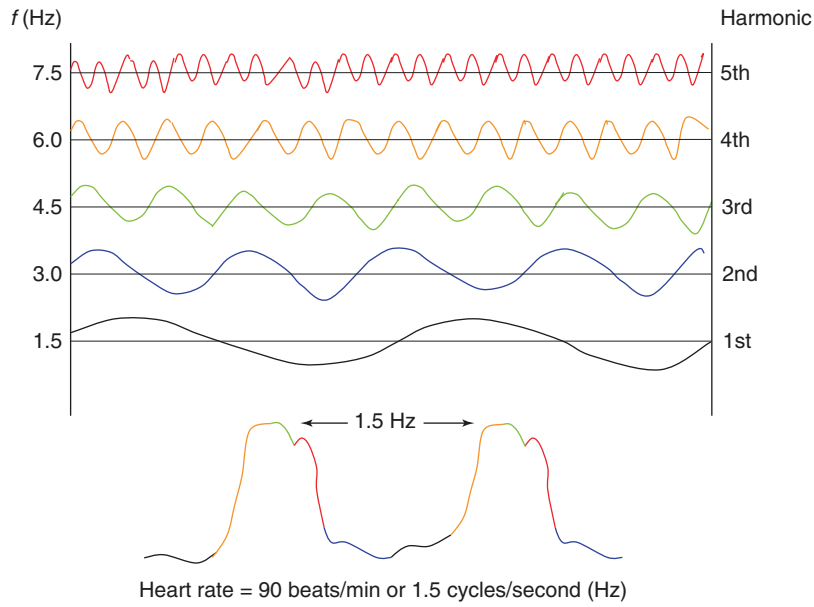

Fig. 14.1 Harmonics in hemodynamic assessment. The aortic pressure waves shown at the bottom are composed of simpler sinusoidal harmonic waves. Each harmonic is a multiple of the fundamental frequency, in this case 1.5 Hz. The data contained within each harmonic contributes in some way to the reconstructed waveform, depicted in this illustration by color. Exclusion of one or more harmonics by a monitoring system can produce a distorted, inaccurate pressure tracing

American physician Carl J. Wiggers (1883–1963). Wiggers employed a fluid-filled catheter system in contact with a rubber diaphragm coupled to a recording device and this design, after several refinements, is still used in monitoring devices today.

The fidelity of pressure measurements obtained by fluid-filled catheters is heavily dependent on the characteristics of the transducer membrane. Flexible membranes are *sensitive* because they can accurately reflect most received amplitudes but they do not respond well to higher frequency harmonics. Conversely rigid membranes respond to a wide range of harmonic frequencies (have better *frequency response*) but tend to be less sensitive. Recording systems used in modern clinical practice tend to have stiffer membranes in order to capture the range of harmonics expected in human physiology, sacrificing sensitivity to some degree.

Another major hindrance to accurate pressure measurement is the fact that transducer membranes resonate in response to stimulation, generating their own pressure waves at a fundamental frequency called the *natural frequency*. When the harmonic frequency of a recorded wave approaches the natural frequency of the monitoring system the amplitudes reflected to the monitor at or near that frequency will be greatly exaggerated. The ability of a catheter system to attenuate the pressure waves produced by the transducer membrane is referred to as *damping*. An ideally damped system is one in which the ratio of input amplitude to output amplitude is maintained close to 1:1 across a broad range of frequencies. Natural frequency (and also frequency response) increases with membrane stiffness and catheter diameter and decreases with catheter length, catheter stiffness, and fluid viscosity. Damping responds in the opposite manner to these factors. Thus, catheters with high-fidelity, tip-mounted transducers (Millar Instruments, Houston, TX) have excellent frequency response and are well suited for capturing high-frequency pressure changes over short time intervals (i.e., measurement of left ventricular dP/dt). Longer, stiffer, fluid-filled catheters coupled to a transducer at the hub are well damped and reasonably sensitive across most of the harmonic frequencies encountered in human studies.

The basic equipment required for pressure measurement in the catheterization lab includes a fluid-filled hollow catheter, multi-port manifold, transducer membrane in contact with an electrical strain gauge, signal amplifier, and a monitor. The catheter tip is placed in the cardiac chamber of interest and connected to the transducer via a dedicated port on the manifold. Pressures at the catheter tip are transmitted through the fluid medium (saline, blood, or contrast) to the transducer membrane, which stretches and vibrates in response to the pressure it sees. The membrane is coupled to a tiny strain gauge contained within a housing unit that has been equilibrated to atmospheric pressure (referred to as *zeroing*). Movement of the piston across the wires of the strain gauge produces an electrical current that is subsequently amplified, reconfigured, and displayed on the monitor.

Hemodynamic waveforms obtained from fluid-filled catheters are subject to a variety of artifacts. Common encountered artifacts are demonstrated and extensively reviewed in Fig. 14.2a–e.

Blood Flow Measurements

Accurate measurement of cardiac output is vital not only as an index of myocardial performance but also as a component in the quantification of valvular stenoses, vascular resistances, and shunts. In clinical practice, cardiac output is assessed by two methods: Fick method and thermodilution.

Oxygen Extraction and Utilization: The Fick Method

The German physiologist Adolph Fick (1829–1901) theorized that the utilization of any substance by an organ can be expressed as the product of the blood flow to the organ and the difference between the arterial and venous concentrations of the substance. When this principle is applied to the lungs, oxygen uptake (VO_2) would be equal to pulmonary blood flow x the difference between pulmonary arterial ($A[O_2]$) and venous ($V[O_2]$) oxygen content. Assuming that there is no pulmonary-systemic shunt and that flow through the pulmonary and systemic circuits are equal, the Fick equation can provide a measure of cardiac output (CO):

$$\text{Fick equation} \quad \text{CO}\left(\text{L/min}\right) = \frac{\text{VO}_2 \ \left(\text{mL/min}\right)}{\text{A}\left[\text{O}_2\right] - \text{V}\left[\text{O}_2\right] \ \left(\text{mL/L}\right)}$$

Oxygen consumption for an individual patient can be directly measured by devices that employ a closed rebreathing circuit with a CO_2 detector. However, this approach is expensive and technically cumbersome and many laboratories assume a resting VO_2 of 1.25 mL/m^2. The reader should be aware that assumed VO_2 values are based on studies of basal metabolic activity in predominantly young subjects. Measured VO_2 can significantly vary from baseline in subjects with underlying cardiopulmonary disease so the use of assumed oxygen consumption values can introduce significant error in the calculation of cardiac output.

Hemoglobin binds approximately 1.36 mL of elemental oxygen per gram and oxygen bound to the hemoglobin molecule accounts for over 98% of the total oxygen content of human blood. Oxygen dissolved in plasma accounts for the rest and is represented by the product of oxygen solubility in plasma (0.003 mL/dL/mmHg) and the partial pressure of oxygen in plasma, PaO_2. The oxygen content of blood is represented by the following equation:

$$\text{Cb}\left[\text{O}_2\right] = \left\{\left[\text{hemoglobin}\right] \times 1.36 \times \text{SaO}_2 \times 10\right\} + 0.003 \times \text{PaO}_2 \times 10.$$

SaO_2 is the percent oxyhemoglobin as detected by oximetry. For the sake of simplicity the content of dissolved O_2 is often omitted from this calculation, but the reader should be aware that under certain circumstances (i.e., high FiO_2 with positive pressure ventilation) the amount of dissolved oxygen in blood can become clinically relevant.

The Fick method is generally an accurate method of cardiac output measurement but error can be introduced at several levels. The Fick method relies on several key assumptions such as the absence of an intracardiac shunt and the notion that oxygen consumption and cardiac output are constant during measurement. In critically

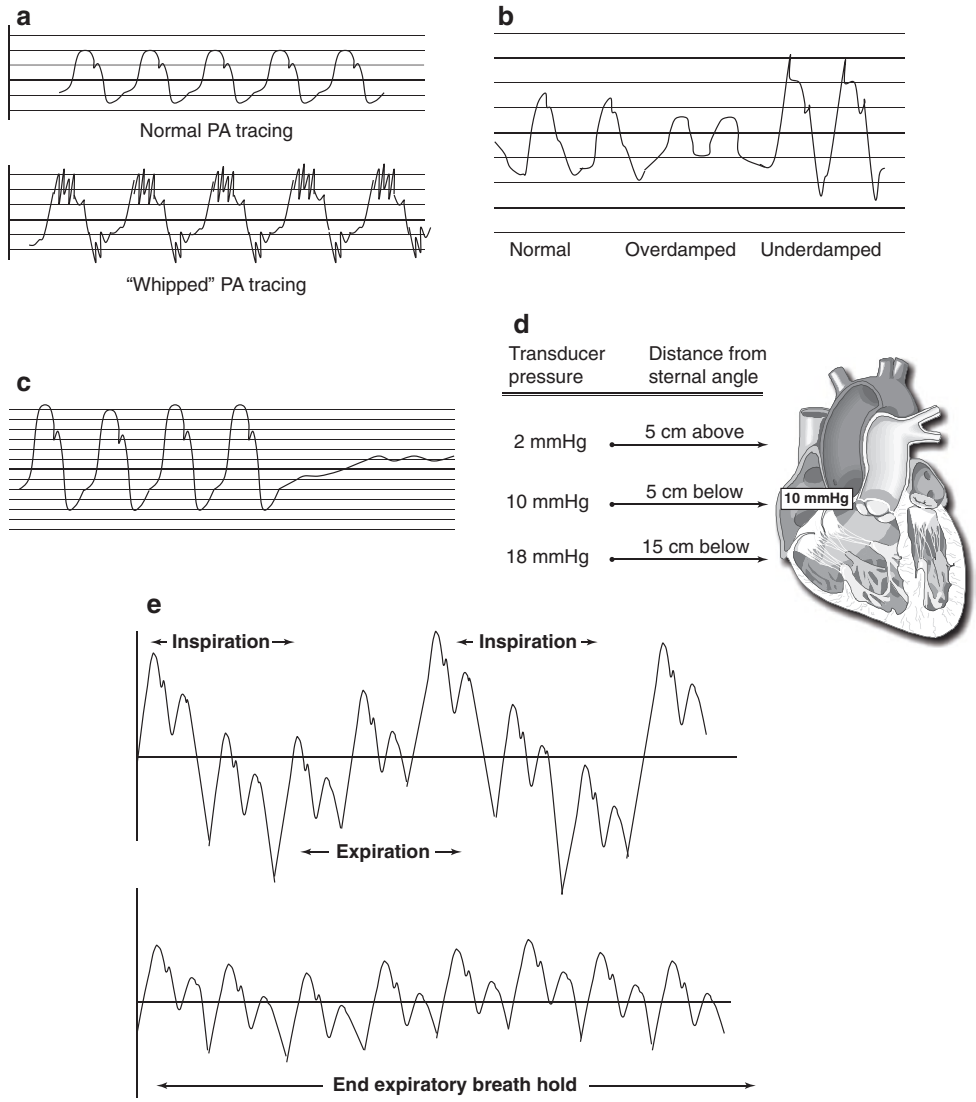

Fig. 14.2 (**a**) Catheter whip in a pulmonary artery (PA) pressure tracing. Whip occurs when the catheter tip vibrates in response to ventricular contraction or valvular motion. Whip causes high-frequency distortion of the waveforms, particularly at the high and low points of the complex. Since the extremes of the waveform are equally affected, the mean pressure obtained from a "whipped" tracing is generally accurate. Whip can be attenuated by catheter repositioning, the use of a high-frequency filter, or increased damping. (**b**) Damping-related artifacts. Overdamping results in a flat, low-amplitude waveform that lacks contour detail. Overdamping can be caused by catheter kinking, air bubbles or blood in the transducer circuit, and the use of long, small-caliber catheters. It can be overcome by removing kinked tubing, flushing of the catheter and manifold, and use of shorter, large-caliber catheters. Under-damping produces exaggerated waveforms with overestimated amplitudes. It occurs when the natural frequency of the catheter system approximates a harmonic frequency in the pressure wave. This can be offset by lowering the natural frequency of the catheter system (longer, smaller-caliber catheters) or the patient (treat tachycardia). (**c**) Positional artifact. This is characterized by flattening of the pressure tracing with a gradual rise in pressure. It most often occurs when the catheter tip is pressed against the wall of a vessel or chamber. Gentle withdrawal and redirection of the catheter typically solves the problem. (**d**) Transducer malposition. In this example, the true mean right atrial pressure is 10 mmHg. When the transducer is zeroed at a level 5 cm below the sternal angle the catheter recording is accurate. When the transducer is zeroed at a level above the chest, the pressure is underestimated. When the transducer is zeroed at a level well below the right atrium, the pressure is overestimated. (**e**) Respiratory variation of right atrial pressure. The thin-walled right-sided chambers are subject to respiratory variation, particularly in subjects with underlying obstructive lung disease. Pressure measurements taken during a few seconds of breath holding at the end of normal expiration (when intrathoracic pressure is theoretically zero) are much less variable

ill patients with pulmonary disease, oxygen consumption can be overestimated since the delivery of oxygen from the lungs to the blood is not uniform. The Fick equation also requires several measurements, each with its own degree of measurement error. The use of an assumed value for oxygen consumption, as mentioned previously, is a major potential source of error; hence, the use of the term "estimated Fick cardiac output" may be the more accurate description of what is actually measured in the routine catheterization laboratory practice.

Indicator Dilution over Time: The Thermodilution Technique

Thermodilution measures the rate of change of blood temperature over time. By injecting a fixed volume (10 mL) of chilled or room air temperature injectate (5% dextrose or 0.9% saline) into the right atrial port of the catheter and continuously measuring temperature with a thermistor located at the catheter tip, we can estimate the rate of flow from the right atrium to the catheter tip. Thermodilution calculations are mathematically complex as they account factors such as the expected degree of catheter warming during injection and the specific heat and gravities of blood and the injectate. Numerical cardiac outputs are provided by computerized analysis of temperature versus time curves and the final cardiac output is typically reported as an average of several injections.

Thermodilution correlates reasonably well with other measures of cardiac output but there are several contributors to measurement error. Pulmonary artery temperature can vary with respiration so injection during the same portion of the respiratory cycle (i.e., end expiration) each time reduces the potential for error. Shorter injection periods (<3 seconds) are preferable to longer ones for similar reasons and the injection periods should be as uniform as possible. Smaller injectate volumes with warmer injectate temperatures (i.e., 5 mL injected at room temperature) produce more measurement error than colder, larger volume injections because the signal-to-noise ratio is lower. Thermodilution is not reliable in the presence of significant tricuspid regurgitation or in low output states because the injectate tends to cycle between the right atrium and right ventricle, resulting in a flattened temperature-time curve.

A recent comparative study indicates that the correlation between thermodilution and estimated Fick methods for the calculation of cardiac output is modest ($r = 0.65$), with a difference of >20% demonstrated in about 38% of patients. Low output by the thermodilution method correlated more closely with 3 and 12 months mortality, indicating that it maybe the preferred method of cardiac output calculation.

Risk of Cardiac Catheterization

Proper informed consent should be obtained from the patient or a designated medical decision maker prior to cardiac catheterization. The major risks related to right and left cardiac catheterization appear in Table 14.1. Decompensated heart failure, shock, acute coronary syndromes, left ventricular dysfunction, morbid obesity, depressed mental status, and advanced kidney disease are all associated with increased procedural risk. The risk for stroke increases significantly with cannulation of the left ventricle. Although debilitating strokes are rare the incidence of small, clinically silent strokes assessed by MRI was found to be 22% in one series of patients with severe aortic stenosis who underwent left ventricular cannulation [2]. For this reason, routine left ventricular catheterization should be avoided in favor of a selective approach, reserving left ventricular cannulation for patients with nondiagnostic or conflicting noninvasive test results.

The most common catheterization complications are related to problems with the vascular access site or subsequent hemostasis. When feasible ultrasound or radiographic guidance should be employed to localize landmarks and guide cannulation of large arteries and veins. Morbid obesity is a common contributor to access-related complications, particularly when femoral access is attempted.

Table 14.1 Complications associated with diagnostic left- and right-heart catheterization[a]

Complication (% risk)	Contributing factors	Prevention
Death (0.11%)	High acuity illness	Reassess necessity of the procedure
	Emergency procedure	Have ACLS equipment on stand by
Myocardial infarction (0.05%)	Acute coronary syndromes	Appropriate medical therapy for ACS
	Profound hypertension	Medical management of hypertension
	Profound tachycardia	Medical management of tachycardia
Stroke (0.07%)	Cannulation of left ventricle	Avoid crossing aortic valve unless absolutely necessary
	Atrial fibrillation	Over-the-wire catheter exchanges
	Ascending aortic atheroma	
Access complications (0.43%)	Anticoagulation	Correction of coagulopathy
Major hematomas	Morbid obesity	Radial artery access
Retroperitoneal bleeds	Agitation	Imaging-guided vascular cannulation
Arteriovenous fistulas		Appropriate conscious sedation
Major arrhythmias (0.38%)	Electrolyte disturbances	Correct metabolic derangements
Ventricular fibrillation	Hypoxemia	Supplement oxygen
Ventricular tachycardia	Right coronary conus branch injection	Cautiously injection of right coronary
Complete heart block		
	Catheter-induced endocardial trauma	Use pigtail catheter in left ventricle
	Underlying bundle branch blocks	
Other embolic events (rare)	Pre-existing deep vein thrombosis	Exclude thromboses prior to study
Pulmonary embolism/ infarction	Prolonged immobility	Limit duration of PA catheterization over-the-wire catheter exchanges
Distal atheroembolism	Aortic atheromatous disease	
Contrast nephropathy (variable)	Pre-existing kidney disease	Adequate hydration
	Diabetes	Use of N-acetylcysteine
	Dehydration	Minimize use of contrast
	Large contrast volume	
Serious allergic reactions	Pre-existing allergies	Pretreatment with corticosteroids and antihistamines
Contrast agents (0.37%)		
Local anesthetic (ester agents)		Use of amide anesthetic agents
Respiratory arrest (variable)	Underlying pulmonary disease	Limit the use of sedatives
	Altered mental status	Optimize heart failure and lung disease prior to the study
	Decompensated heart failure	Frequent airway assessment
	Morbid obesity	Anesthesiology consultation
Other vascular complications (0.28%)	Balloon inflation in small arteriole	Avoid inflation in distal PA
Pulmonary artery perforation	Catheter trauma	Cautious catheter removal
Coronary artery dissection		
Perforation of cardiac chamber	Sub-intimal guide wire route	Use flexible J-tipped wires

Right-Heart Catheterization Technique

Right-heart catheterization is generally performed using a 7- or 8-French vascular sheath placed in the common femoral vein or right internal jugular vein using modified Seldinger technique and typically under ultrasound guidance. A balloon tipped pulmonary artery catheter is inserted through the sheath and the balloon is inflated once the tip of the catheter has cleared the sheath. The catheter tip, guided by flow and the manipulation of the operator, traverses the heart from the great veins to the pulmonary artery and the pulmonary artery wedge position [3]. The catheter is then connected to the pressure transducer via a multi-port manifold. Blood can also be withdrawn from the catheter for oximetry and chemistry sampling. There is a proximal lumen at the level of the right atrium to allow for thermodilution assessment of cardiac output. Rarely, situations arise where direct measurement of left atrial pressure is desirable, such as in the evaluation of severe native or prosthetic mitral stenosis. Left atrial cannulation can be performed from the right atrium by fluoroscopy-guided needle puncture of the interatrial septum at the level of the fossa ovalis and the use of a Brockenbrough catheter.

Left-Heart Catheterization Technique

Left-heart catheterization is performed by placing a 4-, 5-, or 6-French sheath into a large artery using Seldinger or modified Seldinger technique. Most contemporary laboratories utilize radial artery access as the preferred choice for arterial access for diagnostic procedures, although the traditional right or left common femoral artery approach remains an important alternative, when radial access is not feasible or when larger bore devices are planned or needed. Ultrasound and fluoroscopic guidance are important tools to optimize the technique and safety of arterial access. Brachial artery access remains as an option for left-sided catheterization, although usually a last resort. Once vascular access is obtained the arterial catheters are advanced retrogradely through the aorta preceded by a J-tipped flexible guidewire. The catheters are controlled by the operator and there are numerous specialized catheters available for use. Endhole catheters are useful for pressure measurements and contrast injection during coronary angiography. They are not ideal for opacification of the aorta or left ventricle because they promote contrast streaming and ventricular ectopy. Multi-hole pigtail catheters record the pressure and are better for the opacification of large structures because they uniformly distribute a larger volume of pressured contrast within a chamber. Aortography and ventriculography should be performed using a pigtail catheter. Some pigtail catheters have proximal and distal transducer ports to allow for simultaneous pressure measurements across a given structure such as the aortic valve.

Data Derived from Right- and Left-Heart Catheterization

Pressure Measurements

When intracardiac pressure measurements are gated to the surface electrocardiogram, systolic and diastolic performance of the heart can accurately be assessed (Fig. 14.3). Pressure measurements are obtained by advancing the catheter to the chamber of interest and recording waveforms over several cardiac cycles. Right-sided pressures can vary greatly with respiration in some patients (see Fig. 14.2e), making interpretation difficult. In this case, a several-second end-expiratory breath hold will maintain thoracic pressure at its theoretical "zero point" for a few cardiac cycles. Normal cardiovascular waveforms and their descriptions follow.

Right Atrial Pressure (Fig. 14.4a)
The normal right atrial pressure wave includes the "a" wave, produced by atrial contraction and the corresponding "x" descent during atrial relaxation. Early in the "x" descent there may be a small positive reflection called the "c" wave which represents closure of the tricuspid valve.

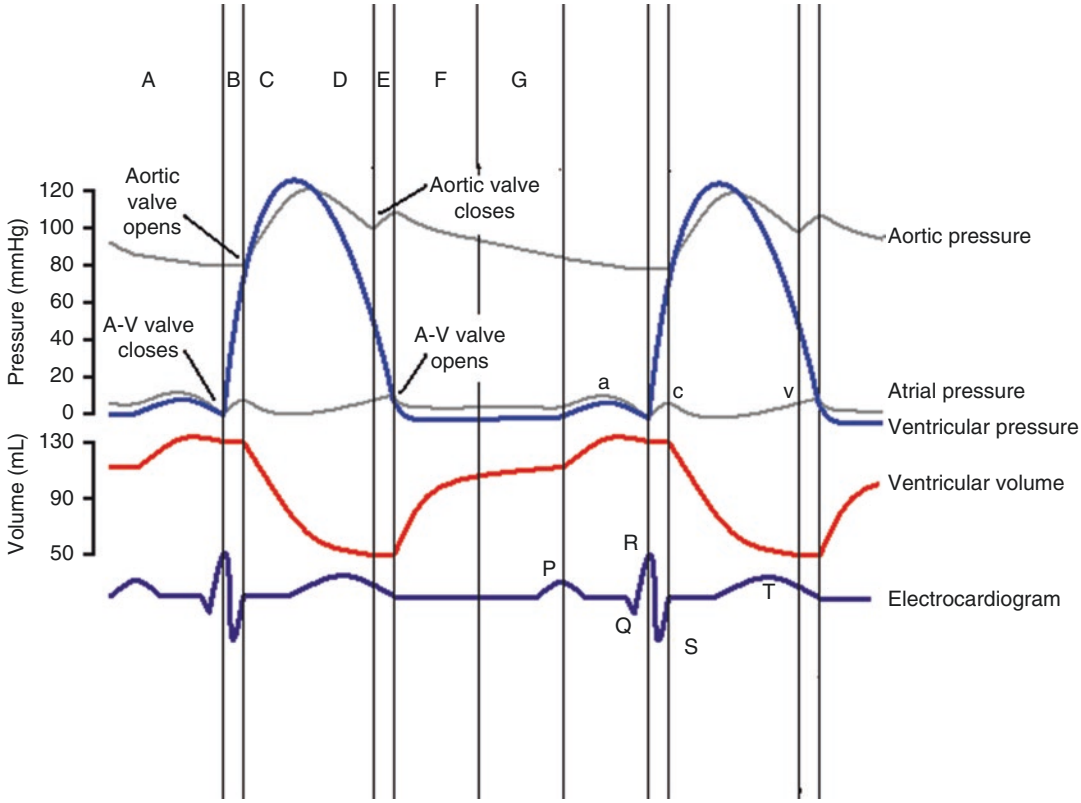

Fig. 14.3 Schematic representation of the major electrical and mechanical events during the cardiac cycle: (**a**) atrial contraction; (**b**) isovolumic contraction; (**c**) rapid ejection; (**d**) reduced ejection; (**e**) isovolumic relaxation; (**f**) rapid ventricular filling; and (**g**) reduced ventricular filling

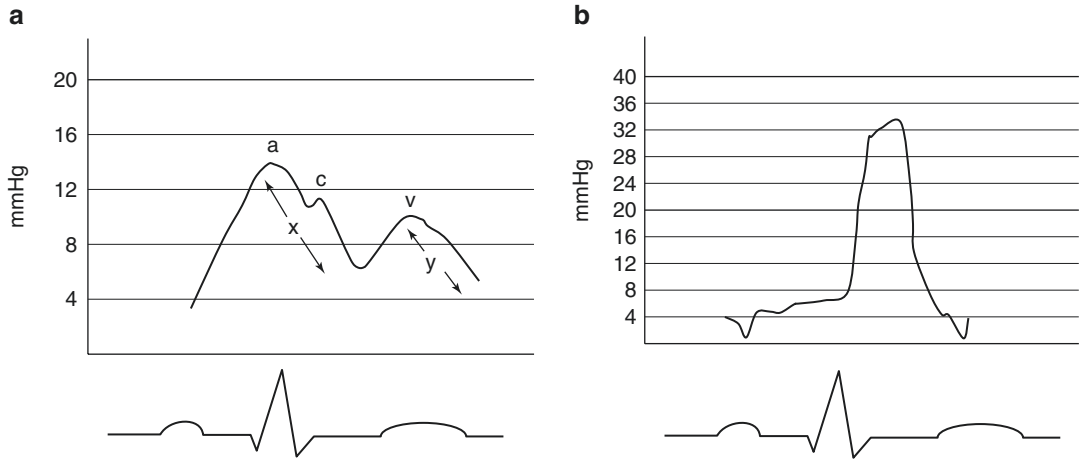

Fig. 14.4 (**a**–**f**) Normal cardiac pressure tracings. Descriptions of each tracing are found within the chapter text. (**g**) Abnormal pressure tracing obtained during selective coronary angiography. In the presence of severe ostial stenosis, the endhole catheter transmits a distorted waveform due to the reflected coronary wedge pressure and appears as a hybrid between aortic and ventricular pressure (ventricularized pressure) waveform

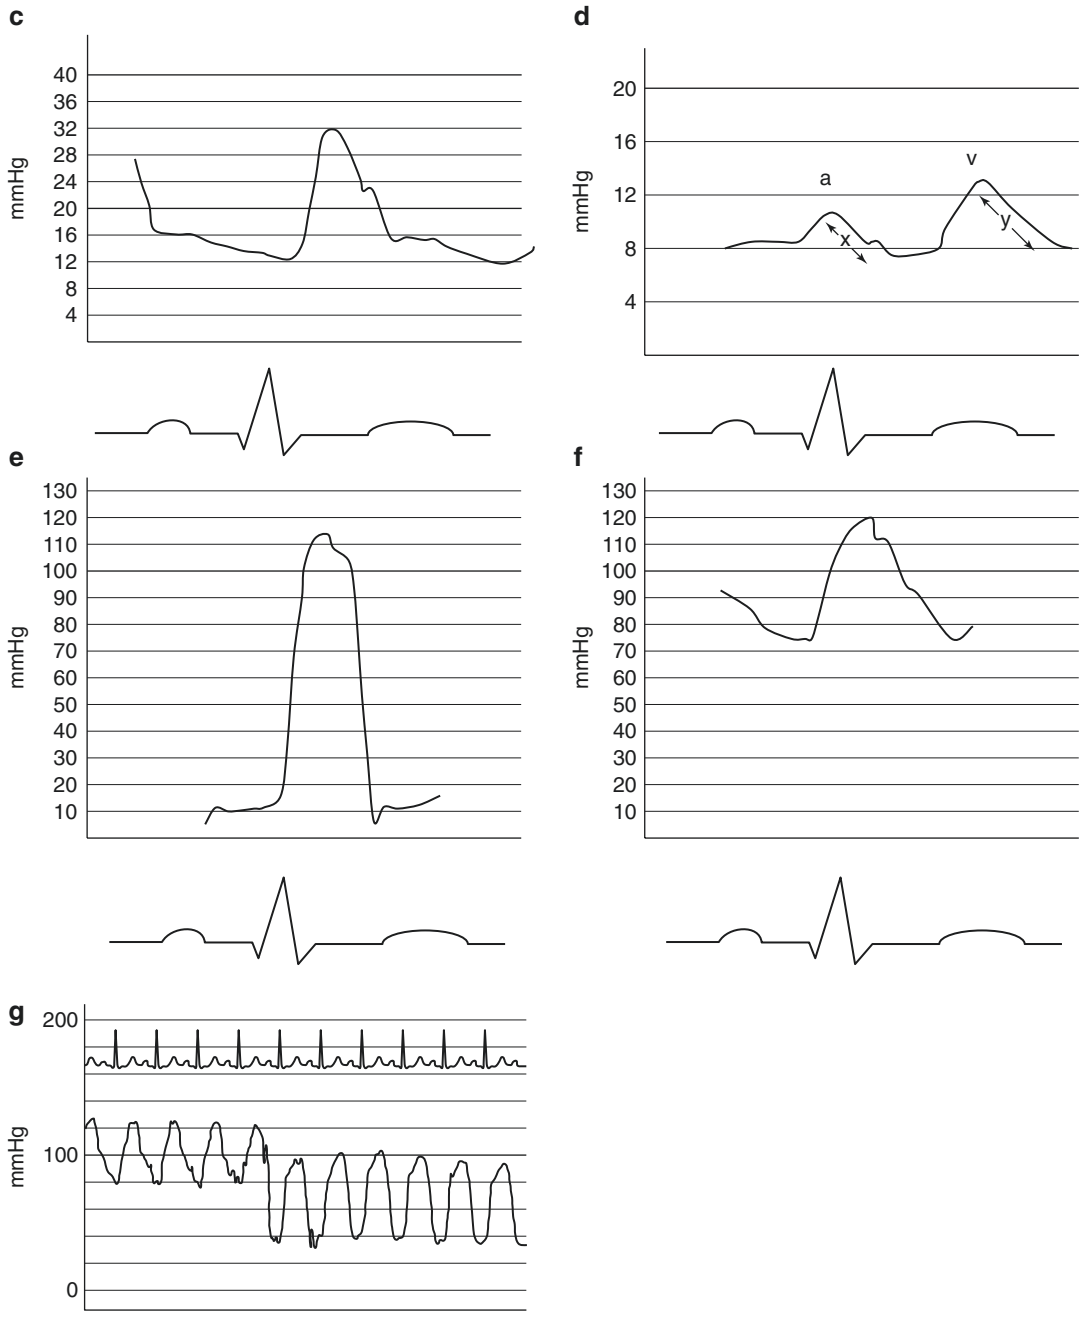

Fig. 14.4 (continued)

The second major wave in the right atrial tracing is the "v" wave, produced by the combination of vena cava flow into the atrium and the upward displacement of the closed tricuspid valve during right ventricular contraction. Once the tricuspid valve opens, the right atrial pressure drops in early diastole, producing the "y" descent. Normal mean right atrial pressure is between 1 and 10 mmHg.

Right Ventricular Pressure (Fig. 14.4b)

The normal right ventricular wave is characterized by a rapid pressure rise during systole followed by

a rapid fall during isovolumic relaxation. Diastolic pressure gradually increases until late systole when the right atrium contracts and right ventricular end-diastolic pressure rises to the level of the atrial "a" wave. Normal right ventricular systolic and diastolic pressure is 15–30 mmHg and 1–10 mmHg, respectively.

Pulmonary Artery Pressure (Fig. 14.4c)

The normal pulmonary artery pressure tracing is a typical arterial waveform with a rapid systolic upstroke. There is a dicrotic notch produced by closure of the pulmonic valve and the diastolic pressure gradually decreases as blood flows from the main pulmonary artery to the lungs. Normal pulmonary artery systolic and diastolic pressure is 15–30 mmHg and 5–10 mmHg, respectively. In intensive care settings, it is common practice to follow the PA end-diastolic pressure as an indirect measure of left atrial pressure. However, this assumption is only true if the pulmonary vascular resistance is close to normal.

Pulmonary Capillary Wedge Pressure, PCWP (Fig. 14.4d)

The PCWP is commonly used as a surrogate for left atrial pressure. This pressure is obtained by cautiously advancing the catheter tip through the pulmonary artery with the balloon inflated until the balloon will no longer advance and appears fixed or "wedged" in the pulmonary bed by fluoroscopy. Inflating the balloon with the catheter tip in the distal pulmonary arterial tree increases the risk for pulmonary artery rupture. The PCWP reflects left atrial pressure because when the balloon is properly wedged there is no longer flow from the proximal PA to the catheter tip. The catheter tip only "sees" the left atrial pressure waves that are reflected back to it through the pulmonary artery capillary bed (Fig. 14.5).

The normal PCWP is analogous to left atrial pressure, with "a" and "v" waves that correspond to left atrial contraction and left ventricular contraction, respectively and their corresponding "x" and "y" descents. It is important to know that left

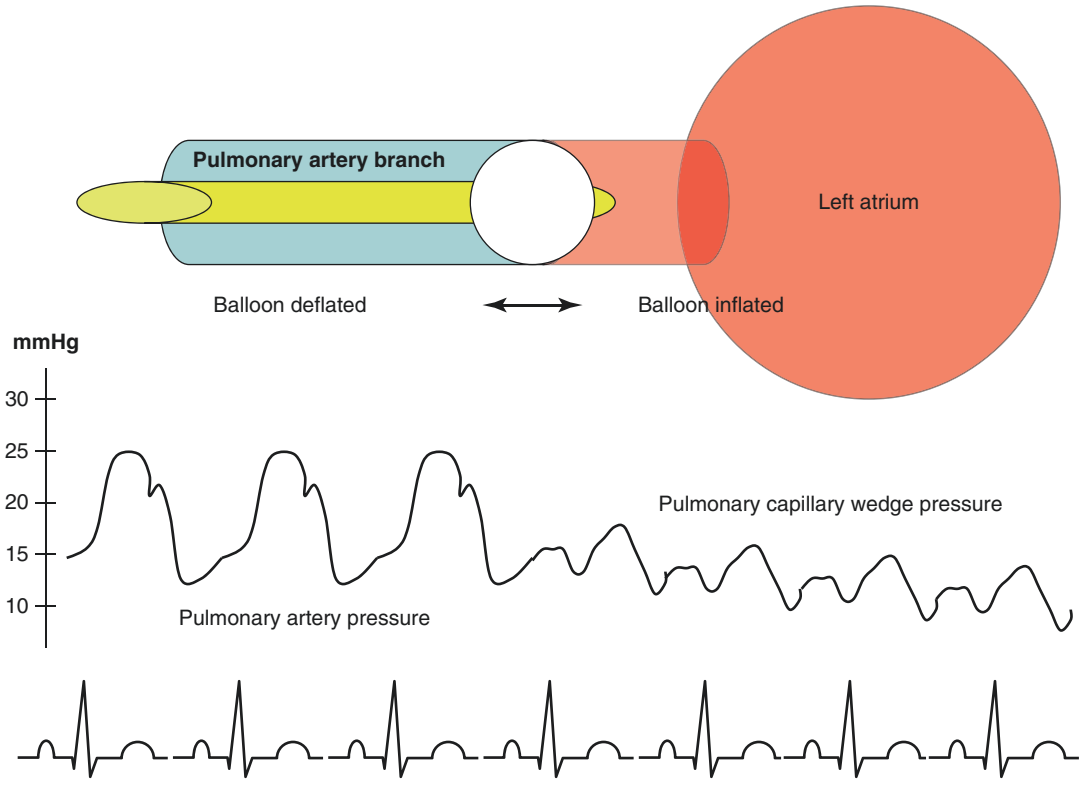

Fig. 14.5 Diagram of the pulmonary capillary wedge technique

atrial activity precedes the reflected wedge pressure by a few milliseconds. This causes the PCWP "v" wave to appear later than the left atrial "v" wave. When the PCWP and left ventricular pressures are superimposed during assessment for mitral stenosis, the result may be overestimation of the transmitral pressure gradient. Normal mean PCWP pressure is between 5 and 12 mmHg, and in the absence of mitral stenosis, it approximates left ventricular end-diastolic pressure.

Left Ventricular Pressure (Fig. 14.4e)
Left ventricular pressure has a rapid upstroke during early systole followed by a rapid descent. Diastolic pressure is low in early diastole and rises slowly until the left atrium contracts. The left ventricular end-diastolic pressure (LVEDP) represents the true preload for the left ventricle, and it is typically measured just prior to abrupt rise in systolic pressure. Normal LVEDP is 5–12 mmHg.

Aortic Pressure and Waveform
(Fig. 14.4f)
Aortic pressure is measured with the catheter tip in the proximal aorta. Central aortic pressures are usually 10–20 mmHg lower than femoral artery pressures due to the greater size and elasticity of the normal aorta. In a normal, high fidelity system, the aortic waveform is characterized by a dicrotic notch which occurs at the closure of aortic valve.

Endhole catheters used for selective coronary angiography should normally transmit a normal waveform of central aortic pressure. In the presence of severe ostial coronary stenosis, the waveform is distorted by the reflected coronary wedge pressure and appears as a hybrid between aortic and ventricular pressure (ventricularized pressure) waveform. The systolic pressure is decreased and the diastolic pressure is markedly decreased, compared to the normal aortic waveform. This should immediately raise concern about severe ostial right or left main coronary stenosis, although the differential diagnosis can simply be a non-coaxial catheter position, with the tip against the wall of the artery (Fig. 14.4g).

Cardiac Output

The Fick method requires sampling of blood from both sides of the pulmonary vascular bed, namely, the pulmonary artery and pulmonary veins or left atrium. Pulmonary artery blood is obtained via aspiration from the distal port of the right-heart catheter. Direct sampling from the left atrium requires transseptal puncture which is impractical for routine diagnostic testing. For this reason, an arterial blood sample (i.e., from the femoral artery sheath) is typically used as a substitute. The thermodilution technique has been previously described.

Normal cardiac output is between 5.0 and 7.5 L/min but varies broadly with patient size and gender (men generally have higher cardiac outputs than women). The human heart can augment its cardiac output over fivefold in certain disease states (i.e., severe anemia, thyrotoxicosis). The cardiac index (cardiac output divided by body surface area, BSA) is a better measure of myocardial performance than cardiac output. The normal range for cardiac index is 2.5–4.0 L/min/m^2. A cardiac index <1.0 L/min/m^2 is not compatible with life.

Vascular Resistance

In a fluid-filled system, resistance (R) is proportional to the pressure difference across the system (ΔP) and inversely proportional to flow (Q); $R = \Delta P/Q$.

By measuring mean aortic pressure (AoP) and mean right atrial pressure (RAP), we can calculate systemic vascular resistance (SVR) in the following manner:

$$\text{Systemic vascular resistance}$$
$$\text{SVR} = \frac{(\text{mean AoP} - \text{mean RAP})}{\text{Cardiac Output}}$$

Similarly, by measuring the mean pulmonary artery pressure (PAP) and left atrial pressure (LAP), either directly or with its surrogate (wedge pressure), we can calculate the pulmonary vascular resistance (PVR):

$$\text{Pulmonary vascular resistance}$$
$$\text{PVR} = \frac{\left(\text{mean PAP} - \text{mean LAP / PCWP}\right)}{\text{Cardiac Output}}$$

Vascular resistances can be expressed in Wood units (mmHg/L/min) or dynes∗s/cm^{-5}. A dyne is the amount of force required to accelerate a 1 gram mass to 1 cm/s^2. 1 Wood unit = 80 dynes∗s/cm^{-5}. Normal systemic vascular resistance is between 8 and 20 Wood units. Normal pulmonary vascular resistance is between 0.25 and 1.6 Wood units.

Shunt Assessment

Shunt flow from the systemic circulation to the pulmonary circulation can be localized and quantified during right-heart catheterization by performing an oximetry saturation run. As the catheter is passed through the great veins to the pulmonary artery, small (2 mL) aliquots of blood are obtained for oximetry from the proximal and distal superior vena cava (SVC), proximal and distal inferior vena cava (IVC), right atrium (low, mid, and high), right ventricle (proximal, mid, and apex), pulmonary artery (main, left, and right), left ventricle, and aorta distal to the ductus arteriosus.

A left-to-right shunt is detected by an oximetry "step-up," where oxygenated left circulation blood mixes with deoxygenated right circulation blood. A "step-up" of ≥7% is considered significant at the level of the great veins and right atrium. A step-up of ≥5% is considered significant at levels distal to the right atrium. Right-to-left shunts are difficult to locate and quantify, and oximetry to detect a "step-down" is generally not performed.

The degree of left-to-right shunting can be quantified by calculating the ratio of pulmonary blood flow (Qp; oxygen consumption divided by the difference in arteriovenous oxygen content across the lungs) to systemic blood flow (Qs; oxygen consumption divided by the difference in arteriovenous oxygen content across the systemic circulation). Systemic mixed venous saturation (MVO_2) is defined as:

$$\text{Mixed venous saturation} \quad \text{MVO}_2 = \frac{\left[(3)\text{SVC saturation} + \text{IVC saturation}\right]}{4}$$

If we assume constant oxygen consumption, hemoglobin concentration, and atmospheric pressure, then many of the terms in this complex calculation cancel out, leaving only the oximetry saturations:

$$\text{Shunt fraction} \quad \text{Qp / Qs} = \frac{\left(\text{Arterial sat}\right) - \left(\text{MVO}_2\text{sat}\right)}{\left(\text{Arterial sat}\right) - \left(\text{pulmonary artery sat}\right)}$$

The pulmonary venous saturation cannot be obtained without transseptal puncture or retrograde catheterization through the mitral and aortic valves. In the absence of a significant right-to-left shunt at the level of the left atrium, ventricle, or proximal aorta, we would expect systemic arterial saturation and pulmonary venous saturation to be the same; thus pulmonary venous saturation is often replaced by systemic arterial saturation in this equation.

Small shunts are defined by Qp/Qs < 1.5 and are often asymptomatic. Large shunts are defined by Qp/Qs > 2.0 and often require closure. Frequently, the location of the shunt is known or suspected from an alternative study such as an echocardiogram, CT scan, or MRI, and catheterization is used to quantify the shunt fraction. In this case, it is not necessary to sample from multiple levels in the same chamber or vessel.

Assessment of Valvular Stenosis

The invasive assessment of valvular stenosis requires measurement of the cardiac output and measurement of the pressure difference across the valve in question. Ideally, pressure measurements should be made simultaneously with two catheters, each coupled to its own transducer and neither crossing the affected valve. The catheters should be placed in the chambers or vessels on either side of the valve, and the pressure tracings should be superimposed to accurately calculate

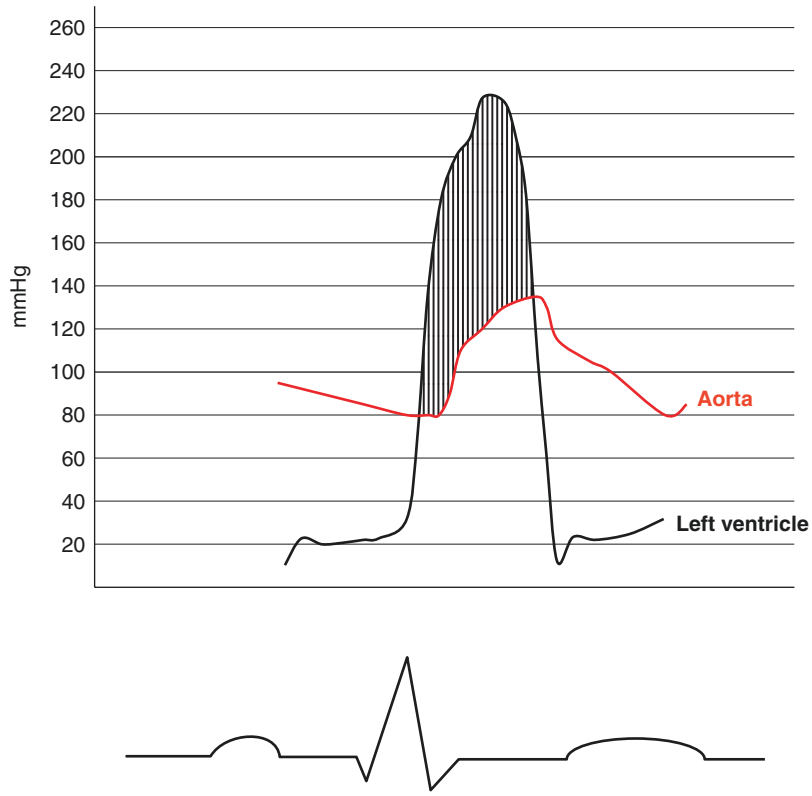

Fig. 14.6 Estimating the transaortic pressure gradient. The pressure waves produced by simultaneous catheterization of the left ventricle and proximal ascending aorta are superimposed. The shaded area under the curve (AUC) is calculated, providing the mean transvalvular gradient

the mean pressure gradient (area under the curve, AUC) (Fig. 14.6).

Assessment of mitral stenosis is performed by measuring simultaneous left ventricular and left atrial pressures. If transseptal puncture is not desired, the pulmonary capillary wedge pressure may be used as a surrogate for the left atrium; however, this may overestimate the magnitude of the gradient since the wedge pressure lags behind true left atrial pressure by a few milliseconds. Assessment of aortic stenosis involves simultaneous measurements in the left ventricle and ascending aorta. Two arterial sheaths can be placed, but this increases the risk for access site complications. Dual lumen pigtail catheters have proximal (ascending aorta) and distal (left ventricle) ports that require two transducers but one arterial access site. Another method is the "pull-back method," where the catheter is withdrawn from the left ventricle into the ascending aorta during continuous recording. This allows for a peak-to-peak measurement of the systolic pressure difference that is not simultaneous and provides a crude approximation of the integrated or mean pressure difference. When aortic stenosis is severe, the catheter itself promotes stenosis, resulting in a higher gradient and potential overestimation of stenosis severity.

The Gorlin formula is typically used to calculate valve areas in the catheterization lab:

$$\text{Gorlin formula} \quad \text{Valve Area}\left(\text{cm}^2\right) = \frac{\text{CO}/[\text{HR}][\text{EP}]}{44.3\times(\text{K})\times\sqrt{\Delta P}},$$

where CO is the cardiac output (L/min), HR is the heart rate (bpm), EP is the ejection period (systolic or diastolic as calculated from the ECG, in seconds/beat), 44.3 is a constant that accounts for energy loss due to acceleration and gravity (cm/s/s), K is a unit-less correction factor (1.0 for the aortic valve and 0.85 for the mitral valve), and $\sqrt{\Delta P}$ is the square root of the mean pressure gradient across the valve. An abbreviated version of

Table 14.2 Criteria for the angiographic assessment of mitral regurgitation

Severity	Grade	Criterion
Mild	1+	Incomplete opacification of left atrium
Moderate	2+	Complete opacification of left atrium but with less relative intensity than the left ventricle
Moderately severe	3+	Complete opacification of left atrium with intensity equal to the left ventricle after 4 beats
Severe	4+	Complete opacification of left atrium with intensity equal the left ventricle within 3 beats

the Gorlin formula, called the Hakki formula, provides a reasonable estimate of valve area as well.

$$\text{Hakki formula} \quad \text{Valve area}\left(\text{cm}^2\right) = \frac{\text{CO}}{\sqrt{\Delta P}}$$

The normal aortic valve orifice area is 3.0–4.0 cm^2. The normal mitral valve orifice area is 4.0–6.0 cm^2.

Assessment of Valvular Regurgitation

The invasive assessment of valvular regurgitation is largely subjective. The severity of aortic and mitral regurgitation can be estimated by applying qualitative criteria to the appearance of aortography and ventriculography, respectively (Table 14.2). The severity of tricuspid and mitral regurgitation can be estimated from the relative magnitude of the "v" waves in the right atrial and PCWP tracings, respectively. However, atrial compliance and ventricular function also influence the amplitude of "v" waves, making this approach fairly non-specific.

Case Presentation

A 47-year-old female with history of systemic lupus erythematosus (SLE) presents with exertional dyspnea. She reports development of peripheral edema in the past month and has had onset of exertional dyspnea in the past few days.

Salient physical examination findings include a heart rate of 92, blood pressure of 136/72, elevated JVP at 16 mmHg, and grade I/VI early systolic murmur at left lower sternal border. The lung fields are clear. There is 2+ pitting lower extremity edema. Pulsus paradoxus is measured to be 8 mmHg.

A chest X-ray shows an enlarged cardiac silhouette. An ECG shows electrical alternans (Fig. 15.1). An urgent echocardiogram shows increased respirophasic variation across mitral and tricuspid valves (Fig. 15.2a, b).

The patient is admitted to the hospital for further evaluation and management. Over the course of the admission, the patient becomes gradually confused. Laboratory evaluation reveals evidence of mild renal dysfunction and a mild transaminitis. She now has a heart rate of 108 and her blood pressure is 92/56. She is transferred to the Intensive Care Unit and a pulmonary artery catheter is placed, which notes right atrial tracings showing blunted *y* descent (Fig. 15.3a). She subsequently receives a pericardiocentesis with improvement in hemodynamics (post-pericardiocentesis tracings shown in Fig. 15.3b). The patient improves clinically and subsequently is discharged on an intensified treatment regimen for SLE. A follow-up echocardiogram is scheduled.

Introduction

Anatomy

The myocardium is encased in a relatively rigid and noncompliant sac called the pericardium. The pericardium is formed by two layers. The outer sac, called the fibrous pericardium, is composed of fibrous tissue and encases the inner layer of pericardium and the heart. The inner sac has two layers – called the parietal and visceral pericardium. The parietal pericardium is attached to the internal surface of the fibrous pericardium and is contiguous with the visceral pericardium as it gets reflected on the cardiac surfaces. In between the visceral and the parietal pericardium is the pericardial space. This space

normally contains up to 50 mL of serous fluid to maintain a low friction environment for the myocardium as it contracts and relaxes within the pericardium throughout the cardiac cycle. The pericardium effectively restrains the cardiac chambers to a confined space and due to this pericardial constraint, any change in the volume of one chamber of the heart is reciprocated by changes in other chambers in the opposite direction [1]. It is this complex interaction of pericardial space with the intracardiac chambers that leads to the hemodynamic consequences of pericardial effusions.

Several diseases and complications of invasive procedures may lead to pathologic accumulation of fluid in the pericardial space, which may impact cardiac output. When the accumulation of pericardial fluid interferes with diastolic filling of the heart, hemodynamic consequences associated with varied clinical presentations including tamponade ensue.

Pathophysiology of Tamponade

Pericardial effusion can be classified according to its onset, size, distribution and composition. The onset can be acute, subacute or chronic (>3 months). The size is based on echocardiogram assessment and is classified as mild (<10 mm), moderate (10–20 mm), or large (>20 mm). Pericardial fluid (exudate, transudate or blood) may distribute in a circumferential or loculated fashion. A variety of different processes can cause pericardial effusion which may eventually lead to cardiac tamponade. Some of these etiologies include malignancy, acute pericarditis, trauma, uremia, iatrogenic, idiopathic, post-acute myocardial infarction, other causes (infection, collagen vascular disease, radiation, heart failure, hypothyroidism).

Progression of a pericardial effusion to tamponade depends on several factors. These include the rate of fluid accumulation, tensile properties of the pericardium, intracardiac pressures, and tensile properties of the myocardium. Ultimately, it is the intrapericardial pressure and its interaction with intracardiac pressures (transmural pressure) that determines the presence of tamponade.

$$\text{Transmural pressure} = \text{intracardiac pressure} - \text{intrapericardial pressure}$$

When the intrapericardial pressure equalizes or exceeds that of the intracardiac chambers, the transmural pressure is then <0, and impaired filling occurs. In patients with pericardial effusions, negative transmural pressure is more often due to increased pericardial pressure but decreased intracardiac pressures also contribute to the development of tamponade.

In cardiac tamponade, increased pericardial pressure from fluid accumulation leads to compression of the cardiac chambers. Hemodynamics of the left and right heart chambers are greatly influenced by each other, which is commonly known as ventricular interdependence. During inspiration, intrathoracic pressure decreases which gets transmitted through the pericardium to the right side of the heart and pulmonary vasculature, causing increased venous return to the right heart. Normally, the free wall expands to accommodate the increased venous return; however, in cardiac tamponade, the free wall cannot expand properly. Hence, the interventricular septum bulges toward the left ventricle to allow right-sided filling, thereby reducing left ventricular compliance and filling during inspiration.

Determinants of intrapericardial pressure include the volume of pericardial fluid and the compliance of the pericardium. The relationship between the size of the effusion and the associated increase in pressure is not linear and is modified by the compliance of the pericardium itself. As such, a larger but chronic effusion might be better tolerated than a smaller but rapidly accumulating one, due to a higher pericardial compliance that develops in the chronic setting (Fig. 15.4). Therefore, the size of the effusion should not be used as a sole criterion for the presence of tamponade.

Progression of a pericardial effusion to tamponade also depends on the intravascular volume status of the patient as well as the compliance of the myocardium. Patients who are intravascularly depleted are more likely to present with compromised hemodynamics due to diminished filling pressures in the cardiac chambers. On the

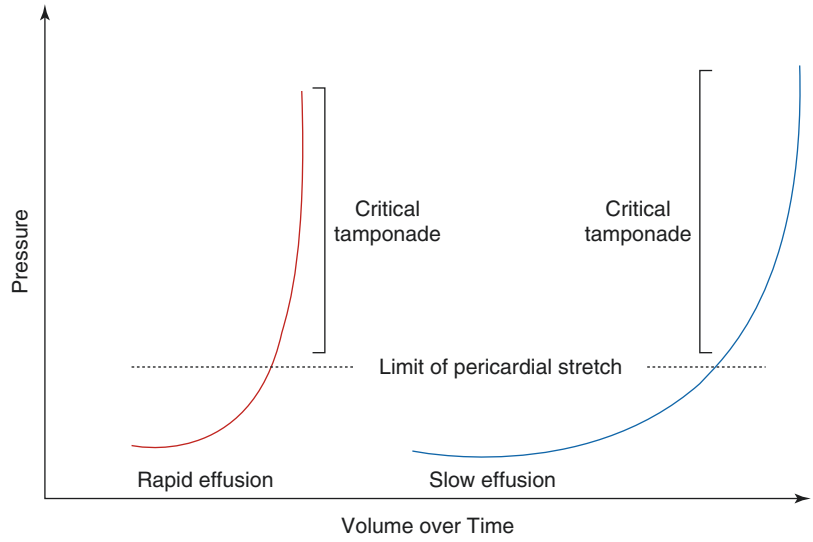

Fig. 15.4 Intrapericardial pressure that is critical in determining the transmural pressure is affected by the time course of fluid accumulation. Rapidly developing effusions reach the limits of the pericardial stretch sooner, whereas slowly developing effusions are better tolerated due to the time allowed for the pericardium to adapt to the changes imposed by the effusion. (Adapted from Spodick [10])

contrary, those with ventricular hypertrophy or restrictive heart disease may not present with tamponade physiology for a given intrapericardial pressure as this pressure is not readily transmitted to the intracardiac chambers due to the diminished compliance of the myocardium.

Table 15.1 Three stages of tamponade

1. Pre-tamponade: no clinical evidence of tamponade as transmural pressure >0; however exaggerated tricuspid and mitral inflow patterns noted
2. Early tamponade: right-sided chambers are affected as the pericardial pressure increases. Clinical presentation might become apparent
3. Tamponade: both right and left-sided chambers are affected as there is equalization of pressures with pericardium. Clinical tamponade is evident

Stages of Pericardial Tamponade

Pericardial tamponade was previously thought of as an "all or none" clinical disorder [2]. However, it is now recognized that patients might present at different stages along the spectrum of tamponade physiology (Table 15.1). The first stage (pre-tamponade) occurs when the pressure in the pericardium is less than right and left ventricular end diastolic pressures (transmural pressure still >0). In this stage, the effusion does not have a clinically significant hemodynamic impact; however, there may be subtle changes in echocardiographic respiratory flow variation across mitral and tricuspid valves and minimally increased pulsus paradoxus pressure (<10 mmHg). In the second stage, the pericardial pressure equals the right ventricular diastolic pressure leading to collapse of the right ventricle during early diastole. In this case, while there is no collapse in the left ventricle, clinical and hemodynamic evidence for tamponade is present with decrease in right ventricular stroke volume. Hypotension, compensatory tachycardia, and elevated pulsus paradoxus might be present. Finally, the most severe stage presents when left ventricular filling is also affected by the increased pericardial pressure. In this case, there is equilibration of pericardial, right ventricular and left ventricular diastolic pressures leading to severely impaired filling of the ventricles and low stroke volume (Fig. 15.5) [3]. Patients in the final stage of tamponade require expeditious diagnosis with direct intervention to drain the pericardial fluid and reestablish hemodynamic stability.

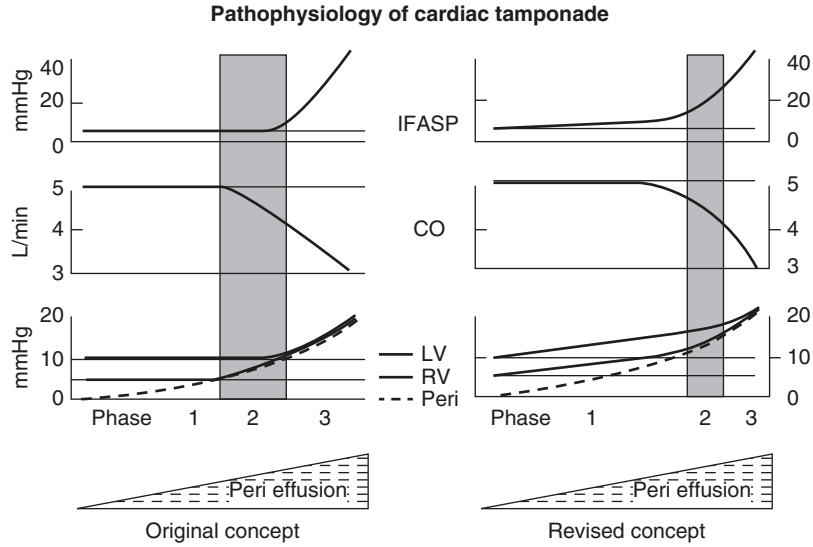

Fig. 15.5 Stages of pericardial tamponade showing pressures in the right atrium, right ventricle, pulmonary capillary wedge pressure, and intrapericardium (peri pericardium, RV right ventricle, LV left ventricle, CO cardiac output, IFASP inspiratory decrease in arterial systolic pressure). Initial concept and its revision with further data are shown below detailing changes in the pressures across stages of tamponade. (Adapted from Reddy et al. [3])

Low-Pressure Tamponade

This condition has been described as a form of tamponade in which relatively low intrapericardial pressure causes cardiac chamber compression in patients with low diastolic pressures (6–12 mmHg). Reported to be present in 20% of patients with tamponade physiology, this condition might be associated with hypovolemia and/or vasodilator and diuretic use [4]. Overall, findings from pulmonary artery catheterization are similar, with equalization of diastolic pressures noted, albeit at lower pericardial and diastolic pressures. Characteristic respiratory fluctuations in transvalvular diastolic Doppler flows are also typically noted. Given the low pressures, patients might not present with typical physical examination findings (elevated JVD, tachycardia); however, they do benefit from pericardiocentesis [4]. When evaluating a patient with a pericardial effusion and hypotension, this clinical entity should be kept in mind.

Diagnosis

Physical Exam Findings

While physical exam might vary in patients with tamponade, there are certain classic findings as defined by Dr. Claude Beck in 1935: low blood pressure, jugular venous distention, and muffled heart sounds. While all three might not be present even in the most advanced cases of tamponade, hypotension and tachycardia, with a narrow pulse pressure, should alert the clinician to its presence.

Pulsus Paradoxus

Originally described by Kussmaul in 1873, pulsus paradoxus is defined by a $\geq$ 10–12 mmHg or a > 9% decline in arterial systemic pressure with inspiration [5]. While the etiology of this drop is debatable, the most widely accepted explanation has to do with intrathoracic pressure changes with

inspiration and the fact that the total volume within the pericardium is fixed. Intrapericardial pressure normally ranges from −5 to +5 cm of water and fluctuates significantly with respiratory cycle. The drop in the intrathoracic pressure with inspiration is transmitted to the pericardium and the right atrium which results in increased venous return to the right side of the heart. The opposite occurs in the left heart, where there is diminished filling of the left ventricle in early inspiration and slightly reduced systemic stroke volume. The reverse is true in expiration: As the intrathoracic pressure increases, the right-sided filling diminishes resulting in improved filling of the left ventricle leading to a higher systemic stroke volume. In a normal individual, these respiratory changes result in a 3–4 mm change in systolic pressure as measured peripherally. When there is a hemodynamically significant tamponade, however, there is interventricular dependence of LV and RV, which leads to exaggeration of the above-described pressure changes with respiration. This is due to the fixed space that the myocardium is constrained within as the increased filling of the RV compromises the filling of the LV, which subsequently leads to the diminished systemic stroke volume with the next contraction. As the underfilled LV cannot generate the normal stroke volume, the blood pressure drops >10 mmHg, which is recognized as pulsus paradoxus on physical exam.

While checking for the presence of pulsus paradoxus allows for quick assessment of patient at the bedside, several coexisting conditions might diminish the accuracy of this test. In patients who have lung disease and shock, pulsus paradoxus might already be present without tamponade. Also, this finding might be absent despite a hemodynamically significant tamponade in the presence of coexisting LV dysfunction with elevated LVEDP, severe aortic insufficiency, pulmonary hypertension, and right ventricular hypertrophy [6, 7].

ECG Findings

Sinus tachycardia, low QRS voltage and electrical alternans are possible ECG findings in tamponade. Sinus tachycardia is the most common finding as heart rate increases to help maintain cardiac output. The amplitudes of the QRS complexes can be low as the fluid collection between the heart and the recording electrodes have a damping effect. Electrical alternans is a phenomenon where QRS complexes alternate in height as the heart swings back and forth within a large fluid filled pericardium (Fig. 15.1). This is a relatively specific finding for tamponade; however, it is not very sensitive.

Echocardiographic Findings

Although tamponade is a clinical diagnosis, echocardiographic evaluation of the patient is a very useful adjunct as it provides direct visualization of the pericardium, the cardiac chambers, and early hemodynamic signs of tamponade physiology. Several echocardiographic parameters may be used to evaluate for evidence of tamponade including M-mode, Doppler interrogation, and 2D visualization. While 2D and M-mode provide visual confirmation of the effusion and the collapse of chambers, Doppler evaluation can be useful in determining the abovementioned flow variations in tamponade (Table 15.2).

Exaggerated diastolic right atrial free wall collapse and diastolic right ventricular outflow tract collapse are early signs of elevated intrapericardial pressure. Brief inversion of the atrial wall can be seen during atrial contraction and does not represent tamponade physiology. Prolonged atrial wall inversion (>1/3 of cardiac cycle) is more indicative of increased intrapericardial pressures. The right ventricular outflow tract is the most easily compressible component of the right ventricle, and may also be affected early

Table 15.2 Evidence of tamponade on echocardiogram

Presence of an effusion. Size, while predictive, is not a reliable determinant of clinical tamponade
Early diastolic collapse of right ventricle
Late diastolic right atrial inversion
Dilated inferior vena cava (>2.5 cm) with failure to collapse of the vessel with inspiration >50%
Respiratory inflow variations across the tricuspid valve (>40%) and the mitral valve (>25%)

Table 15.3 Typical order of findings in tamponade

Tricuspid inflow variation with respiration increased
Mitral inflow variation with respiration increased
Right atrial exaggerated late diastolic collapse (sensitive, nonspecific finding on echocardiogram)
Right ventricular outflow tract collapse (specific finding on echocardiogram)
Right ventricular free wall collapse
Left ventricular free wall collapse

from elevated intrapericardial pressure. As the intrapericardial pressure increases, the right ventricular free wall may also collapse in diastole. Collapse of these above right-sided chambers is indirect evidence that the intrapericardial pressure has exceeded the intracardiac pressures, leading to the inversion of the free walls [1]. As tamponade progresses, further collapse of the left ventricle can also be seen due to similar mechanisms (Table 15.3). Both 2D and M-mode techniques may be used to identify these anatomic manifestations of tamponade.

Doppler evaluation is very helpful in assessing the hemodynamic impact of the pericardial effusion. Outflow across aortic and pulmonary valve (Velocity Time Integral) and inflow across mitral and tricuspid valves (peak velocity) can be measured. In a normal patient, these parameters of flow demonstrate minimal respiratory variation, with the pulmonic and aortic valve velocity time integral varying <10% and the mitral and tricuspid valve peak inflow velocities varying <15% and <25%, respectively. In patients with tamponade, however, respiratory variation across the mitral valve is usually >25% and that across the tricuspid valve >40% (Fig. 15.6). This exaggerated variation in flow across valves provides indirect evidence for ventricular interdependence and suggests a hemodynamically significant effusion.

Also helpful, although often ignored, is the Doppler flow pattern of the hepatic vein. The hepatic vein flow pattern reflects the venous pressure. The normal hepatic vein flow has three major waves: positive systolic and diastolic flows (toward the atrium) and a negative flow corresponding to the atrial contraction (away from the atrium). The systolic flow wave corresponds to the *x* descent and the diastolic flow wave to the *y* descent. In patients with tamponade physiology, blood enters the right atrium only or mostly during ventricular systole. This is reflected in the hepatic vein flow as a predominant systolic wave with decreased or even absent diastolic flow wave (i.e., corresponding to blunted *y* descent on the RA tracing). After pericardiocentesis, the diastolic flow is reestablished (Fig. 15.7).

Pulmonary Artery Catheter Findings

While not routinely used for diagnosis, insertion of a pulmonary artery catheter may provide insight into the pathophysiology of tamponade as it can help clarify the diagnosis.

The cardinal finding on PA catheterization during tamponade is diastolic equalization of pressures of the right atrium, RV diastolic pressure, pulmonary arterial diastolic pressure, and pulmonary capillary wedge pressure. A difference <5 mmHg suffices to establish this equivalency. This pressure is felt to be the passive pressure in the intra-cardiac chambers and should be equal to the intrapericardial pressure in severe tamponade (Fig. 15.8).

As mentioned above, the other abnormal finding is blunted *y* descent following the *v* wave in the right atrial tracing. In tamponade, the *a* wave, *x* descent, and *v* wave remain unaffected as the contraction of the atrium, its relaxation, and rapid filling remain unchanged. The *y* descent, which represents the rapid emptying of the atrium into the right ventricle, is blunted. This is due to the impaired RV relaxation in early diastole due to the effusion-related elevation in RV diastolic pressure. Thus, the rapid emptying of atrium to ventricle, i.e., the *y* descent is blunted (Fig. 15.9). This finding is readily reversed when pericardiocentesis is performed and the intrapericardial pressure is reduced. As the right ventricle is able to relax more efficiently, there is improved flow from the atrium to the ventricle hence a normalized *y* descent.

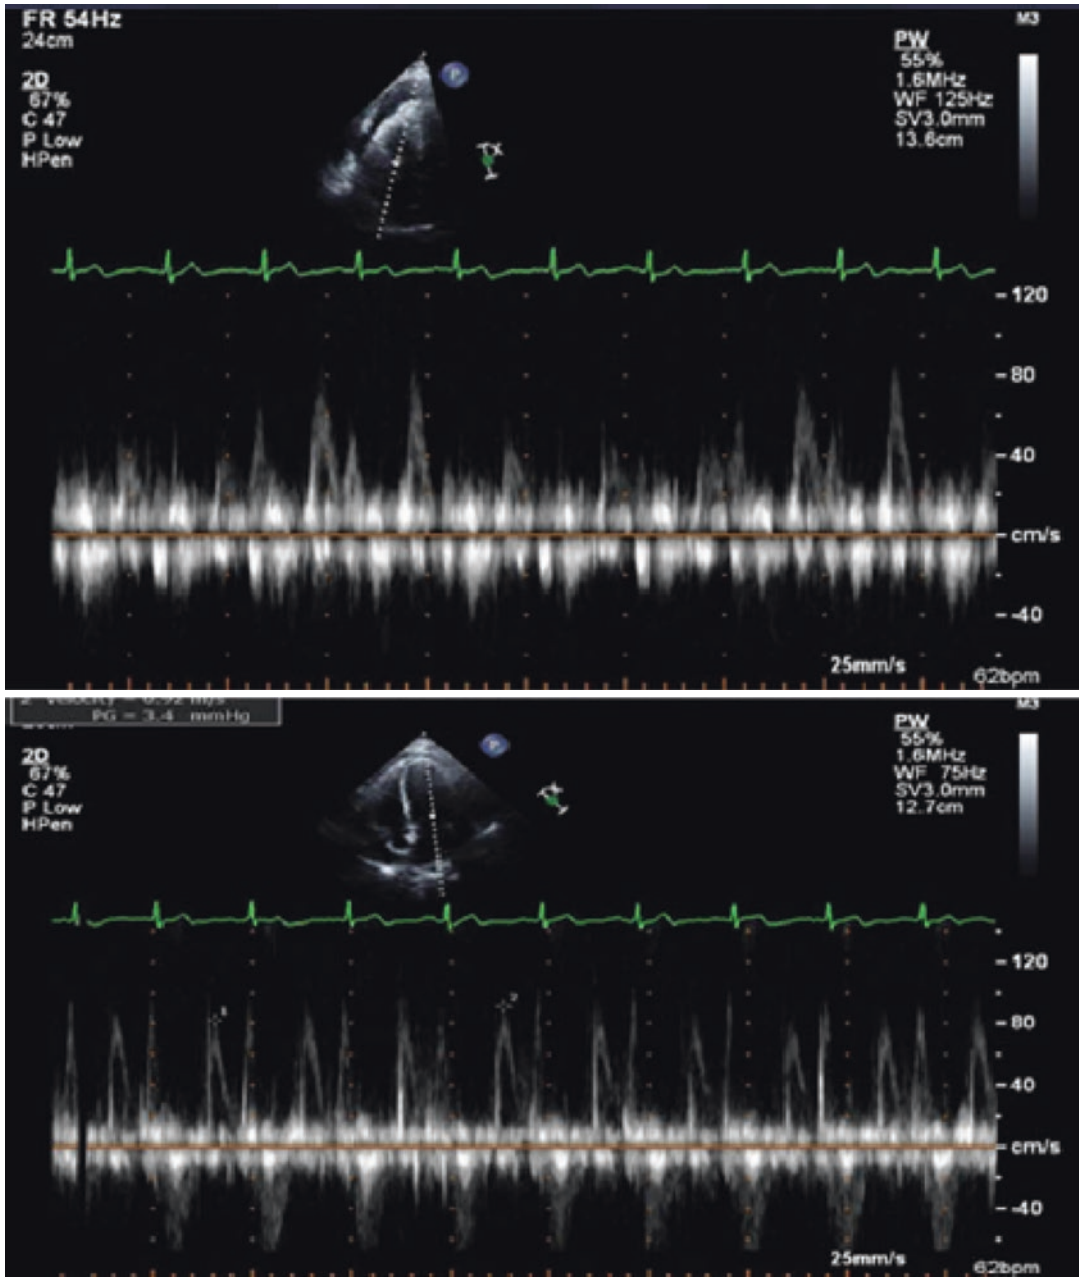

Fig. 15.6 *Top panel* showing tricuspid and *bottom panel* showing mitral valve inflow pattern

Distinction from Constriction

Intrathoracic pressures and changes during inspiration are readily transmitted to the pericardium and the intracardiac chambers in the case of a pericardial effusion with a relatively normal pericardium. In patients who have constrictive pericardium, these pressures are not transmitted, which as a result leads to differences in physical exam and invasive hemodynamic findings. Constriction is notable for lack of decreased right-sided pressure with inspiration, leading to the Kussmaul's sign, a finding not seen in

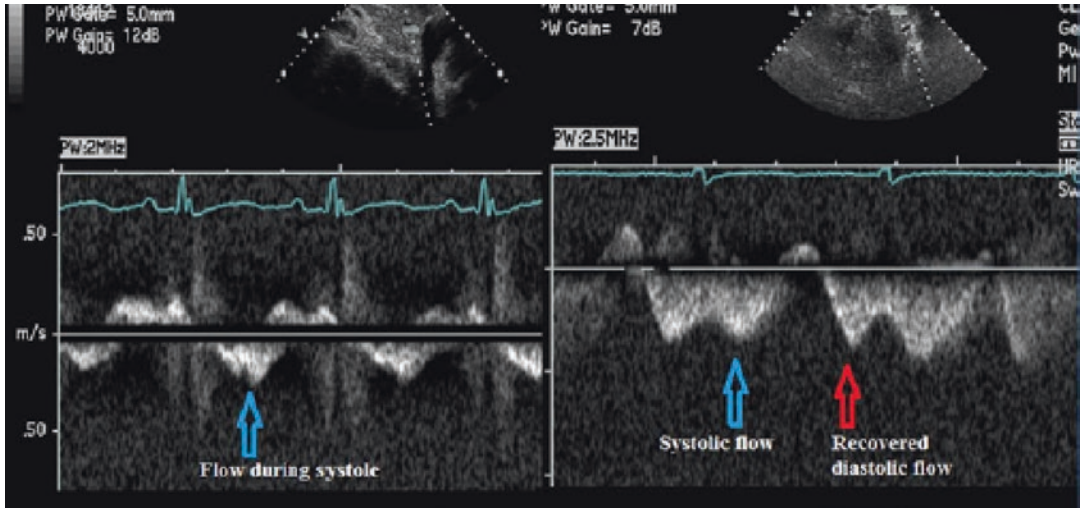

Fig. 15.7 Hepatic vein tracing showing flow to the atrium predominantly during systole and blunted return in diastole. After pericardiocentesis, flow to atrium during diastole is recovered

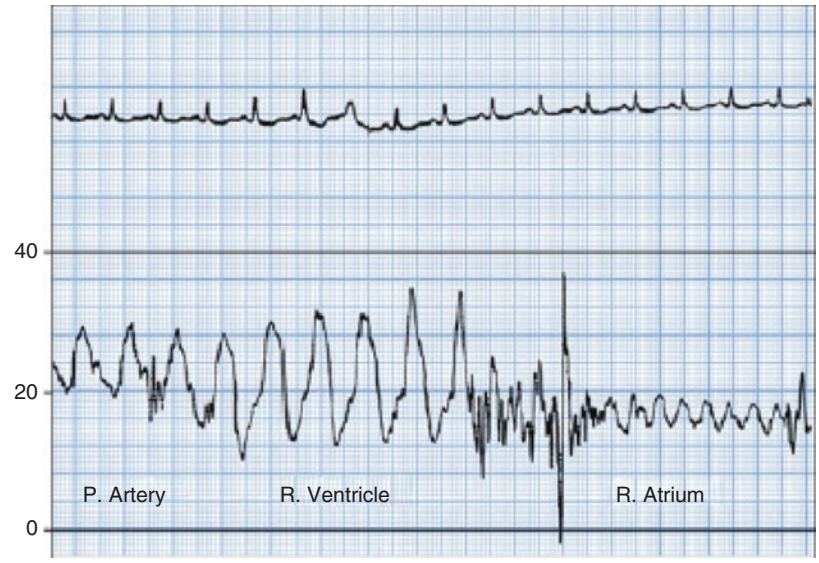

Fig. 15.8 Diastolic equalization of right atrial (mean), right ventricular end diastolic, pulmonary arterial diastolic pressures demonstrated as the PA catheter is pulled back from the pulmonary artery

tamponade. Furthermore, in patients with constriction, there is rapid ventricular filling in early diastole, which is recognized as a prominent *y* descent with a "dip and plateau" appearance (square-root sign) on pulmonary artery catheterization. Such is not the case for tamponade where ventricular filling in early diastole is in fact impaired leading to a blunted *y* descent.

Computed Tomography and Magnetic Resonance Imaging

Advanced imaging such as CT and MRI may be useful to evaluate chronic pericardial effusions but should not be used in the setting of tamponade.

Pericardial effusion might be incidentally diagnosed with these imaging modalities. CT

Fig. 15.9 Right atrial pressure waveform with blunted *y* descent

findings of tamponade include enlargement of the inferior vena cava (IVC) with possible reflux of contrast material within the IVC, enlargement of the vena cava, reflux of contrast material within the azygous vein, flattening of the anterior surface of the heart, and enlargement of hepatic and renal veins [8]. These findings are not specific but collectively can suggest tamponade.

When cardiac tamponade is suspected, clinical assessment of the patient should be performed. In the event that there is a question of tamponade, hemodynamic assessment with a focused physical exam and echocardiography should not be delayed. MRI, in fact, can provide further hemodynamic information in these patients; however, when tamponade is suspected, testing and treatment should not be delayed for performing this test.

Pericardial Tamponade in the Postsurgical Patient

While most effusions seen in clinical practice are circumferential, loculated effusions may be seen in postoperative settings and post trauma. Chronic effusions, though initially circumferential, might organize into loculated effusions as well. In this setting, the aforementioned discussions about hemodynamics might not hold true. There may be focal compression of a cardiac chamber that might only be visible by 2D echocardiography. Doppler findings are also less helpful in postsurgical effusions; it is not uncommon to see exaggerated respiratory flow variation even in patients with small effusions. This may be due to increased respiratory effort secondary to pleural effusions or abnormal respiratory dynamics. When a case of focal tamponade is suspected, the clinical status of the patient and location of the effusion should be carefully assessed for further management.

Management

Patients who present with clinical tamponade should be treated emergently. While preparing the patient for removal of the pericardial fluid, intravenous administration of fluids to maintain adequate perfusion pressure is necessary. The administration of fluids improves the intracardiac filling and might stabilize the patient's hemodynamics by increasing the transmural pressure. Either a pericardiocentesis or a pericardial window might be necessary to resolve the compression of the cardiac chambers. Typically anterior,

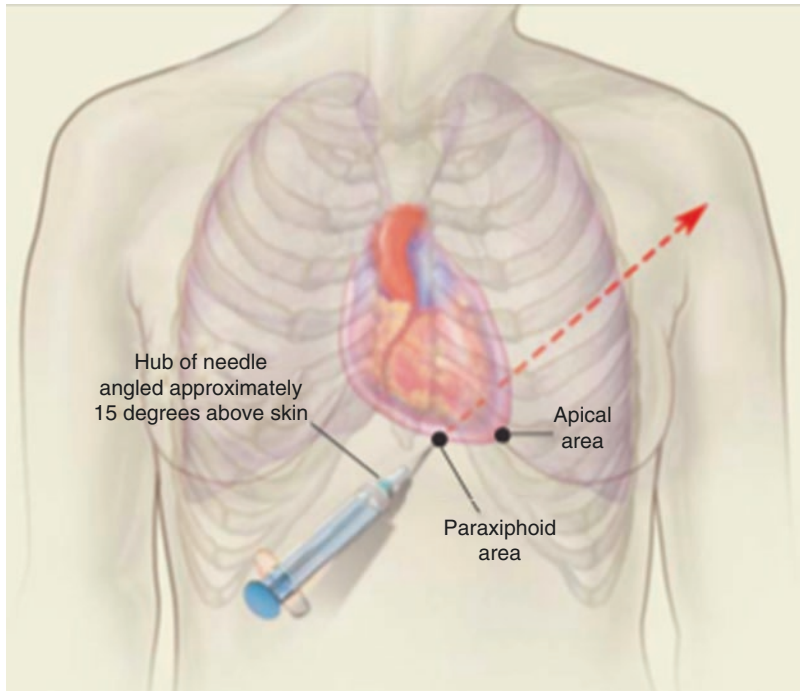

Fig. 15.10 Pericardiocentesis can be performed using paraxiphoid approach where the needle is inserted between xiphoid process and left costal margin at a 15° angle above the skin. In apical approach, the needle is inserted 1–2 cm lateral to the apex within the fifth, sixth, or seventh intercostal space. (Adapted from Spodick [10])

lateral, and apical effusions might be drained by a percutaneous approach; however, surgical drainage is preferred for postoperative patients, loculated, and posterior effusions. The risks and benefits of both approaches in conjunction with the clinical scenario should be taken into account (Fig. 15.10).

Pearls of Assessment

- Pericardial tamponade is a clinical diagnosis.
- Tamponade occurs when transmural pressure is <0.
- When tamponade is in question, all measures for accurate diagnosis and stabilization of the patients should be undertaken.
- Echocardiography is the primary modality to establish the presence of an effusion and support the clinical diagnosis of tamponade.
  - Right atrial and/or ventricular wall inversion.
  - Increased respiratory variation in mitral and tricuspid flows.
  - IVC plethora – dilated IVC with blunted diastolic hepatic vein flow is the most sensitive early echocardiographic finding in tamponade. This may be absent in patients with low-pressure tamponade.
- Pulmonary artery catheterization might be useful to confirm the clinical suspicion in select cases.

Board-Style Questions

1. A 72-year-old man presents with exertional dyspnea and work up including an echocardiogram shows a large pericardial effusion. Which of the following is more specific sign of tamponade?
   A. Systolic flow reversal in hepatic veins
   B. Early diastolic collapse of right atrium
   C. Diastolic collapse of right ventricle
   D. Hypotension in a patient with pericardial effusion
   E. Presence of a large pericardial effusion

2. A 67-year-old female with morbid obesity and rheumatoid arthritis presents with hypotension of unclear etiology. An echocardiogram is performed; however, parasternal and apical windows are difficult to interpret due to body habitus, but there is a moderate circumferential pericardial effusion. Best Doppler hemodynamics are only obtained in the subcostal views. What's expected in the hepatic vein flow pattern in the setting of tamponade?
   A. Diminished forward flow during systole
   B. Diminished forward flow during diastole
   C. Flow reversal during systole
   D. Hepatic vein flow pattern is not expected to change with tamponade
   E. Exaggerated forward flow during diastole
3. Which of the following is not a part of Beck's triad?
   A. Muffled heart sounds
   B. Hypotension
   C. Elevated JVD
   D. Kussmaul's sign
4. A 39-year-old female with a history of tuberculosis as a child presents with pitting peripheral edema and increased fatigue. Echocardiographic evaluation shows pericardial thickening with a moderate effusion. Her heart rate is 102 and blood pressure is 94/64. Which of the following can be helpful in distinguishing tamponade from constriction?
   A. Presence of a pericardial effusion
   B. Absence of Kussmaul's sign
   C. Pericardial thickening seen on CT
   D. Exaggerated flow across tricuspid valve during inspiration
   E. None of the above
5. What's the initial treatment strategy in a hypotensive and tachycardic patient with a pericardial effusion if tamponade is suspected?
   A. Pericardiocentesis
   B. IV fluid infusion
   C. Inotrope infusion
   D. Consultation with cardiothoracic surgery for a pericardial window
   E. Beta blocker administration

Answers to Board-Style Questions

1. Correct answer is C. Systolic flow reversal in hepatic veins is seen in severe tricuspid regurgitation. While options other than C can be seen in tamponade, they are not specific to tamponade.
2. Correct answer is B. Diastolic forward flow is expected to be reduced in the hepatic veins due to elevated right ventricular pressures. Other options do not apply in tamponade.
3. Correct answer is D. Beck's triad consists of muffled heart sounds, hypotension, and elevated neck veins.
4. Correct answer is B. Other options can be seen with both conditions; however, Kussmaul's sign is specific to constriction and is not seen with tamponade.
5. Correct answer is B. An unstable patient in tamponade needs to be fluid repleted emergently in attempt to overcome the pericardial pressure. Further treatment modalities might include pericardiocentesis or a surgical window placement. Beta blockers are contraindicated in compensatory tachycardia.

Constructive Pericarditis and Restrictive Cardiomyopathy

16

Chun Pong Wong and Allan Klein

Introduction

Despite being different disease processes, constrictive pericarditis (CP) and restrictive cardiomyopathy (RCM) are often discussed together due to their similar clinical and hemodynamic features. Physiologically, both processes lead to diastolic dysfunction but mechanisms are different; a rigid, adherent pericardium is noted in constriction while abnormal myocardium is the culprit in restriction. CP is usually a chronic process, and variant forms do exist (effusive-constrictive, subacute, transient, occult) which share many of the clinical findings, but have subtle clinical differences that distinguish each type. In RCM, the pericardium is merely normal, and the pathological process occurs in the myocardium which is often associated with infiltrative diseases such as amyloidosis, hemochromatosis, sarcoidosis, etc. Given the spectrum of disease and the various clinical manifestations of CP and RCM, initial history and physical examination along with hemodynamic considerations and newer non-invasive imaging criteria now lead the way in making the diagnosis. However, using all available data in distinguishing between the two diseases becomes important, as the treatment is very different.

Pathophysiology

Constrictive Pericarditis

Constrictive pericarditis is a form of diastolic heart failure caused by an inelastic pericardium that inhibits cardiac filling. Because its treatment differs markedly from all other forms of heart failure, accurate diagnosis is imperative.

The overall incidence of clinical CP is rare. After an episode of acute pericarditis, only 1.8% of patients have been found to develop chronic CP. The incidence was lower in patients with idiopathic or viral pericarditis when compared with other etiologies such as rheumatologic disease, malignancy, or bacterial infection. In patients after cardiac surgery, the incidence of chronic, symptomatic CP appears to be similarly low, with the reported rates of 0.2–2.4%. It is unknown how often constrictive physiology is detected on imaging in these diseases.

In Europe and North America, most cases are idiopathic, related to prior cardiac surgery or chest irradiation. There are also increasing number of cases of post cardiac injury syndrome especially in patients after invasive cardiac procedures, e.g. cardiac surgery, radiofrequency

ablation for atrial fibrillation, automated implantable cardioverter defibrillator implantation, etc.

However, in other parts of the world, tuberculosis still remains a dominant cause of CP. Other possible causes include connective tissue disease, infection, malignancy, trauma and asbestosis [1].

Hippocrates (c. 460–370 BC) described the normal pericardium as "a smooth mantle surrounding the heart and containing a small amount of fluid resembling urine" [2]. The pericardium, a roughly flask-shaped membranous sac, envelops almost the entire heart except the region of left atrium around the pulmonary venous ostia. It consists of fibrous and serosal component. The outer fibrous sac is composed primarily of collagen fibers with interspersed short elastic fibrils. The serosal component consists of a single layer of mesothelium that forms a parietal and a visceral layer enclosing the pericardial cavity. The parietal layer lines the fibrous pericardium, and together, these structures form the parietal pericardium (Fig. 16.1a, b). The visceral layer is also known as the epicardium and covers the heart (Fig. 16.1c, d). Between the visceral pericardium and the myocardium is a variable amount of epicardial fat. The pericardial cavity normally contains <50 mL of serous fluid which serves as a lubricant during cardiac motion between the adjoining layers to prevent irritation.

The fibrous pericardium is relatively elastic at low volumes but when stretched it becomes rapidly inelastic. The pericardial pressure-volume relationship is non-linear; initially the slope is flat but subsequently becomes very steep, and this also depends on the rate of fluid accumulation (Fig. 16.2). When a scarred or calcified, noncompliant pericardium becomes adherent to various areas on the surface of the heart, in the case of constriction, the cardiac chambers are unable to relax completely during diastole due to extrinsic limits placed by the pericardium. As a result, in the ventricles, mid- and late-diastolic filling occurs earlier in diastole as the constraining force on the ventricle prevents further expansion and filling of the cavity leading to elevation in end-diastolic pressures and decrease in cardiac output. Once identified, pericardial "stripping"/pericardiectomy is the treatment of choice, as medical therapy alone will typically not provide symptomatic relief.

During inspiration, negative intrathoracic pressure is developed (−6 to 0 mmHg), and it is transmitted to the heart via the pericardium and pericardial space of right atrium (RA). This negative pressure results in increased systemic venous return to the right heart as well as augmenting passive filling of the right ventricle (RV). In the presence of a normal pericardium, as the RV fills, the free walls are able to expand and allow for the capacitance of RV. In CP, this process is impeded as the rigid encasement of the ventricles prevents transmission of the negative intrathoracic pressure to the heart. As the stiff outer shell limits capacitance, the RV free walls are unable to expand and accommodate the increased systemic venous inflow during inspiration. This leads to bowing of the septum toward the left ventricle (LV) to accommodate the volume of the RV inflow. The pulmonary venous circulation, which sits outside of the pericardium, behaves similarly to changes in intrathoracic pressure as the systemic venous system, thus leading to changes in LV filling during the respiratory cycle. On inspiration, the pulmonary venous pressure decreases; however, the negative intrathoracic pressure is not transmitted to the LV, leading to decreased flow gradient across the LV and thus limiting LV filling. During expiration, positive intrathoracic pressure reduces systemic venous return leading to decreased RV end-diastolic pressure. Passive filling of the LV now overcomes RV pressure and the interventricular septum shifts rightward into the RV. This phenomenon is known as *ventricular interdependence*; it occurs to a lesser extent in normal physiology but is exaggerated in CP.

Restrictive Cardiomyopathy

Restrictive cardiomyopathy (RCM) is a myocardial disorder that usually results from increased myocardial stiffness leading to impaired ventricular relaxation with restricted filling. Biventricular chamber size and systolic function are usually normal or near normal until later stages of the

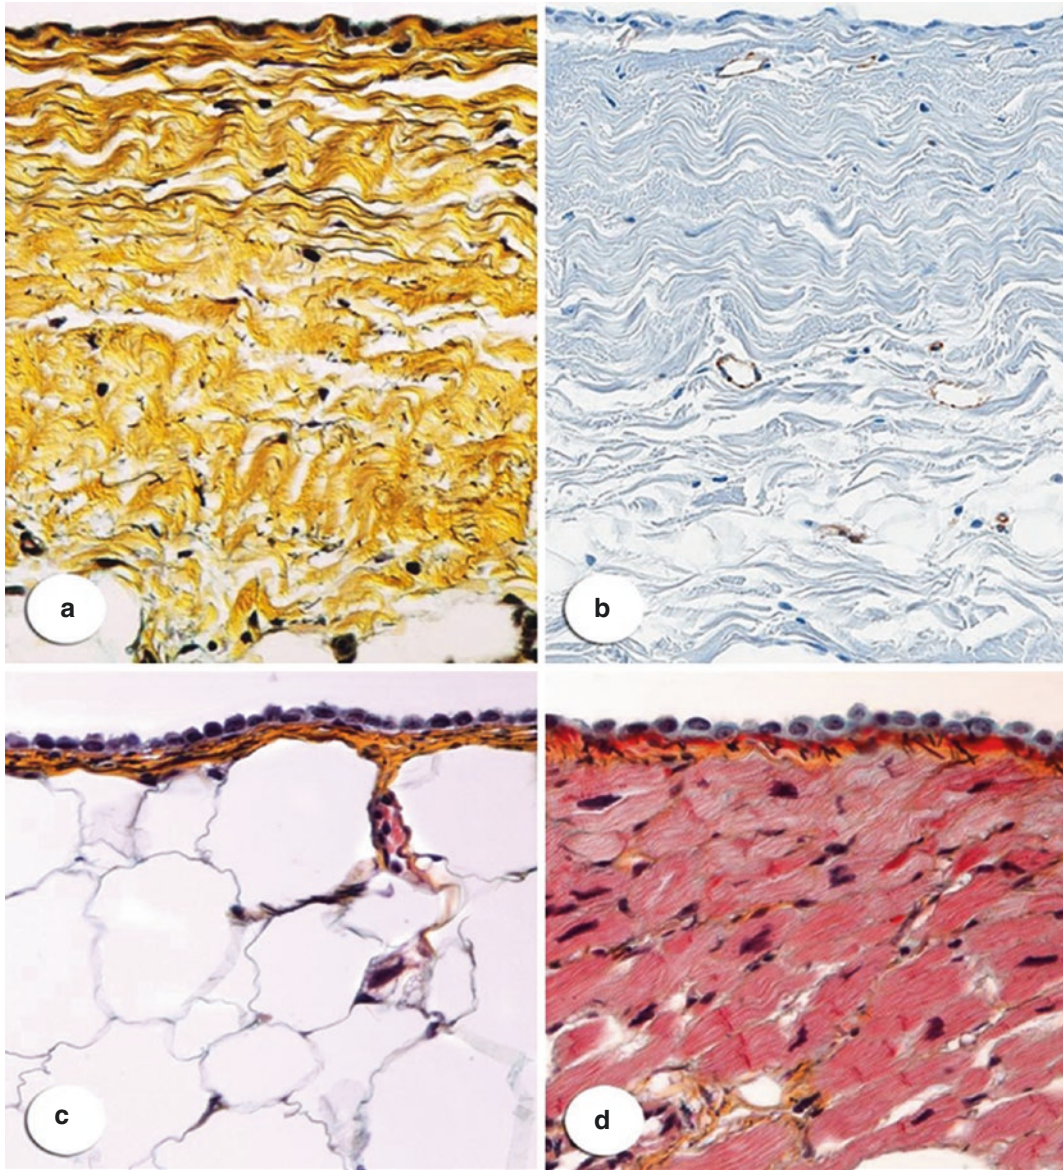

Fig. 16.1 (**a**) Normal, full-thickness parietal pericardium is shown. It consists of a layer of mesothelial cells and compact layers of dense wavy collagen (yellow) with interspersed short elastic fibers (black). (**b**) Fibroblasts with elongated nuclei and scant thin blood vessels are normally present in the parietal pericardium. CD34 immunostaining highlights the endothelial cells of capillaries. (**c**) The visceral pericardium (also called epicardium) consists of a mesothelial cell layer and a thin subepithelial layer of collagen with elastic fibers. The mesothelial cells show distinct microvilli. Beneath the visceral pericardium is epicardial adipose tissue. (**d**) In other areas of the visceral pericardium (or epicardium), only a thin layer of fibrous tissue (yellow) separates the mesothelial cells from the myocardium with absence of epicardial fat. Original magnifications 400×; (**a**, **c**, and **d**): Movat pentachrome stain; (**b**): CD34 immunoperoxidase. (From Klein et al. [9])

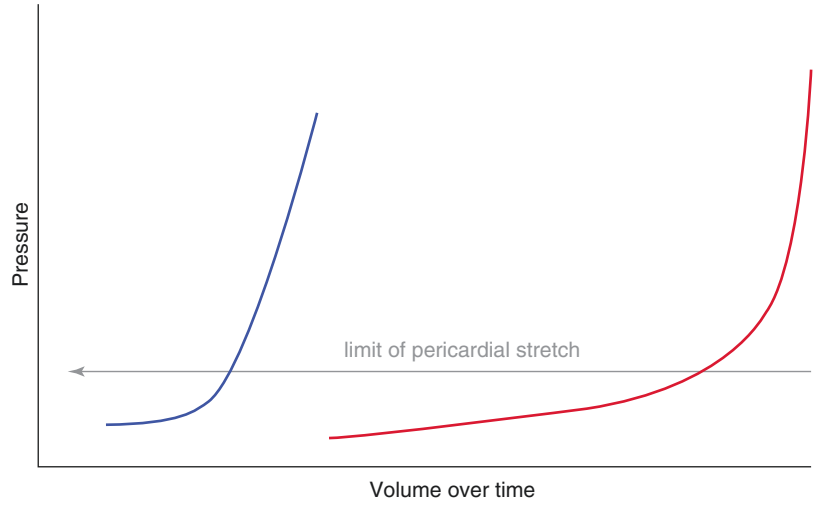

Fig. 16.2 Pericardial pressure-volume curves are shown in which the volume increases slowly or rapidly over time. (Blue curve) Rapidly increasing pericardial fluid first reaches the limit of the pericardial reserve volume (the initial flat segment) and then quickly exceeds the limit of parietal pericardial stretch, causing a steep rise in pressure, which becomes even steeper as smaller increments in fluid cause a disproportionate increase in the pericardial pressure. (Red curve) A slower rate of pericardial filling takes longer to exceed the limit of pericardial stretch, because there is more time for the pericardium to stretch and for compensatory mechanisms to become activated

disease. Affecting either or both ventricles, RCM may cause signs or symptoms of left and/or right heart failure. There may be associated arrhythmias and conduction disturbances. RCM may result from inherited or acquired predispositions and disease or a combination; thereof, which broadly can be classified as infiltrative, storage disease, non-infiltrative, and endomyocardial. Histologically, the infiltrative disorders are associated with deposits in the interstitial space between myocytes, while storage disorders focus primarily on accumulation within the cardiac myocytes. Due to the heterogenous nature of the origins and manifestations of RCM, and the concomitant challenges in diagnosing these diseases, the incidence and prevalence of RCM cannot be accurately estimated.

RCM can also be classified as genetic/familial or non-genetic/non-familial. Familial RCM is often characterized by autosomal dominant inheritance, which in some families is caused by mutations in the desmin gene; in others, familial RCM is associated with conduction defects, caused by mutations in the desmin gene, usually associated with skeletal myopathy. Rarely, familial cases can be associated with autosomal recessive inheritance, e.g. hemochromatosis or glycogen storage disease, or with X-linked inheritance, e.g. Fabry disease [3].

RCM is the least common type of cardiomyopathies [4]. The pericardium and pericardial compliance are normal in pure restrictive cardiomyopathies; however, depending on the cause (e.g. radiation), features of both restriction and constriction can coexist.

Pathophysiologically, the increased stiffness of the LV leads to rapid changes in LV pressure with incremental volume increases. This leads to the characteristic hemodynamic "dip-and-plateau" filling pattern, due to rapid early diastolic filling (dip) and cessation or diastasis of flow in mid- and late-diastole (plateau).

Evaluation

History/Clinical Presentation

Distinguishing between constriction and restriction is often difficult due to similar presenting

symptoms and physical findings. However, there are subtle findings in the history and physical examination that can help to differentiate which process is responsible for the patient's symptoms. The history should be aimed at elucidating any etiologies for either constriction or restriction. For example, an antecedent history of cardiac trauma, cardiac surgery/procedure, or pericarditis would favor constriction, while a prior history of infiltrative or glycogen storage diseases, e.g. amyloidosis, sarcoidosis, or hemochromatosis, suggests restriction. More importantly, a history of radiotherapy especially mantle radiation can lead to symptoms via a myriad of physiological processes including constriction, restriction, pulmonary fibrosis, as well as valvular heart disease. Patients will present with a varying degree of symptoms depending on how advanced the disease process is. Dyspnea on exertion or at rest, edema (lower extremity, ascites, and effusions), pulmonary congestion, and eventually symptoms of low cardiac output are noted in both processes. Late stages of both are heralded by severe heart failure. Table 16.1 lists the different etiologies of CP and RCM.

Physical Examination

Most patients with CP and RCM have elevated jugular venous pressure (JVP). Kussmaul's sign is a paradoxical rise in JVP on inspiration, or a failure in the appropriate fall of the JVP with inspiration. Due to the inability of the RA to accommodate increased venous return, JVP paradoxically increases with inspiration. Kussmaul's sign can be seen in both conditions; however, it is more common in CP. A steep/rapid *Y*-descent of the JVP, i.e. Friedreich's sign, along with peripheral edema, ascites, hepatic congestion, and pleural effusions can also be seen in both conditions as the markers of right-sided heart failure. Physical findings suggestive of CP are the presence of a pericardial knock which occurs at the nadir of the Y-descent and is the diastolic gallop usually heard before S3 consistent with abrupt cessation of ventricular filling; friction rub if active pericarditis; and apical retraction which is secondary to the inability to transmit a palpable ventricular impulse due to a calcified pericardium. An audible S3 and prominent apical impulse are more indicative of restriction. Pulsus

Table 16.1 Causes of constrictive pericarditis and restrictive cardiomyopathy

Constrictive pericarditis	Restrictive cardiomyopathy	
Idiopathic	*Infiltrative*	*Storage diseases*
Viral	Amyloidosis	Fabry disease
Post-surgical	Sarcoidosis	Gaucher disease
Post-radiotherapy	Primary hyperoxaluria	Hemochromatosis
Connective tissue disease	*Endomyocardial*	Glycogen storage disease
Post-MI (Dressler's syndrome)	Carcinoid heart disease	Mucopolysaccharidosis type I (Hurler syndrome)
Post-infectious	Endomyocardial fibrosis	Mucopolysaccharidosis type II (Hunter syndrome)
Uremia	Hypereosinophilic syndrome	Niemann–Pick disease
Sarcoidosis	Chronic eosinophilic leukemia	*Non-infiltrative*
	Drugs (serotonin, methysergide, ergotamine, mercurial agents, busulfan)	Diabetic cardiomyopathy
	Endocardial fibroelastosis	Scleroderma
	Consequence of cancer/cancer therapy	Myofibrillar myopathies
	Metastatic cancer	Pseuxanthoma elasticum
	Drugs (anthracyclines)	Sarcomeric protein disorders
	Radiation	Werner's syndrome

Adapted from Muchtar et al. [4]

paradoxus, which is defined as an abnormal (>10 mmHg) decrease in systolic blood pressure with inspiration, is seen occasionally in CP cases involving pericardial effusion, such as effusive-constrictive pericarditis.

Chest Radiography and Electrocardiography

Pericardial calcification is often seen on chest X-ray and is indicative of CP; however, it is not always present (Fig. 16.8a, b). Cardiomegaly due to biatrial, rather than ventricular enlargement is seen in cases of restrictive cardiomyopathy. Electrocardiography (ECG) findings, such as atrial fibrillation and repolarization abnormalities, are often seen in both conditions, while LV hypertrophy, low voltage QRS, and conduction abnormalities may be a clue to the presence of restriction.

Echocardiography

Echocardiography (TTE) is the first-line and most essential tool in establishing a diagnosis of CP and RCM. In the context of the other diagnostic information, the ability to obtain both anatomic and hemodynamic information is useful in making the diagnosis.

2D and M-Mode

TTE can be used to image the pericardium, regarding the appearance of the pericardium and also the presence of concomitant pericardial effusion. However, measurement of pericardial thickness using TTE is not recommended. Pericardial thickness can also be obtained by transesophageal echocardiography (TEE), though Computed tomography (CT) and cardiac magnetic resonance imaging (CMR) are the gold standard. 2D echocardiography is also useful in assessing atrial and ventricular cavity sizes as well as in characterizing the myocardium. Depending on the etiology, different morphological characteristics can be present, such as thickened myocardium with speckling or a granular pattern which is found in amyloidosis (Fig. 16.3a, b). In RCM, biatrial enlargement, which is less frequent in CP, can be seen on TTE along with a tendency for inter-atrial septal bulging to the right due to increased pressure in the left atrium (LA) as compared to RA (Fig. 16.3b). The characteristic findings of CP on TTE are ventricular septal bounce, myocardial tethering, as well as inferior vena cava (IVC) and hepatic vein plethora. However, ventricular septal shift (VSS) is different from septal bounce. The presence of VSS is defined as any degree of cyclic movement of the ventricular septum toward the left ventricle with inspiration and toward the right ventricle with expiration, which resembles ventricular interdependence. VSS is a sensitive sign of CP with a sensitivity of 93% and specificity of 69% [5]. The features of VSS, septal shudder, and bounce in CP are better appreciated using M-mode imaging due to its high temporal resolution (Fig. 16.4).

Doppler Echocardiography and Tissue Doppler Imaging

Physiologically, both CP and RCM lead to diastolic dysfunction. Information obtained from Doppler echocardiography and tissue Doppler imaging (TDI) has been vital in diagnosing diastolic dysfunction. In additions, TDI information on mitral annular velocities has improved the overall sensitivity and specificity of echocardiography in diagnosing CP while also distinguishing cases of CP from RCM. Doppler has been beneficial by allowing a hemodynamic assessment non-invasively. Specifically, it looks at ventricular filling, i.e., mitral and tricuspid inflow velocities, pulmonary and hepatic venous flow, and especially the respiro-phasic changes brought by CP and RCM in these parameters.

In both CP and RCM, the trans-mitral flow velocity pattern is characteristic of markedly elevated LV filling pressure, i.e. restrictive pattern. The high left atrial pressure (LAP) is associated with high LA–LV gradient at the time of mitral valve opening; therefore, E wave velocity is high, A wave velocity is low, and E/A ratio is high, usually >2.0. However, A wave may not be visible in patients with atrial fibrillation or flutter. Poor LV compliance results in rapid rise of LV

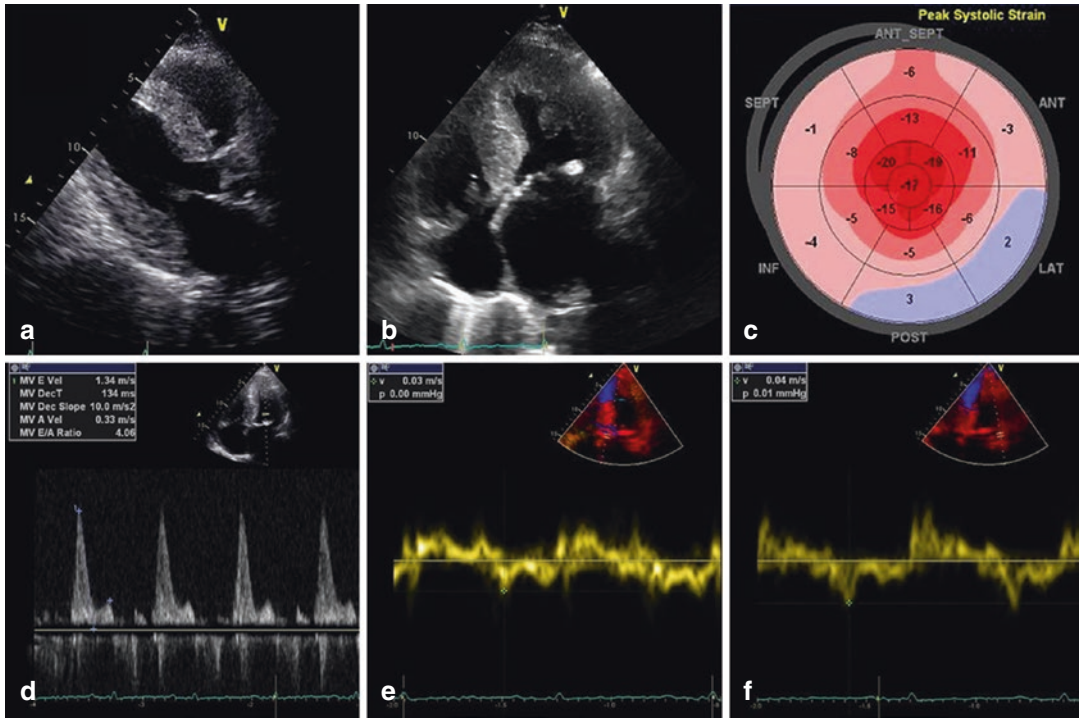

Fig. 16.3 Echocardiography of patient with amyloidosis shows (**a**) thickened myocardium with speckling or a granular pattern and (**b**) biatrial enlargement with inter-atrial septal bulging to the right. (**c**) Global longitudinal strain (GLS) study shows a pattern of apical sparing suggestive of amyloidosis. (**d**) The pulsed wave Doppler study of the mitral inflow shows high E/A ratio of ~4.1 and short deceleration time of ~134 ms. Tissue Doppler imaging (TDI) of mitral annulus shows markedly reduced velocities in both (**e**) septal e' of 3 cm/s and (**f**) lateral e' of 4 cm/s

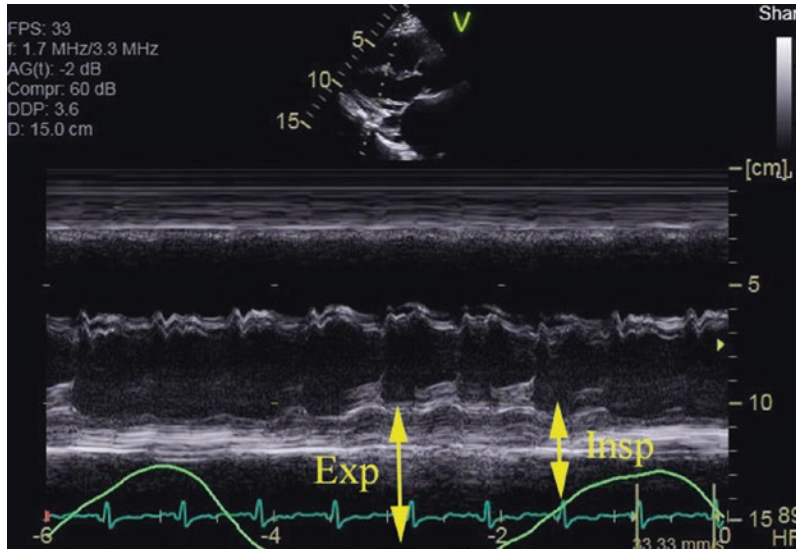

Fig. 16.4 Midventricular septal M-mode recording (parasternal long axis) in a patient with constrictive pericarditis. There is leftward ventricular septal shift in inspiration. Exp indicates expiration and Insp inspiration

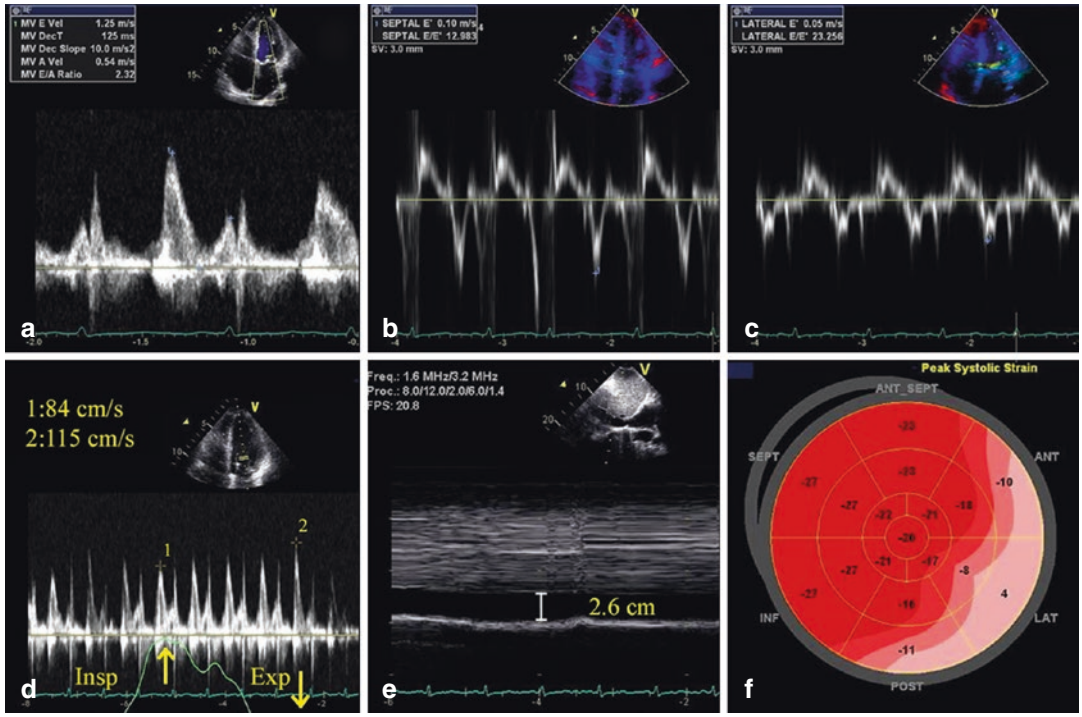

Fig. 16.5 Echocardiography of a patient with constrictive pericarditis. (**a**) The pulse wave Doppler study of the mitral inflow shows high E/A ratio which is ~2.3 and short deceleration time of 125 ms. Tissue Doppler imaging (TDI) of mitral annulus shows "annulus reversus" with (**b**) septal e' of 10 cm/s and (**c**) lateral e' of 5 cm/s. (**d**) There is significant respiratory variation in the mitral inflow [(expiration – inspiration)/expiration; (115–84)/115 × 100% = ~27.0%]. Insp indicates inspiration and Exp, expiration. (**e**) M-mode image shows plethoric inferior vena cava (IVC) with diameter of 2.6 cm and <50% change in diameter during respiration. (**f**) Global longitudinal strain (GLS) study shows LV antero-lateral wall shortening strains were lower than the septal shortening strains

diastolic pressure, which leads to rapid decline of LA–LV pressure gradient. As a result, there is a rapid, early diastolic deceleration of trans-mitral inflow, with shorter than normal deceleration time, i.e., <160 ms (Figs. 16.3d and 16.5a).

Pulmonary artery systolic pressure (PASP), provided pulmonary vascular disease is excluded, can be served as an indirect estimate of LAP and identify patients with increased LV filling pressures. A significant correlation exists between PASP and noninvasively derived LAP. In the absence of pulmonary disease, increased PASP suggests elevated LAP. Calculation of PASP can be done by measuring the peak tricuspid regurgitation (TR) velocity, then applying the modified Bernoulli equation to convert this value into pressure values and adding the estimated right atrial pressure. The American Society if Echocardiography (ASE) recommends the cutoff value for peak TR velocity of >2.8 m/s for diagnosing diastolic dysfunction [5].

TDI of mitral annular velocities have become an integral part of the diastology assessment as well as the diagnosis of CP and restriction. The mitral annular velocity (e′) is measured at the septal/medial and lateral annulus – both of which give information regarding the motion of the annulus with respect to the axis of measurement, i.e., cursor line. These measurements give information about myocardial relaxation and longitudinal motion of the heart, which are affected in CP and restriction. In cases with abnormal relaxation, i.e., restriction, tissue Doppler velocities are predictably reduced (septal e' velocity <7 cm/s or lateral e' velocity <10 cm/s). In RCM, both septal and lateral e' velocities are diminished. In pure CP without myocardial involvement, the septal mitral annulus velocity can be

normal or mildly elevated, i.e., septal e' ≥ 9 cm/s [5]. This is due to the limited lateral expansion of the heart during filling secondary to pericardial encasement which results in a compensatory increase in longitudinal movement of the septum in order to accommodate filling. In patients without pericardial disease, the septal e' is typically lower than the lateral e'. In CP, this relationship reverses; the septal e' velocity is greater than the lateral one, and hence this phenomenon is called "annulus reversus." Tissue Doppler E/e' is a non-invasive estimate of LAP. The ASE guidelines for assessment of diastolic dysfunction recommend using an average of the septal and lateral e' velocities, whereas an average E/e' of >14 indicates elevated LAP [6]. Although LAP is increased in both CP and RCM, E/e' does not increase despite elevated pulmonary capillary wedge pressure (PCWP) in CP, i.e., "annulus paradoxus." However, this only occurs in pure constriction rather than in constriction with myocardial disease [7–8].

The respiratory variation of diastolic inflow velocities across both the mitral and tricuspid valve, i.e., E wave velocities, is different in CP and RCM and can provide compelling evidence for either diagnosis while ruling out other processes. The ASE recommends the calculation of percentage of respiratory variation in CP for mitral and tricuspid inflow as follows:

$$\left(\text{expiration} - \text{inspiration}\right) / \text{expiration} \times 100\%$$

For peak mitral E inflow, the maximal drop occurs with the first beat of inspiration and the first beat of expiration. It usually exceeds 25% respiratory variation (Fig. 16.6d). For peak tricuspid E inflow, the maximal drop is on the first beat in expiration at the same time as the hepatic vein atrial reversal and usually exceeds 40% respiratory variation. The calculated % will be a negative value [9]. These phenomena are manifestations of greatly enhanced ventricular interaction and are not present in either normal subjects or patients with restrictive cardiomyopathy. In restriction, the mitral *E* velocities vary with respiration but to a much lesser degree (usually <10%). These findings can be affected by preload conditions in the LA; an increase in left atrial pressure will diminish the variation with respiration, while volume depleted states will exaggerate it.

Pulmonary and hepatic venous flows represent left and right-sided filling and are also another important measurement in distinguishing constrictive and restrictive physiology. Pulmonary vein systolic flow (*S* wave) is diminished and diastolic flow (*D* wave) is increased irrespective of respiration in restriction. In CP, however, there is increase in both systolic and diastolic flow during expiration as compared to blunted *S* and *D* during inspiration, which is a distinguishing feature (Fig. 16.6).

Hepatic vein flows, designated by *S* and *D* waves can also be used to further identify patients sus-

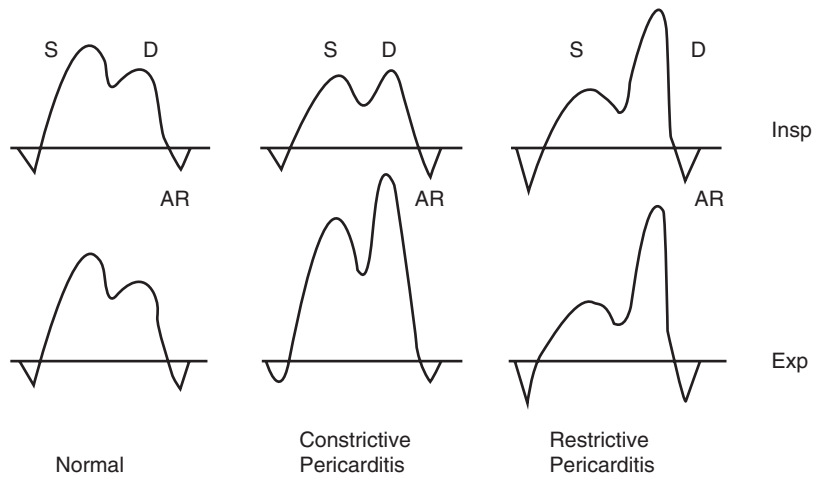

Fig. 16.6 Pulmonary venous flow during different phases of respiration in different conditions. S indicates pulmonary vein systolic flow; D pulmonary vein diastolic flow; AR atrial reversal; Insp inspiration; Exp expiration

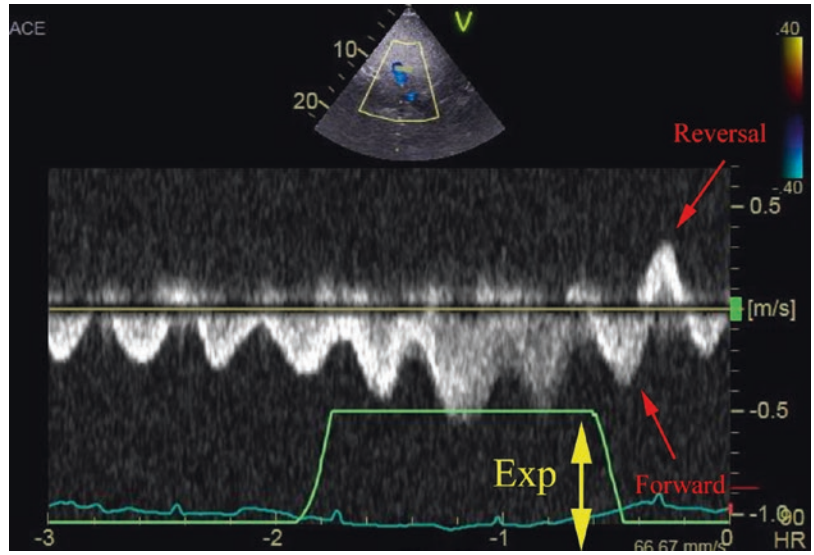

Fig. 16.7 Pulsed-wave Doppler recording (subcostal window) within the hepatic vein in a patient with constrictive pericarditis. Note prominent diastolic flow reversals in expiration, with the diastolic reversal ratio defined as reversal velocity divided by forward velocity (~0.35 m/s reversal velocity divided by ~0.40 cm/s forward flow velocity yields a diastolic reversal ratio of 0.875). Exp indicates expiration

pected of having CP or restriction. Normal patients will have a more prominent *S* wave as compared to the *D* wave; however, there is little to no respiratory variation. In those with CP, there is a significant increase in the diastolic flow, i.e. *D* wave during inspiration and marked blunting during expiration with diastolic flow reversal, whereas restriction patients have an increased diastolic flow, i.e. *D* wave as compared to *S* wave without respiratory variation. However, this is better expressed as the hepatic vein expiratory diastolic reversal ratio, which is defined as follows:

$$\left(\text{diastolic reversal velocity / forward velocity}\right)\text{in expiration.}$$

The finding of a reversal ratio ≥0.79 has a specificity of 88% for CP [5] (Fig. 16.7).

Global Longitudinal Strain (GLS)

Strain in the myocardium can be measured by TDI or speckle-tracking echocardiography (STE). Nowadays, STE is the most widely used strain modality. STE utilizes the phenomenon in which natural acoustic markers in gray scale ultrasound images form interference patterns, i.e., speckles within myocardial tissue. These patterns are quite stable over the short period of time between two consecutive frames, and the 2D displacement for each point in the myocardium is found by automatic search for similar patterns in the two frames (block matching). This process is repeated for all frames through the cardiac cycle to produce a 2D displacement curve for each point in the myocardium. Subsequently, strains are calculated from each LV segment in circumferential, longitudinal, or radial directions [10]. When the information obtained from conventional echocardiography is adequate, GLS is usually not necessary for diagnosis. However, GLS can provide more information in order to exclude other differential diagnosis.

In the cases of RCM, there are often findings of normal or near normal LV systolic function, diastolic dysfunction and left ventricular hypertrophy. The pattern of apical sparing in GLS (Fig. 16.3c) can be an assurance for the diagnosis of amyloidosis in RCM; whereas in hypertrophic cardiomyopathy, myocardial longitudinal deformation is typically reduced at the site of hypertrophy [11]. Due to the tethering of LV free wall in CP, LV septal shortening strains are seen to be higher than the lateral wall shortening strains (Fig. 16.5f), which depends on the location and extent of pericardial calcification. Moreover, the average GLS value is higher in patients with CP than in those with RCM [12].

In distinguishing CP and RCM, Welch TD et al. suggest a relatively simple approach. In the article of the Mayo Clinic diagnostic criteria of constrictive pericarditis, respiration-related ventricular septal shift, preserved or increased septal mitral annular e' velocity, and prominent hepatic vein expiratory diastolic flow reversal are the echocardiographic features which are independently associated with the diagnosis of CP. The presence of VSS with either septal mitral annular e' velocity of ≥9 cm/s or hepatic vein expiratory diastolic reversal ratio of ≥0.79 yields the diagnostic sensitivity of 87% and specificity of 91% for CP [5].

Transesophageal Echocardiography

Given some of the limitations of TTE, TEE may be useful whenever TTE is non-diagnostic or image quality is affected by body habitus or positioning. It can be used in the post-op setting to assess localized effusive-constrictive disease. TEE can be used to image the pericardium to assess thickness and the areas of adherence, as well as to obtain higher fidelity Doppler signals through the MV/TV (*E* velocity) and pulmonary vein flows. Often TEE evaluation is useful as an adjunctive modality since it is better for imaging the posterior aspect of the heart, as well as the RA, RV, and IVC which improves the accuracy of the overall assessment. However, TDI measurement of mitral annulus velocities has not been validated in TEE.

Computed Tomography and Magnetic Resonance Imaging

CT and CMR imaging offer higher resolution and additional information as compared to echocardiography in the evaluation of CP and RCM. CT can assess pericardial thickening (>4 mm) and calcification better than TTE or TEE (Fig. 16.8c, d), though the absence of either does not rule out CP. Talreja DR et al. reported 18% of patients had normal pericardial thickness on histological examination, and 28% of patients had normal pericardial thickness on CT in a study of 143 patients with surgically confirmed CP [13]. It also offers information regarding IVC volume status, as well as ventricular and septal contours associated with constriction. In patients with a prior history of cardiothoracic surgery, CT is useful in assessing the location of important vascular structures prior to surgery as well as assessing for any lung injury or entrapment especially with prior history of radiation exposure.

Gated CMR provides better visualization and resolution of the pericardium than either CT or echocardiography. CT still offers a better assessment of pericardial calcification, but CMR is superior in the evaluation of tissue characterization including pericardial inflammation and edema, pericardial scarring, small pericardial effusions, and myocardial tethering as well as resolving hemodynamic correlates such as IVC plethora and VSS (Fig. 16.9). The ability of CMR for tissue characterization has been used to diagnose and monitor both constrictive physiology and pericardial inflammation in transient CP. Transient CP is an increasingly recognized sub-type of the more typically known CP. It was first described back in 1987, when a small group of subjects with CP demonstrated spontaneous and permanent resolution of constrictive physiology on serial echocardiograms and CMR [14]. Pathologically, transient CP is usually a result of fluctuating pericardial edema, inflammation and fibrin deposition, rather than more fixed pericardial fibrosis or calcification [15]. It may resolve spontaneously or with the assistance of anti-inflammatory therapy. It is likely that in some cases, transient CP may actually represent an early manifestation in the spectrum of CP disease, before chronic inflammation leads to accumulation of fibroblasts and collagen and constrictive physiology becomes irreversible. For the inter-atrial septum (IAS), a thickness of >6 mm is considered significant. This finding is virtually diagnostic of cardiac amyloidosis. Lipomatous hypertrophy can also cause increased thickness of IAS, but it can be easily differentiated by its hyperintense signal on T1-weighted sequence due to fat content [16].

Besides, the delayed enhanced inversion recovery imaging in CMR is the most valuable

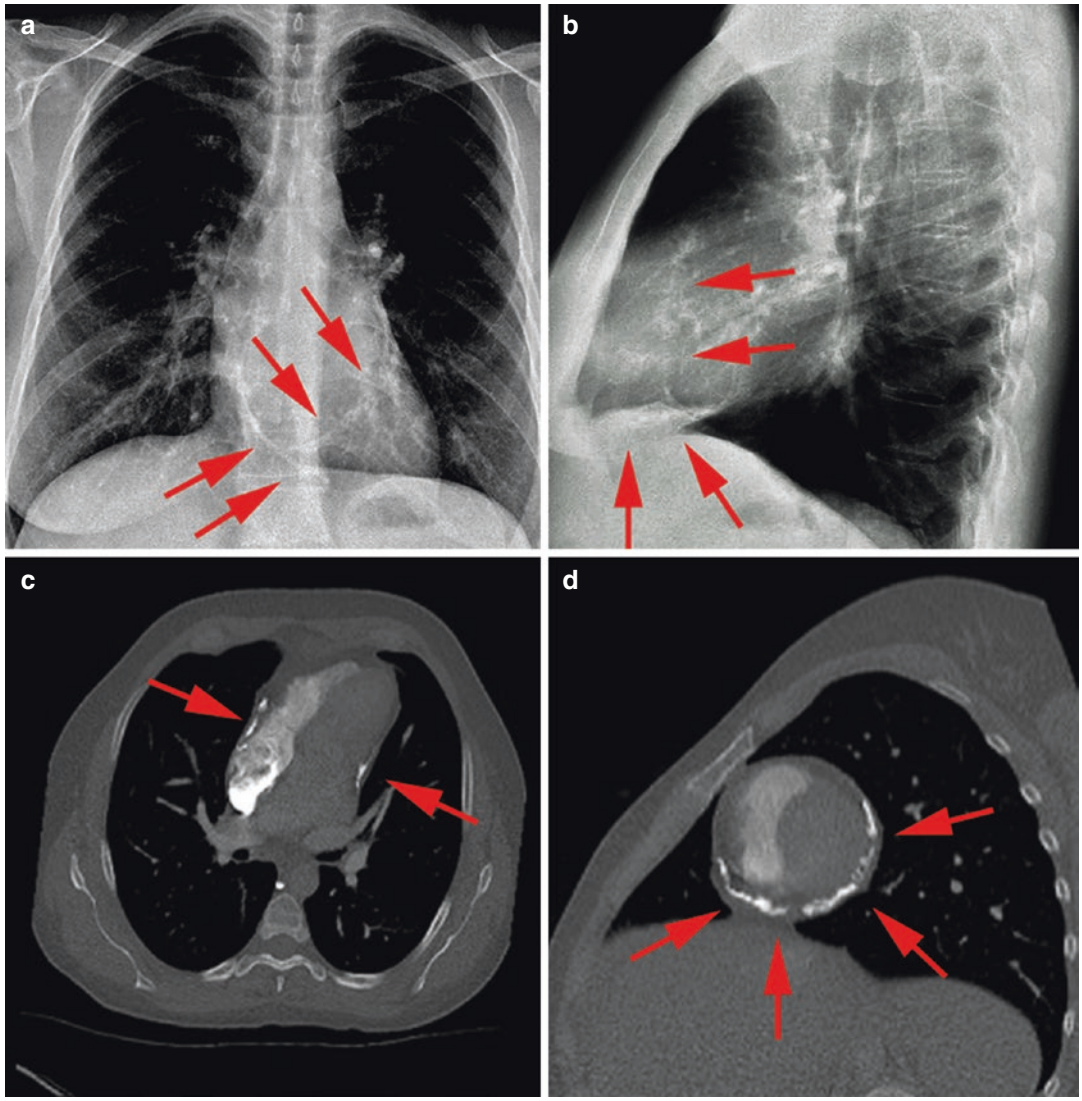

Fig. 16.8 Pericardial calcification seen on CXR (**a** and **b**) and CT scan (**c** and **d**). Red arrows indicate the location of pericardial calcification

sequence for tissue characterization and providing clues as to the underlying cause, especially in the cases of RCM. In cardiac amyloidosis, the late gadolinium enhancement (LGE) is usually global in distribution and predominantly subendocardial but may be transmural. CMR also provides some information about amyloid load (intramyocardial T1 gradient) in the heart, which is helpful in the non-invasive follow-up of patients on treatment [17]. Cardiac sarcoidosis is pathologically characterized by patchy and focal myocardial involvement by granulomatous inflammation, which can leave scar tissue after healing. There are three successive histological stages: edema, non-caseating granulomatous infiltration, and patchy myocardial fibrosis. CMR has been shown to accurately reflect these changes. The acute inflammatory phase shows the presence of focal increased signal on T2-weighted images with myocardial thickening reflecting edema (Fig. 16.10a). Well-formed granulomas are seen as foci of decreased T1 and T2 signal within the area of increased T2 signal. A central low signal area reflects hyaline fibrotic

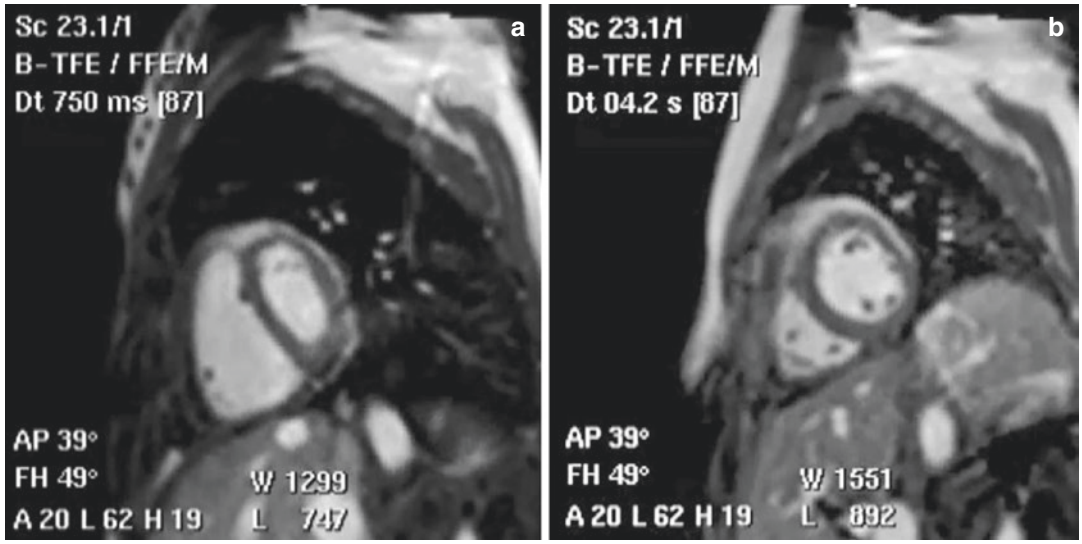

Fig. 16.9 CMR free breathing sequence shows the presence of ventricular septal shift. The ventricular septum moves toward the left ventricle with inspiration during diastole (**a**) and toward the right ventricle with expiration during diastole (**b**)

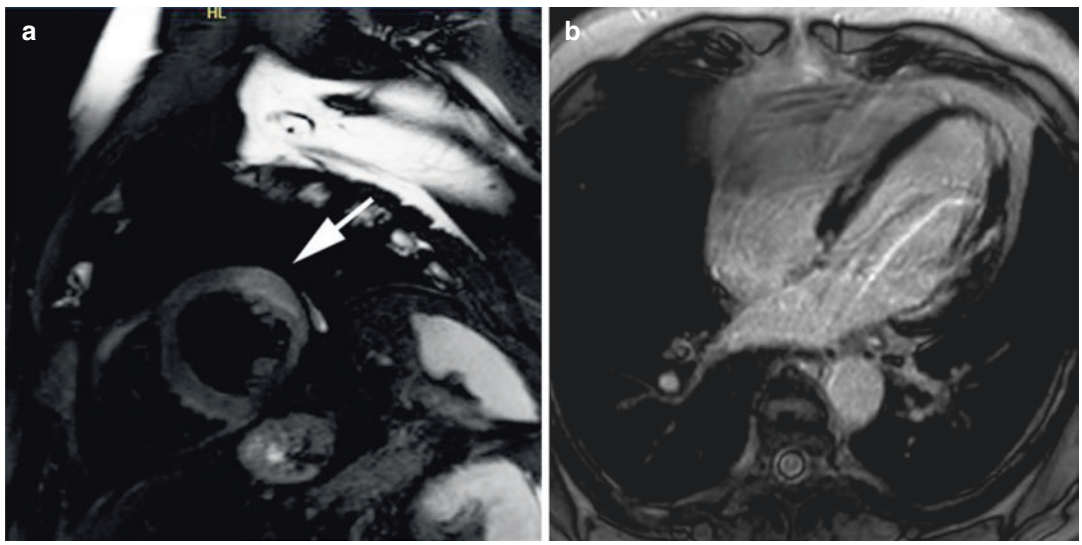

Fig. 16.10 CMR of a patient with sarcoidosis. (**a**) There is increased myocardial signal intensity on T2-STIR imaging to suggest myocardial edema (white arrow). (**b**) Delayed-enhancement imaging reveals late gadolinium enhancement (LGE) in a non-ischemic pattern. There is near transmural LGE in the basal and mid inferoseptum (sparing the endocardium) and mid-myocardial LGE in the mid-anterolateral and transmural LGE at the inferolateral apex

change and peripheral high signal area denotes edema due to granulomatous inflammation. LGE imaging shows hyperenhancement in areas of fibrosis, which does not correspond to any particular coronary artery distribution. These are also more linear in appearance (Fig. 16.10b), compared to the focal, more rounded lesions in the inflammatory stage [16].

In hemochromatosis, CMR is also vital in the detection and quantification of cardiac involvement. Deposition of iron in the myocardium causes a decrease in T2∗ relaxation time, which

can be detected by multi-echo gradient sequences [16]. The ability of CMR to detect myocardial iron overload at an early stage, direct timely institution of chelation therapy, and monitor treatment follow-up have been shown to reduce the morbidity as well as mortality in hemochromatosis [18].

Catheterization/Hemodynamic Assessment

Left and right heart catheterization has been used in the past as the gold standard in distinguishing between CP and RCM. Improvements in non-invasive imaging have helped in increasing the early diagnosis of CP and restriction. Although there are many similar hemodynamic characteristics in CP and RCM, certain unique findings, if present, can help to differentiate the diagnosis.

Hemodynamic findings often seen in patients with CP are increased RA pressure due to the adherent pericardium around RA prevents expansion, Kussmaul's sign (usually present), as well as prominent *x* and *y*-descents of RA pressure tracings because of rapid atrial emptying and underfilled RV (M/W pattern) (Fig. 16.11a). The presence of an increased RV end-diastolic pressure (usually greater than or equal to one-third of the RV systolic pressure) is due to constraint of the RV leading to higher filling pressure. Constriction is generally not known to cause pulmonary hypertension; thus, the RV systolic pressure is not affected. The "dip-and-plateau"/"square-root" sign is seen in the RV and LV pressure tracings as a result of rapid early diastolic flow (dip) and diastasis once pressure equalization occurs (plateau) during mid- and late-diastole. Another key feature is found in the diastolic (plateau) pressures of the LV and RV, which equalize due to the rigid non-elastic pericardium (Fig. 16.11b). This finding is relatively common in patients who undergo catheterization and have constriction; however, in some patients, it is only seen on inspiration, secondary to increased systemic venous return. Lastly, RV and LV systolic pressures exhibit an inverse relation as a result of ventricular interde-

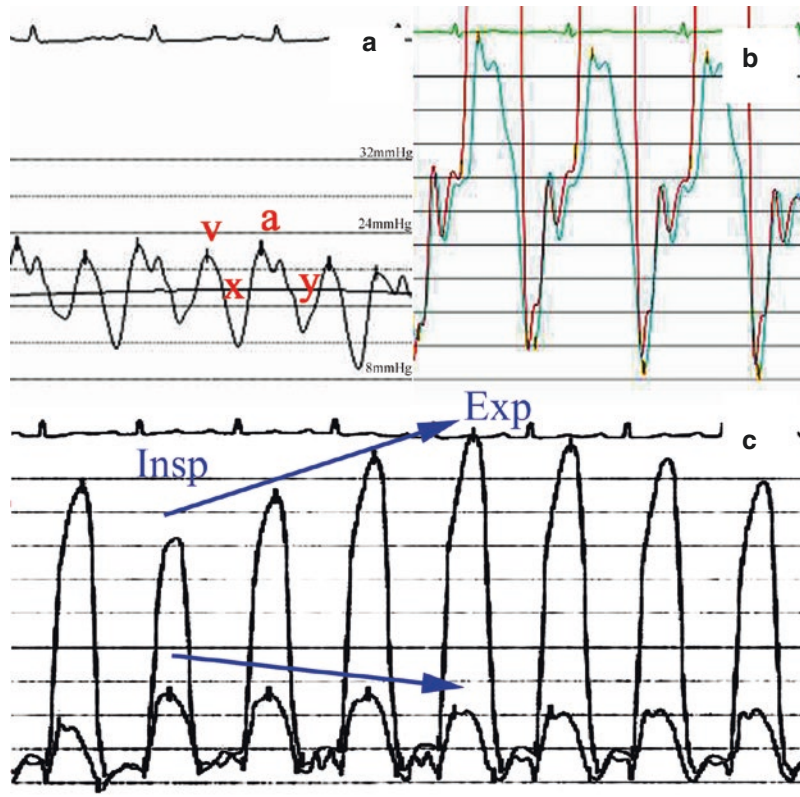

Fig. 16.11 Left and right heart catheterization of a patient with constrictive pericarditis. (**a**) Pressure tracing of the right atrium shows prominent x- and y-descents. v indicates v wave; a, a wave; x, x-descent; and y, y-descent. (**b**) Simultaneous recording of LV and RV pressure tracings shows "dip-and-plateau"/"square-root" sign and equalization of both ventricular diastolic pressures. (**c**) Simultaneous recording of LV and RV pressure tracings with respiratory variation shows ventricular interdependence. LV indicates left ventricle and RV, right ventricle

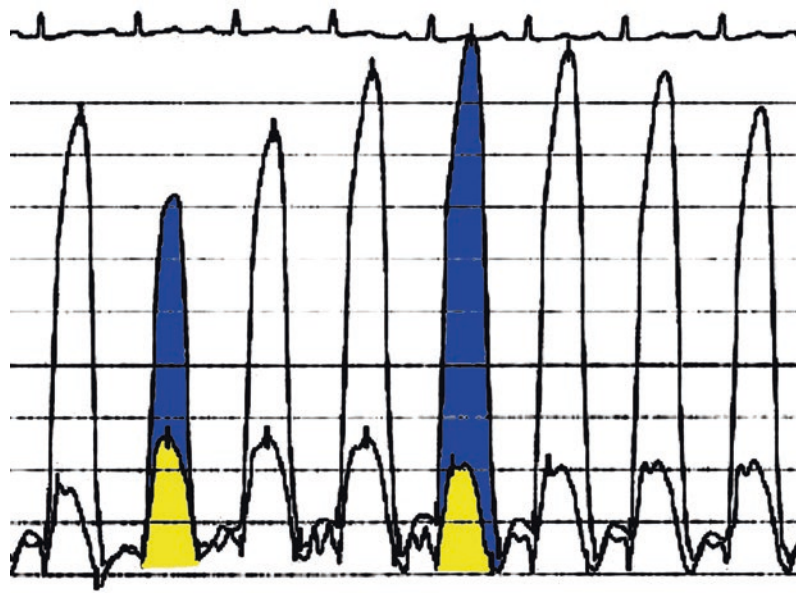

Fig. 16.12 A patient with constrictive pericarditis. During inspiration there is an increase in the area of the RV pressure curve (yellow-shaded area) compared with expiration. The area of the LV pressure curve (blue shaded area) decreases during inspiration as compared with expiration

pendence. With inspiration, the LV systolic pressure falls and the RV systolic pressure rises and vice versa with expiration (Fig. 16.11c). Patients with restrictive cardiomyopathy have ventricular concordance. Systolic area index is used to further quantify this hemodynamic difference. The area under the ventricular pressure curve was used to determine the change in the relative volumes of the LV and RV, which is a better determinant of beat-to-beat stroke volume than the peak pressure alone. The systolic area index is defined as the ratio of the RV area (mmHg × s) to the LV area (mmHg × s) in inspiration versus expiration. An index of greater than 1.1 has been shown to have 97% sensitivity in predicting patients with CP [19] (Fig. 16.12).

Clinical Examples

Calcific Constrictive Pericarditis

A 45-year-old female presented with a history of increasing dyspnea on exertion and progressive heart failure symptoms. She had a history of recurrent pericarditis, otherwise unremarkable. On physical exam, she had bilateral pitting LE edema, elevated JVP, and a pericardial knock. Chest radiography (CXR) showed no pulmonary edema or effusion but was significant for scattered calcification of the pericardium (Fig. 16.8a, b). Echocardiogram showed preserved LV and RV functions, but grade III diastolic dysfunction, VSS and IVC plethora (Fig. 16.5e). Grade III diastolic dysfunction was diagnosed as the LA was dilated with indexed LA volume of ~36 ml/m^2. Transmitral inflow showed high E/A ratio was ~2.3 (Fig. 16.5a). Moreover, the TDI of mitral annulus velocities demonstrated "annulus reversus" with septal e' of 10 cm/s and lateral e' of 5 cm/s (Fig. 16.5b, c), and the average E/e' was ~18.8. The TR signal was insufficient to estimate PASP. Significant respiratory variation in mitral inflow was also present, i.e., >25% respiratory variation in peak mitral E inflow (Fig. 16.5d). GLS study showed LV lateral wall shortening strains were lower than the septal shortening strains (Fig. 16.5f).

Left and right heart catheterization showed normal coronary arteries and confirmed the diagnosis of CP with the hemodynamic finding of CP. There were diastolic equalization of pressures in both the LV and RV and ventricular interdependence (Fig. 16.11b, c).

The patient was referred for pericardiectomy in view of the above findings and persistent symptoms despite medical therapy. She had marked improvement in her symptoms after surgery.

Effusive-Constrictive Pericarditis

A 39-year-old female presents with a history of chest and dyspnea. She had medical history of systolic lupus erythematosus and interstitial lung disease with pulmonary fibrosis. On physical examination, pericardial rubs could be heard. ECG showed sinus tachycardia with diffused ST elevations and PR depressions in lead II. ESR and CRP were both raised. Echocardiography showed large circumferential pericardial effusion with features of cardiac tamponade. Pericardiocentesis was then performed and found exudative pericardial effusion with negative culture and cytology. However, the echocardiography repeated after pericardiocentesis showed small residual pericar-

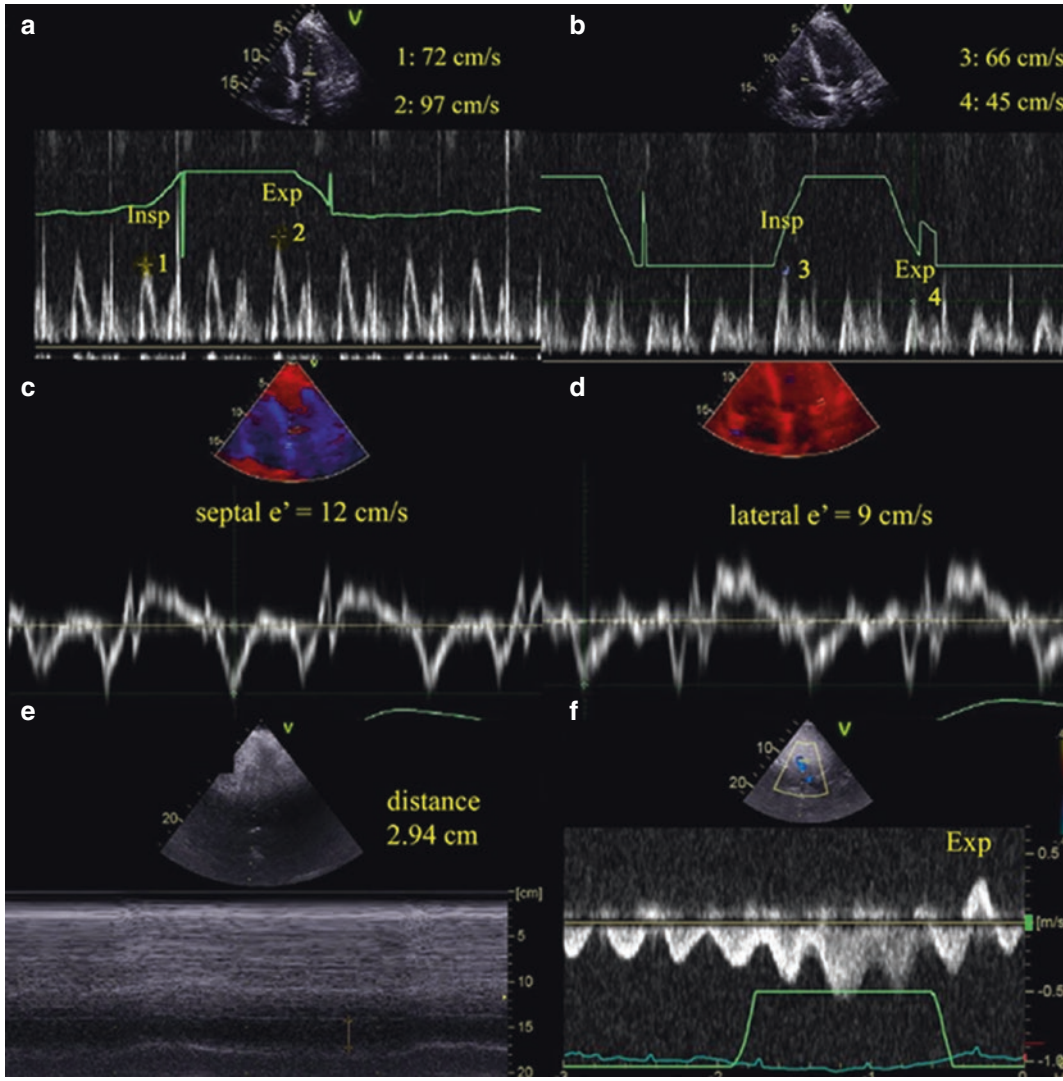

Fig. 16.13 Echocardiography of a patient with effusive-constrictive pericarditis. (**a**) There is significant respiratory variation in the mitral inflow [(expiration – inspiration)/expiration; (97–72)/97 × 100% = ~25.8%]. Insp indicates inspiration and Exp expiration. (**b**) There is significant respiratory variation in the tricuspid inflow [(expiration – inspiration)/expiration; (45–66)/45 × 100% = ~ −46.7%]. Tissue Doppler imaging (TDI) of mitral annulus shows "annulus reversus" with (**c**) septal e' of 12 cm/s and (**d**) lateral e' of 9 cm/s. (**e**) Inferior vena cava is plethoric with diameter of ~2.9 cm and <50% variation in size during respiration. (**f**) Pulsed wave Doppler of hepatic vein flow showed significant end expiratory diastolic flow reversal with hepatic vein expiratory diastolic reversal ratio of ~0.9

dial effusion with features of constriction. There were ventricular septal shift and significant respiratory variation in both mitral and tricuspid inflows, 25.8% and −46.7%, respectively (Fig. 16.13a, b). "Annulus reversus" was present (Fig. 16.13c, d). IVC was still plethoric (Fig. 16.13e). Hepatic vein flow showed significant end expiratory diastolic flow reversal with the hepatic vein expiratory diastolic reversal ratio of ~0.9 (Fig. 16.13f). Since the central venous pressure before and after pericardiocentesis were still >20 mmHg, the diagnosis of effusive-constrictive pericarditis (ECP) is confirmed.

ECP is an uncommon clinical syndrome characterized by the coexistence of tense pericardial effusion and constriction of the heart by the visceral pericardium. Incidence ranges from 2% to 15% of patients with pericarditis, depending on the difference in patient populations, methodologies, and definition. The hallmark of ECP is the presence of the persistently elevated right atrial pressure measured by invasive hemodynamic assessment after intra-pericardial pressure is reduced to a normal level by pericardiocentesis.

Patient was treated with steroids and colchicine. The repeated echocardiography 1 year later did not reveal any more feature of constriction.

Restrictive Cardiomyopathy (Cardiac Amyloidosis)

A 72-year-old male initially presented with new onset atrial fibrillation and dyspnea at rest. Echocardiogram performed was performed during sinus rhythm and showed a depressed ejection fraction of ~40%, marked biatrial enlargement with grade III diastolic dysfunction, moderate pulmonary hypertension, increased left ventricular wall thickness and a speckling pattern of myocardium. GLS study showed the pattern of apical sparing (Fig. 16.3c). The patient was treated with beta-blockers and diuretics presumptively, while serum and urine electrophoresis were negative. The bone marrow biopsy was significant for plasma cell population, and Congo red staining was consistent with amyloidosis. Given the diagnosis of systemic amyloidosis and severe diastolic dysfunction, the patient was presumed to have cardiac amyloidosis and started on treatment for amyloidosis with prednisone and intra-venous melphalan. Due to the chronic nature of the condition and the late presentation as well as the lack of efficacious treatment options, the patient did not respond to therapy and continued to deteriorate over the next few months. Cardiac amyloidosis usually presents later in life with an insidious onset and often is diagnosed as a result of key echocardiographic features. In this case, further testing including CT, MRI, or catheterization was not warranted for diagnosis.

Pearls of Assessment

When assessing a patient with suspected CP or RCM, a focused history and physical examination with emphasis on symptoms as well as clues or signs that suggest either diagnosis is essential. Chest X-ray and ECG are also useful in the initial workup to assess for cardiomegaly and pericardial calcification as well as voltage pattern for possible RCM. Non-invasive imaging is the mainstay and first line of the workup and echocardiography with respirometer to assess for changes in filling velocity and pressures, as well as pericardial thickening is usually the next step. Depending on the echocardiographic results and suspicion for a pericardial or myocardial process, further non-invasive imaging including either a cardiac CT or CMR can be useful to obtain more information that cannot be provided by echocardiography, e.g. pericardial calcification, pericardial inflammation, myocardial fibrosis, etc. If the diagnosis is still inconclusive, left and right heart catheterization with a focus on the hemodynamic findings of "dip-and-plateau" on RV and LV pressure tracings as well as ventricular interdependence which point to a specific diagnosis of CP. Table 16.2 summarizes the key distinguishing features of constrictive pericarditis and restrictive cardiomyopathy. Treatment of symptoms with diuretics is usually a temporizing measure and often patients require surgical pericardiectomy for symptomatic relief of CP. Treatment of RCM depends on the underlying etiology.

Table 16.2 Key distinguishing features of constrictive pericarditis and restrictive cardiomyopathy

	Constrictive pericarditis	Restrictive cardiomyopathy
Physical examination	Pericardial knock	S4 (early) and S3 (late presentation)
	Apical retraction	Prominent apical impulse
Echocardiography		
2D images	Pericardial thickening	Biatrial enlargement
	Ventricular septal shift	Ventricular hypertrophy (usually present)
	Pericardial effusion (may be present)	Myocardial speckling (amyloidosis)
PW mitral inflow	*E*/*A* ratio ≥ 2	*E*/*A* ratio ≥ 2
	>25% respiratory variation in E wave[a]	<25% respiratory variation in *E* wave[a]
PW tricuspid inflow	>40% respiratory variation in E wave[a, b]	<40% respiratory variation in E wave[a, b]
TDI	"Annulus reversus" – lateral e' velocity is reduced, whereas septal e' velocity is normal or higher than normal	Both septal and lateral e' velocities are reduced
PW hepatic vein flow	Hepatic vein flow reversal ratio ≥ 0.79	Hepatic vein flow reversal ratio < 0.79
GLS	LV septum > free wall	Apical sparing (amyloidosis)
Left and right heart catheterization	Diastolic equalization of pressure between LV and RV	LVEDP may be equal to or greater than RVEDP
	Ventricular interdependence	Ventricular concordance
	Systolic area index >1.1	Systolic area index <1.1
	Pulmonary pressure usually normal	Pulmonary hypertension (RVSP >50 mmHg)

GLS Global longitudinal strain, *LV* left ventricle, *LVEDP* left ventricular end-diastolic pressure, *PW* pulse wave Doppler, *RA* right atrium, *RV* right ventricle, *RVEDP* right ventricular end-diastolic pressure, *RVSP* right ventricular systolic pressure, *TDI* tissue Doppler imaging

[a]Respiratory variation = (expiration – inspiration)/expiration × 100%

[b]This is negative value

Review Questions

1. Which of the following(s) is/are cause(s) of pericardial constriction?
   A. Infection
   B. Prior cardiac surgery
   C. Mantle radiation for lymphoma
   D. A and B
   E. All of the above

   Answer: E. Infection, prior cardiac surgery, and mantle radiation for lymphoma are established causes of constrictive pericarditis.
2. Which of the following features of left and right heart cardiac catheterization are seen in constriction?
   A. Diastolic equalization of pressure between LV and RV
   B. Ventricular interdependence
   C. M (or W) pattern on right atrial waveform
   D. Steep or rapid *y*-descent
   E. All of the above

   Answer: E. All of the findings listed above are typically seen in constrictive pericarditis.
3. Which of the following statement is false regarding constrictive pericarditis?
   A. "Annulus reversus" results from a compensatory increase in longitudinal movement of the septum in order to accommodate filling secondary to the limited lateral expansion of the heart during filling secondary to pericardial encasement.
   B. "Pulsus paradoxus" means there is an abnormal (>10 mmHg) decrease in systolic blood pressure with inspiration.
   C. A pericardial knock occurs at the nadir of the x-descent and is consistent with abrupt cessation of ventricular filling.
   D. The American Society of Echocardiography recommends the calculation of percentage of respiratory variation in constrictive pericarditis for mitral and tricuspid inflow is (expiration – inspiration)/expiration × 100%.
   E. Measurement of pericardial thickness using transthoracic echocardiogram is not recommended.

   Answer: C. A pericardial knock occurs at the nadir of the y-descent and is consistent with abrupt cessation of ventricular filling.

4. Which of the following echocardiographic findings is not consistent with restrictive physiology?
   A. Large atria
   B. Blunted *S*/*D* ratio in pulmonary and hepatic vein flows
   C. Low septal and lateral e' velocity on TDI (i.e., septal e' velocity <7 cm/s; lateral e' velocity <10 cm/s)
   D. Decreased mitral inflow velocity (*E* wave) with inspiration
   E. E/A ratio >2

   Answer: D. Decreased mitral inflow (*E* wave) is found in constrictive pericarditis, whereas in restrictive cardiomyopathy, mitral inflow is not changed with respiration. The other findings are all seen in restrictive cardiomyopathy.
5. Which of the following is not the distinguishing features of constrictive pericarditis and restrictive cardiomyopathy?
   A. Ventricular septal shift
   B. Kussmaul's sign
   C. Ventricular interdependence
   D. Hepatic vein flow reversal ratio ≥0.79
   E. Annulus reversus

   Answer: B. Kussmaul's sign can be present in both constrictive pericarditis and restrictive cardiomyopathy.

Valvular Heart Disease

17

Amar Krishnaswamy and Brian P. Griffin

Introduction

The diagnosis and management of valvular heart disease are challenging and require a knowledge of the relevant historical clues, appreciation of salient physical exam findings, and the ability to critically interpret imaging and invasive hemodynamic data. This chapter will focus on diagnosis of the valve disorders most frequently encountered in the care of patients on the cardiac ward.

Aortic Stenosis

Case Presentation

The patient is a 78-year-old man with a history of hypertension, hyperlipidemia, and percutaneous coronary intervention with drug-eluting stent to the mid-left anterior descending artery 4 years prior. He noted the development of exertional dyspnea over the past 6–12 months, as well as mild chest discomfort over the past 3 months that resolved with rest. Initially attributed to "old age," he finally decided to seek medical attention due to progression of his symptoms.

Salient physical examination findings included mild hypertension (BP 145/90 mmHg) and a normal heart rate (70 bpm). The PMI was not displaced and an S4 gallop was appreciated. A 2/6 systolic crescendo/decrescendo murmur was heard at the upper sternal border peaking late in systole, radiating to the carotids bilaterally. The carotid artery upstrokes were mildly delayed and weak.

Given the symptoms and physical exam findings, transthoracic echocardiography (TTE) was performed. The TTE revealed normal left ventricular function with moderate concentric hypertrophy, a moderately thickened and calcified aortic valve, and severe aortic stenosis (AS) with peak and mean gradients of 85 and 50 mmHg, respectively. With a diagnosis of severe, symptomatic aortic stenosis, the patient was referred for coronary angiography in anticipation of open-heart surgery. Angiography revealed only mild CAD and a patent stent in the mid-LAD, and the patient went to have uneventful valve replacement with an aortic bioprosthesis.

Epidemiology and Pathophysiology

Aortic stenosis (AS) is present in almost 5% of individuals over the age of 75 years [1]. AS may develop due to a congenital valve disorder

(unicuspid or bicuspid valve), as a result of rheumatic valvular heart disease, as a complication of chest radiation, or most commonly due to degenerative ("senile") thickening and calcification. Over time, AS causes increased pressure on the left ventricle (LV) and leads to a chronically increased afterload state. In order to compensate, the ventricle hypertrophies. Due to increased LV mass and worsening diastolic filling mechanics, diastolic dysfunction ensues. With worsening and long-standing stenosis, LV systolic function eventually falls. Furthermore, impaired LV diastolic and/or systolic function may lead to pulmonary hypertension due to left-sided heart disease. Since senile AS shares many risk factors with coronary artery disease (CAD), the clinical presentation may reflect progressive coronary stenosis in these patients in addition to increased myocardial oxygen demand due to the valvular stenosis.

Patients with aortic stenosis may live for years with a "known murmur" that is clinically silent, especially in cases of bicuspid or rheumatic valve disease. It is estimated that the valve area decreases by approximately 0.12 cm^2/year in patients with senile disease, providing a long period of asymptomatic disease [2]. On the other hand, the development of symptoms portends a grave prognosis: without treatment, angina, syncope, and heart failure are associated with a 50% mortality at 5 years, 3 years, and 2 years, respectively [3].

Physical Examination

The physical examination of patients with AS provides a number of characteristic findings. A systolic murmur is best heard in the aortic position (right upper sternal border) and radiates to the carotid arteries. As stenosis worsens, the peak of the murmur moves closer to the second heart sound (S2) since LV ejection across the valve requires a longer ejection time. With very severe disease, the S2 may be almost inaudible due to the proximity of the murmur's peak to the closing of the valve. With severe AS, a murmur mimicking mitral regurgitation (MR) may also be heard at the apex, but does not radiate to the axilla; this is known as Gallivardin's phenomenon. Palpation of the pulse (preferably at the carotid arteries) in patients with severe AS reveals the characteristic slow ascent (*parvus*) and delayed (*tardus*) peak. Additionally, palpation of the pulses at the upper extremity may reveal a "brachio-radial" delay in patients with severe AS that often presents prior to LV failure or clinical symptoms. Of note, the finding is subtle, with a measured delay of 53.5 msec [4]. An S4 gallop may be heard in the setting of left ventricular hypertrophy (LVH) and a stiffened ventricle.

An important differentiation to be made is between the murmur of AS and that of hypertrophic cardiomyopathy (HCM). In patients with AS, a reduction in preload (i.e., with the Valsalva maneuver or moving from squatting to standing) will reduce flow across the stenotic valve and therefore lessen the murmur. Conversely, a reduction in preload causes decreased filling of the LV cavity resulting in a smaller left ventricular outflow tract (LVOT) diameter and worsening systolic anterior motion (SAM) of the mitral valve and therefore augments the murmur in patients with HCM.

Echocardiography

Transthoracic echocardiography (TTE) is the cornerstone of AS assessment and provides information on left ventricular function, aortic valve morphology, degree of stenosis, and an assessment of pulmonary pressures. Rarely, transesophageal echocardiography (TEE) may be necessary for diagnosis if TTE images are limited or for precise planimetry of the valve area (discussed below). In the early stages of AS, LV systolic function is preserved, with varying degrees of compensatory LVH. Over time, with LV stiffening, diastolic filling becomes more dependent upon atrial systole and diastolic dysfunction ensues. Eventually, the chronically afterloaded LV dilates, and left ventricular systolic function declines.

The degree of valvular stenosis can be assessed both qualitatively and quantitatively. The presence of congenital disorders (i.e., unicuspid, bicuspid, etc.) is assessed in the parasternal long-axis (the valve does not coapt in the center line or may have a "doming" appearance) and short-axis

views (the number of cusps can be identified along with the presence of a "raphe"), as well as the degree of thickening and calcification. The short-axis view is also useful for performing planimetry of the aortic orifice.

Hemodynamic assessment of AS by TTE requires an assessment of the following: jet velocity, peak and mean gradients, and the dimensionless index (DI) (Table 17.1) [5]. Peak jet velocity gives a rough estimate of stenosis severity; velocity >4 m/sec is considered severe. The peak gradient is calculated using the peak velocity via the Bernoulli equation ($\Delta P = 4v^2$).

Table 17.1 Echocardiographic evaluation of aortic stenosis severity

	Mild	Moderate	Severe
Peak jet velocity (m/sec)	<3.0	3.0–4.0	>4.0
Mean gradient (mmHg)	<25	25–40	>40
Valve area (cm^2)	>1.5	1.0–1.5	<1.0
Dimensionless index	*	*	<0.25

The mean gradient is calculated using the velocity time integral (VTI), which sums the velocities over an entire cardiac cycle and is provided by tracing the continuous-wave Doppler aortic outflow envelope. The dimensionless index is a ratio of the velocity (or VTI) in the left ventricular outflow tract (LVOT) to that in the aorta; a ratio <0.25 implies an AVA that is <25% of the LVOT area. The DI is helpful in patients for whom LVOT diameter is difficult to measure.

Calculation of aortic valve area (AVA) may be performed by planimetry as above or by using the continuity equation. The continuity equation makes the assumption that flow and volume are constant. Since flow = cross-sectional area (CSA) × velocity, the relationship can also be described as stroke volume = CSA × VTI, and since volume is constant, the equation can be rearranged as $A_{AV}V_{AV} = A_{LVOT}V_{LVOT}$. Calculation of the AVA is demonstrated in Fig. 17.1. Common mistakes in calculation of the AVA

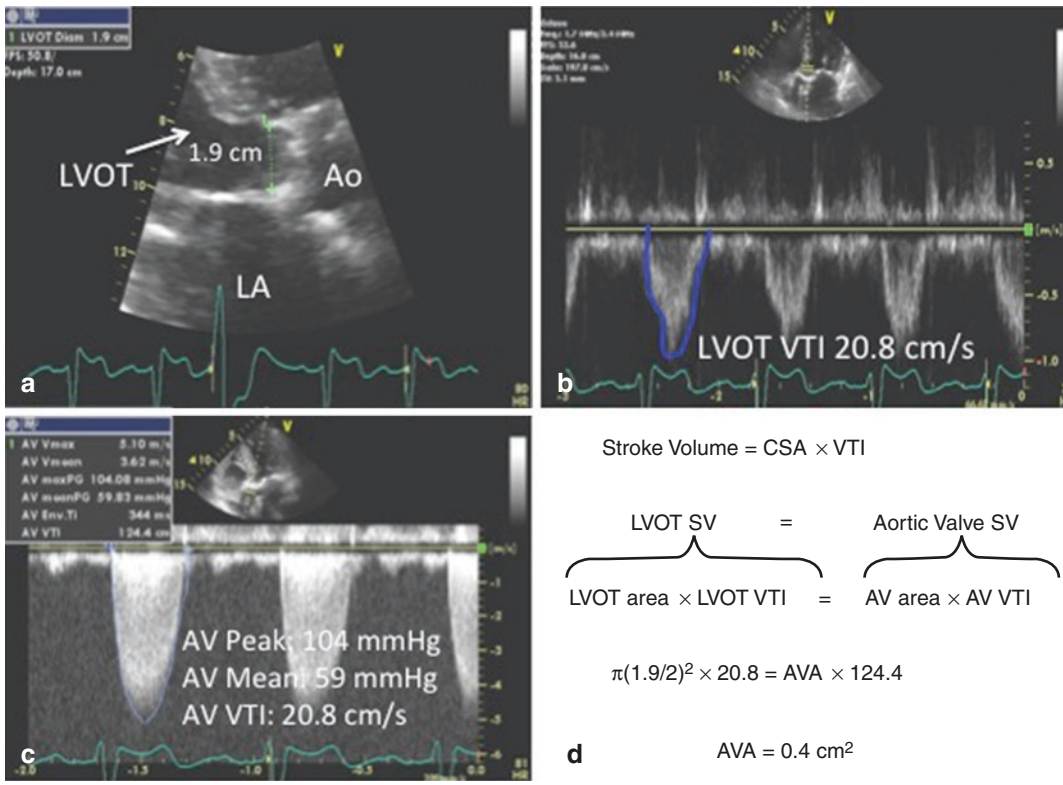

Fig. 17.1 Calculation of aortic valve area (AVA) using the continuity equation. Measurement of the left ventricular outflow tract (LVOT) diameter (**panel A**), velocity time integral (VTI) in the LVOT (**panel B**), and aortic valve (AV) VTI (**panel C**) is necessary to calculate the AVA (**panel D**)

include incorrect measurement of the LVOT diameter (underestimation of the LVOT leads to an underestimation of the AVA) or LVOT/AV outflow gradients.

Low-Flow, Low-Gradient Aortic Stenosis

Patients with chronic pressure overload from AS, CAD, or intrinsic myocardial dysfunction may present with depressed LV function and aortic stenosis with a low gradient. Low-flow/low-gradient (LF/LG) AS is defined as an LVEF <35%, mean gradient <30 mmHg, and AVA < 1.0 cm^2. Evaluation of the true degree of AS in these patients presents a common clinical quandary, as patients may have truly severe AS or "functional" AS caused by poor leaflet excursion in the setting of a low cardiac output (pseudo-AS).

Dobutamine stress echocardiography (DSE) is a common diagnostic tool in this setting. With infusion of increasing doses of dobutamine (DBA; 5–20 mcg), the stroke volume, peak velocity, mean gradient, and AVA are measured/calculated. An increase in SV >20% implies contractile reserve. Increases in peak velocity and/or mean gradient imply true AS; the increased flow across the valve is limited by intrinsic valve disease and results in higher gradients and does not simply cause increased leaflet excursion. An increase in AVA > 0.3 cm^2 implies pseudo-AS; increase in LVOT velocity is greater than the increase in AV velocity due to increased leaflet excursion, providing a higher calculated AVA. The potential outcomes of DSE and the clinical diagnosis are summarized in Table 17.2 [6].

For patients with pseudo-AS, treatment is directed toward the medical management of heart failure. Studies on AVR in patients with LF/LG true AS have shown that perioperative mortality is only mildly increased (5%) in patients with contractile reserve on DSE. On the other hand, patients with LF/LG true AS but without contractile reserve face a significant perioperative mortality (32%) [7]. However, survival thereafter is reasonable, and improvement in ejection fraction is similar in both groups [8].

Table 17.2 Possible outcomes of dobutamine stress echocardiography in low-flow, low-gradient aortic stenosis

Dobutamine response	Diagnosis
Increase in CO and gradient	Contractile reserve present
	True AS
Increase in CO and AVA with constant/decreased gradient	Contractile reserve present
	Pseudo-AS
No response to DBA	No contractile reserve
	Indeterminate re: AS

CO cardiac output, *AVA* aortic valve area, *AS* aortic stenosis, *DBA* dobutamine

Cardiac Catheterization

Outside of the evaluation for coronary artery disease, cardiac catheterization in patients with AS is reserved for situations when the degree of symptoms and severity of AS are contradictory based on noninvasive testing [5]. Catheterization may be used to measure intracardiac pressures, cardiac output, and valve gradient and calculate the AVA.

Historically, measurements of the valve gradient were taken by placing a catheter in the aortic root and another in the LV via transseptal puncture, but this is rarely performed now. Valve gradient may be measured with a dual-lumen pigtail catheter that simultaneously measures pressures in the LV and aorta, or by placing a catheter in the LV and then quickly pulling it back to the aortic root ("pullback gradient"). It should be noted that this "peak-to-peak" gradient is generally lower than the peak gradient obtained by Doppler echocardiography, which is sampled as the peak instantaneous velocity (Fig. 17.2). The peak-to-peak gradient correlates well to the mean gradient.

The valve area is usually calculated using the *Gorlin equation*:

$$\mathrm{AVA} = \mathrm{CO} \div \left(\mathrm{HR} \times \mathrm{SEP} \times 44.3 \times \sqrt{\text{mean gradient}} \right)$$

[CO, cardiac output; HR, heart rate; SEP, systolic ejection period]

Since the Gorlin method is dependent on flow across the aortic valve, patients with LF/LG AS will have a significantly underestimated AVA. In these cases, dobutamine infusion during catheterization may reveal pseudo-AS similar to that

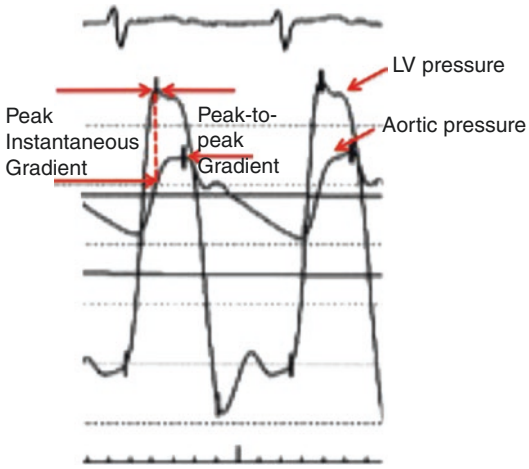

Fig. 17.2 Simultaneous LV and aortic pressure tracing. Peak-to-peak gradient is measured as the difference between peak LV and aortic pressures during cath; peak gradient by echocardiography is an instantaneous peak. Mean gradient is calculated as the average pressure difference between LV and aorta pressures (area between the curves)

described during DSE above (increased cardiac output with increased AVA and stable or decreased gradient).

A simplification of the Gorlin equation is the *Hakki equation*, based upon the assumption that the (HR × SEP × 44.3) approximates 1 under normal conditions [9]:

$$\text{AVA} = \text{CO} \div \sqrt{\text{mean gradient}}$$

For patients with a heart rate >100 bpm, the AVA obtained using the Hakki method should be divided by 1.35 for increased accuracy.

Aortic Regurgitation

Case Presentation

A 42-year-old man presented with progressive dyspnea over a 6-month period. He was quite active previously, running 3 miles every other day, but now required a break after just 2 miles due to dyspnea. He also noticed some dyspnea with walking the three flights of stairs to his apartment, which was new over the prior 1–2 months. He had not experienced orthopnea but has had a few episodes of paroxysmal nocturnal dyspnea over the prior 3 months. He denied chest discomfort or lower extremity edema.

On physical examination, cardiac auscultation was significant for a long, decrescendo, holodiastolic murmur heard best at the left sternal border as the patient leaned forward. Palpation of the brachial pulse revealed a brisk and forceful upstroke and wide pulse pressure. Gentle pressure applied at the tip of the fingernails revealed a "to-and-fro" filling of the nailbeds.

TTE performed revealed a bicuspid aortic valve with fusion of the right and left coronary leaflets and with minimal calcification. There was mild anterior leaflet prolapse resulting in severe, posteriorly directed aortic regurgitation (AR). The aortic root and ascending aorta were normal in size without evidence of dilation. LV systolic function and chamber size were normal.

Given a diagnosis of severe, symptomatic aortic regurgitation, the patient underwent preoperative coronary angiography that revealed minimal atherosclerosis. He then underwent successful aortic valve repair.

Epidemiology and Pathophysiology

Aortic regurgitation (AR) is present in up to 12% of men and may complicate rheumatic valve disease, radiation valvular disease, or bicuspid aortic valve. Infective endocarditis may cause AR due to valve degeneration, leaflet perforation, or paravalvular leakage. Anorectic drugs, such as fenfluramine and phentermine ("fen-phen"), may cause AR through a serotonin-mediated pathway that results in degenerative changes in valve morphology. Additionally, aortic pathology such as ascending dissection or aortic root dilation can cause malcoaptation of the valve and resultant AR. A rare cause of AR is the supracristal VSD, which can result in AR due to prolapse of the noncoronary leaflet.

Of the causes listed above, aortic dissection and endocarditis often cause acute severe AR. This is usually poorly tolerated from a hemodynamic perspective, primarily due to a degree of LV compliance that does not accommodate the

massive increase in volume and leads to acute volume overload and diminished cardiac output. As a result, acute AR is usually a surgical emergency.

The degree of regurgitation is dependent on the diastolic pressure gradient between the aorta and LV, duration of diastole, size of the regurgitant orifice, and LV compliance. In chronic AR, compensatory LV cavity dilation, increase in LV compliance, and LV wall hypertrophy ensue to accommodate the increased filling and afterload. Maintenance of an adequate heart rate (i.e., judicious use of negative chronotropic agents) is also important to minimize diastolic regurgitation time. Together, these changes allow the LVEDP to stay relatively normal and stroke volume to increase. Patients may therefore remain asymptomatic for long periods of time and develop symptoms or LV dysfunction at an average of 4.3% per year [5].

It should also be noted that since diastolic pressure in the aorta is reduced in patients with AR, coronary perfusion pressure is also reduced. Patients may therefore develop symptoms of coronary insufficiency, even in the absence of flow-limiting coronary stenoses, due to decrease coronary flow and increased LV oxygen demand.

Physical Examination

In acute AR, the hallmark diastolic murmur of AR may not be appreciated as easily, since the aortic diastolic and LV diastolic pressures equalize rapidly, and patients are often quite tachycardic due to hemodynamic instability. This also highlights the importance of the judicious use of agents that decrease chronotropy (i.e., beta blockers, non-dihydropyridine calcium-channel blockers, etc.), as slower heart rates allow a longer period of regurgitation.

With chronic AR, however, the long-standing increase in LV volume and concomitant hypertrophy allow the ventricle to accommodate a long period of diastolic backflow through the regurgitant lesion, providing the classic auscultatory diastolic murmur. The murmur is best heard at the aortic position (left sternal border) and may be more easily appreciated with the patient leaning forward. Typically, AR due to aortic dilation is heard at the right sternal border, and that due to valvular disease is heard at the left sternal border. A murmur resembling mitral stenosis (MS) may also be heard at the apex. It is thought that this *Austin Flint* murmur is the result of premature closure of the anterior mitral leaflet due to pressure from the regurgitation jet of AR.

Measurement of the blood pressure often reveals a widened pulse pressure (SBP – DBP). This is due to the fact that the SBP is increased in the setting of higher stroke volume and DBP is decreased due to the regurgitation of blood into the LV.

The peripheral examination in AR provides a number of eponymous findings that have variable degrees of sensitivity and specificity for diagnosis (Table 17.3) [10]. Most of these findings are the result of an increase in stroke volume accompanied by a sudden drop in aortic pressure due to the valvular regurgitation (i.e., wide pulse pressure). Although the majority of these clinical findings lack significant clinical relevance, two signs, Durozier's sign and Hill's sign, have demonstrated clinical correlation with the severity of AR.

Table 17.3 Physical findings in the peripheral examination of severe aortic regurgitation

Physical sign	Description
Corrigan's pulse ("water hammer pulse")	Rapid rise and fall of the arterial pulse
Duroziez's sign	"To-and-fro" murmur heard at the femoral artery elicited with femoral artery compression
Quincke's sign	Capillary pulsations at the nail bed elicited by gentle compression of the distal nail
de Musset's sign	Bobbing of the head
Mueller's sign	Pulsation of the uvula
Hill's sign	Lower extremity BP > upper extremity BP
Rosenbach's sign	Pulsatile liver
Gerhard's sign	Pulsatile spleen

Echocardiography

When suggested by history and physical examination, echocardiography provides the definitive diagnosis of AR and provides an assessment of valve morphology, LV size and function, aortic root structure, and of course regurgitation severity.

An assessment of valve anatomy is important to define the etiology of AR. Congenital bicuspid valve disease is responsible for most cases of valvular AR in the developed world, though rheumatic disease remains the most common cause worldwide. In patients with a bicuspid valve, an assessment of the degree of leaflet degeneration and calcification is important to determine whether valve repair may be feasible or whether valve replacement will be necessary. Similarly, assessment for endocarditis is important for antibiotic management and planning the treatment strategy (i.e., large vegetation, presence of abscess, leaflet perforation, etc.).

LV size and systolic function are important to the treatment algorithm. In patients with severe, asymptomatic AR, surgery is not indicated unless there is evidence of LV dilation (end-diastolic dimension >7.5 cm or end-systolic dimension >5.5 cm) or systolic dysfunction (LVEF <50%). It is therefore recommended that patients with chronic AR have close echocardiographic surveillance in the absence of symptoms (every 1 year with mild/moderate AR and every 6 months with severe AR) [5].

Evaluation of ascending aorta and root structure is important for diagnosis and also may dictate the course of management. For instance, in patients with bicuspid AV, dilation of the aorta beyond 5 cm is considered an indication for surgery, and concomitant AV surgery may therefore be performed even in the absence of symptomatic AR. Aortic dissection involving the ascending aorta is a surgical emergency and should be managed accordingly as appropriate.

An accurate assessment of AR severity is nuanced and requires a critical appraisal of numerous parameters taken together. Considerations include regurgitant jet width/LVOT height, vena contracta (VC), calculation of the proximal isovelocity surface area (PISA), subjective appearance of AR jet density and pressure half-time (PHT) of the AR jet on continuous-wave (CW) Doppler, and evidence of diastolic flow reversal in the descending aorta using pulsed-wave (PW) Doppler (Table 17.4).

Table 17.4 Echocardiographic characteristics of severe aortic regurgitation (AR)

Vena contracta	>0.6 cm
Jet width/LVOT height	>60%
PISA	ERO > 0.3 cm^2
Pressure half-time	<250 msec
Descending aorta pulsed-wave Doppler	Pandiastolic reversal of flow with velocity >20 cm/sec

LVOT left ventricular outlflow tract, *ERO* effective regurgitant orifice

The regurgitant jet width is measured in the LVOT in the parasternal long-axis view and compared to the height of the LVOT; a ratio of >60% indicates severe AR. The VC is usually measured in the same view (though the apical five-chamber view may be used) and is the width of the jet at its narrowest point at the AV; a width of >0.6 cm signifies severe AR. By definition, the VC is smaller than the regurgitant jet width.

The PISA method is used most commonly in the assessment of mitral regurgitation (discussed in detail later in this chapter) but can be applied in AR as well to calculate the effective regurgitant orifice (ERO). An ERO >0.3 cm^2 is considered severe.

The basis for measuring PHT (the time required to reduce the gradient across the valve by ½) is as follows: with worsening AR, the aortic diastolic pressure and LVEDP equilibrate more quickly, resulting in a shorter PHT. A PHT < 250 msec signifies severe AR and PHT > 400 msec mild AR. While this method is used clinically, it should be noted that changes in loading conditions (i.e., alterations in SVR, LV compliance) may have effects on the PHT that are contrary to the regurgitant fraction measured. Furthermore, patients with chronic AR may have modified their LV compliance enough that the LV accommodates a long period of diastolic filling (i.e., long PHT). Therefore, the PHT should be used only as a piece of the diagnostic puzzle [11]. Evaluation of the AR jet density on

CW is a subjective measure, and pitfalls include a lack of coaxial alignment of the Doppler signal with the regurgitant flow. Nevertheless, a dense jet with a short PHT may increase the suspicion of severe AR. It should also be noted that due to the large stroke volume ejected by the LV in chronic severe AR, there may be a small outflow gradient measured though this does not reflect true AS.

The presence of some regurgitant flow in the descending aorta in early diastole is common and is due to closure of the AV. Persistent holodiastolic flow reversal with a velocity >20 cm/sec, however, is a marker of severe AR (Fig. 17.3). The presence of diastolic MR (appreciated on the CW or PW Doppler in the apical four-chamber view) may be seen in patients with severely elevated LV pressures, such as in acute severe AR.

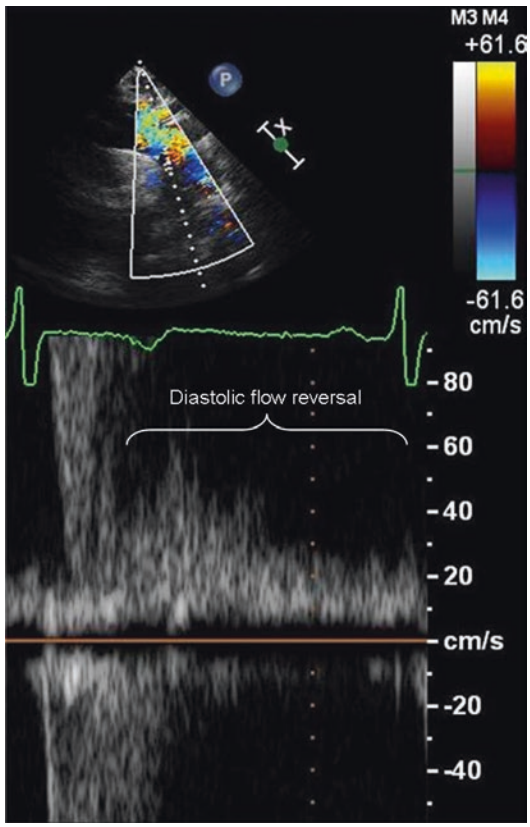

Fig. 17.3 Pulsed-wave Doppler demonstrating pandiastolic flow reversal in the descending thoracic aorta in a patient with severe aortic regurgitation

Cardiac Catheterization

Invasive catheterization holds a diminishing role in the diagnosis of AR. Similar to patients with AS, it is recommended only when the clinical scenario is not substantiated by noninvasive testing. Catheterization can be used to measure the LVEDP, examine the aortic pressure tracing, and quantify the degree of AR.

The aortic pressure tracing reveals elevated SBP (due to increased stroke volume) and a rapid systolic upstroke due to heightened LV contractility. The pulse pressure is widened (as discussed above), and diastolic aortic pressure approximates LVEDP near the end of diastole. In patients with chronic AR, increased LV compliance results in an LVEDP that is near-normal or only mildly elevated. In acute AR, there is a steep, marked rise in LVEDP. The SBP is reduced due to a decline in stroke volume.

The degree of AR is measured using ascending aortography by placing a pigtail catheter in the aortic root, 2 cm above the AV. A left anterior oblique (LAO) projection is selected to properly visualize the ascending aorta and branching arch vessels. Use of a power injector is mandatory, and generally 40 cc of dye is necessary to properly opacify the aorta. The AR is evaluated over two cardiac cycles and quantified as follows: incomplete LV opacification (1+); moderate LV opacification < aortic root opacification (2+); LV opacification = aortic root opacification within two cycles (3+); immediate LV opacification > aortic root opacification (4+).

Mitral Stenosis

Case Presentation

A 48-year-old woman presented to the emergency department with complaints of progressive dyspnea over the past 3 weeks associated with orthopnea and mild lower extremity edema. She had not noticed any chest discomfort or palpitations. She had been having less urine output over the past week, despite a relatively stable diet. She reported a history of rheumatic fever as a teenager, but had

not been followed by a physician for a number of years. She was therefore unaware of any other medical problems.

On examination, she was in mild distress manifest as tachypnea and labored breathing. She was tachycardic with an irregular heart rate of 120 bpm and a BP of 100/65 mmHg. The cardiovascular exam was significant for an opening snap (OS) heard at the left lower sternal border just after the S2, with a short interval between the S2 and OS, followed by a mid-diastolic murmur at the apex heard best in the left lateral position. The JVP was elevated to the angle of the jaw while sitting upright. Examination of the periphery revealed 2+ lower extremity edema bilaterally to the shins and cool extremities.

An ECG revealed atrial fibrillation with a ventricular rate of 125 bpm and no evidence of ischemic changes. Given the examination findings, urgent bedside echocardiography was performed and revealed a low-normal LV ejection fraction (50%) and mild aortic valve thickening and calcification. Most significant was a doming appearance of the anterior mitral leaflet, restricted motion of the posterior mitral leaflet, and fusion of the leaflets at both commissures. The peak and mean gradients across the mitral valve were 34 and 20 mmHg, respectively.

With a clinical diagnosis of suspected cardiogenic shock due to decompensated heart failure and severe mitral stenosis complicated by rapid atrial fibrillation, the patient was moved urgently to the cardiac intensive care unit. Pulmonary artery catheterization (Swan-Ganz) confirmed the diagnosis with a cardiac index of 1.5, PCWP of 35 mmHg, and mixed venous oxygen saturation of 40%. Urgent cardioversion was performed and was successful in restoring a normal sinus rhythm of 70 bpm. With restoration of the rhythm, the patient's urine output increased immediately, and treatment of her volume overload was continued. Repeat TTE revealed a decrease in the mean mitral gradient to 12 mmHg. After successful management of her acute episode, the patient went on to have successful percutaneous mitral balloon valvotomy which decreased her mean mitral gradient to 4 mmHg.

Epidemiology and Pathophysiology

Mitral stenosis (MS) was the first valvular lesion to be diagnosed echocardiographically and treated surgically. Rheumatic heart disease is the leading cause of MS worldwide (prevalence of 6 per 1000 children, compared with 0.5 per 1000 in the United States) [12]. In developed countries, other etiologies such as severe mitral annular calcification due to end-stage renal disease (ESRD), endocarditis, inflammatory disorders (i.e., lupus and rheumatoid arthritis), radiation therapy, and LA myxoma causing MV obstruction are more often considered. MS is a slowly progressive disease that eventually leads to atrial fibrillation (AFib), pulmonary hypertension, and decreased cardiac output. Once symptoms develop, patients face a dismal prognosis, with a 10-year mortality of 70% [13].

In rheumatic fever, inflammation results in nodule formation at the leaflet edge, followed by leaflet thickening, commissural fusion, and chordal thickening and shortening. Smoldering inflammation coupled with turbulent flow across the valve leads to progressive valvular dysfunction [14]. Patients with end-stage kidney disease have disordered calcium metabolism and resultant mitral annular calcification (MAC). As calcification of the annulus progresses to involve the leaflets, obstruction to flow across the valve may occur due to the smaller mitral orifice and restricted leaflet motion [15]. In contrast to rheumatic MS, in which the smallest valve area is at the leaflet tips, obstruction in non-rheumatic MS is predominantly at the annular level.

Physical Examination

The classic findings of MS include the opening snap and mid-diastolic murmur. The source of the OS is mobility of the anterior mitral leaflet and is usually heard best at the LLSB; it is generally not appreciated at the apex. The OS may be differentiated from physiologic splitting of the S2 during exhalation (when the presence of two sounds indicates the OS of MS). A short interval

between the S2 and OS indicates severe MS, as a high LA pressure causes quick opening of the mitral valve in diastole.

The murmur of MS is best heard in the left lateral decubitus position with the stethoscope placed at the ventricular PMI. As with other valve lesions, a louder murmur signifies a large degree of flow (and hence a higher gradient) across the valve. Similarly, in patients with atrial fibrillation, a diastolic murmur leading up to the S1 during a long R-R interval implies severe MS with a persistent gradient even at the end of diastole.

Echocardiography

A subjective assessment of the mitral valve apparatus involves an appraisal of leaflet mobility (typically "doming" of the anterior leaflet and restriction of the posterior leaflet) and thickness, as well as the degree of thickening, calcification, and/or fusion of the commissures and subvalvular apparatus. The systematic scoring system provided by Wilkins and colleagues takes these factors into consideration and is also useful in assessing the feasibility of percutaneous balloon mitral valvotomy (Table 17.5) [16].

The objective evaluation of MS includes a measurement of valve area, valve gradient, and pulmonary artery pressure (PAP) (Table 17.6) [17]. The mitral valve area (MVA) can be assessed using planimetry in the parasternal short-axis projection, though a common pitfall of this method is measuring proximal to the true orifice and thereby overestimating the MVA. Valve area is also estimated using the PHT method, which as with AR is a measure of the time it takes for the gradient across the valve to fall by one-half (Fig. 17.4). Notably, the PHT method is unreliable in patients with severe AR or significant LV diastolic dysfunction since the pressure gradient between the LA and LV equalizes rapidly, providing an abnormally short PHT (thereby overestimating MVA).

The valve gradient in MS is best assessed by tracing the mitral inflow Doppler signal obtained in the apical four-chamber view (Fig. 17.5). The main consideration is the mean gradient, which is automatically calculated by summing the gradient over the cardiac cycle. As shown in the figure,

Table 17.6 Echocardiographic evaluation of mitral stenosis severity

	Mild	Moderate	Severe
Mean gradient	<5 mmHg	5–10 mmHg	>10 mmHg or >15 mmHg with stress
Valve area	>1.5 cm^2	1.0–1.5 cm^2	<1.0 cm^2
Pulmonary artery systolic pressure	<30 mmHg	30–50 mmHg	>50 mmHg or >60 mmHg with stress

Table 17.5 Echocardiographic scoring system for mitral valve stenosis. A score ≤8 is generally associated with favorable outcome from percutaneous mitral balloon valvotomy

Grade	Mobility	Subvalvar thickening	Thickening	Calcification
1	Highly mobile valve with only leaflet tips restricted	Minimal thickening just below the mitral leaflets	Leaflets near normal in thickness (4–5 mm)	A single area of increased echo brightness
2	Leaflet mid and base portions have normal mobility	Thickening of chordal structures extending up to one-third of the chordal length	Mid-leaflets normal, considerable thickening of margins (5–8 mm)	Scattered areas of brightness confined to leaflet margins
3	Valve continues to move forward in diastole, mainly from the base	Thickening extending to the distal third of the chords	Thickening extending through the entire leaflet (5–8 mm)	Brightness extending into the mid-portion of the leaflets
4	No or minimal forward movement of the leaflets in diastole	Extensive thickening and shortening of all chordal structures extending down to the papillary muscles	Considerable thickening of all leaflet tissue (>8–10 mm)	Extensive brightness throughout much of the leaflet tissue

Reproduced with permission from Wilkens et al., Br Heart J. 1988 Oct;60 (4):299–308

a shorter R–R interval results in a marked increase in mitral gradient and highlights the need for appropriate heart rate control in patients with MS, particularly those with concomitant atrial fibrillation.

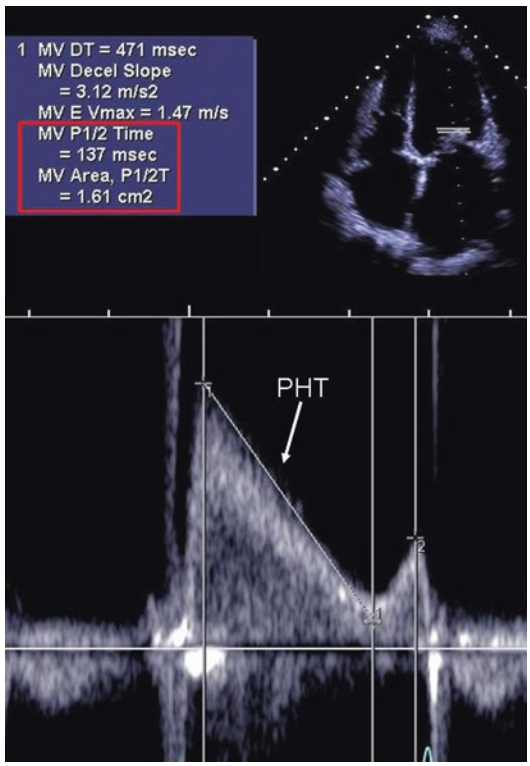

Fig. 17.4 Pulsed-wave Doppler of mitral inflow demonstrating calculation of the mitral valve area (MVA) using the pressure half-time (PHT) method. MVA = 220/PHT

An estimation of pulmonary pressures using the right ventricular systolic pressure (RVSP) is an important part of the evaluation of MS. An RVSP >50 mmHg at rest or > 60 mmHg on exercise TTE is consistent with significant pulmonary hypertension and provides an indication for intervention of MS.

Cardiac Catheterization

As with other valve disorders, catheterization is recommended in the diagnosis of MS when there is discrepancy between the clinical scenario and noninvasive methods [5]. Right heart catheterization (RHC) is often indispensable in the critical care unit to guide management of volume status in patients presenting with pulmonary congestion, depressed cardiac output, and severe mitral stenosis.

The mitral valve gradient is measured by taking simultaneous pressure tracings via an LV catheter and either a pulmonary artery catheter in the wedge position (PCWP) or a direct left atrial catheter (Fig. 17.6). Use of the PCWP is unreliable in patients with pulmonary veno-occlusive disease. It is also important to remember that the "true" wedge pressure is the measured PCWP minus the mean mitral gradient.

As discussed above, the mean gradient is exquisitely sensitive to heart rate, since a faster heart rate leaves less time for diastolic emptying

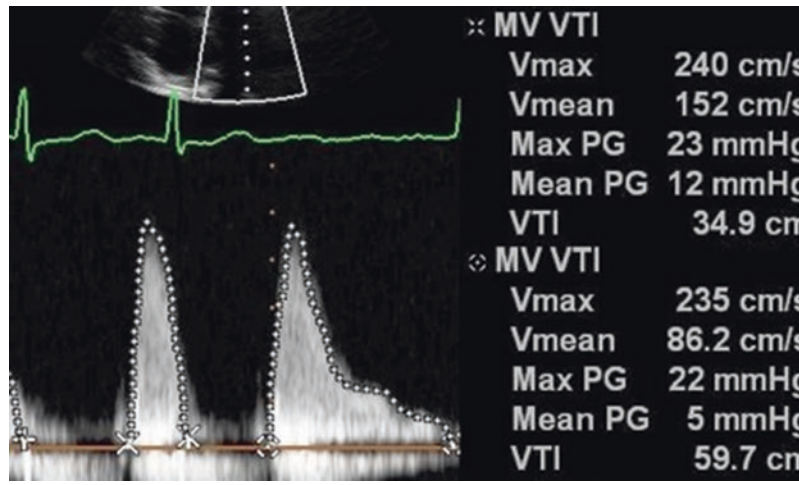

Fig. 17.5 Patient with moderate mitral stenosis and atrial fibrillation. The mean gradient across the mitral valve is significantly increased in the setting of decreased diastolic filling time (i.e., increased heart rate) (beat 1:12 mmHg vs. beat 2:5 mmHg)

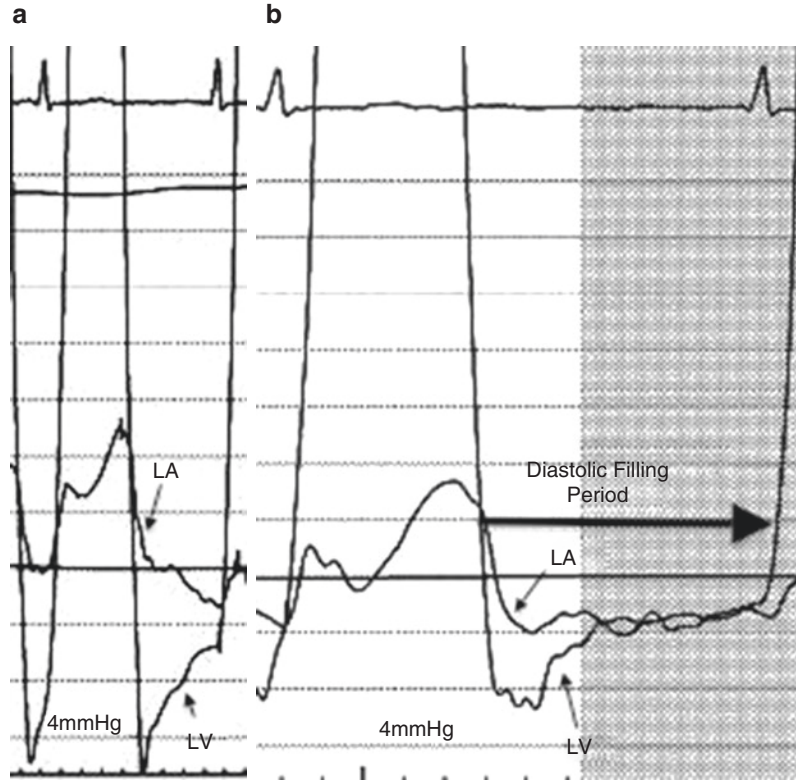

Fig. 17.6 Simultaneous measurement of left atrial (LA) and left ventricular (LV) pressures in a patient with mitral stenosis before (**a**) and after (**b**) percutaneous mitral balloon valvuloplasty. Prior to PMBV, a substantial gradient is present until the end of diastole. In this patient, the pre-procedural resting gradient was 10 mmHg, and post-procedural gradient was 4 mmHg. Paper speed is faster in panel A

of the atrium and results in a higher gradient. In patients with atrial fibrillation, it is therefore recommended to average the gradient over ten cardiac cycles.

The valve area is estimated using the Gorlin formula as follows:

$$\text{MVA} = \left(\text{SV} \div \text{DFP}\right) \div \left(37.7 \times \sqrt{\text{mean gradient}}\right)$$

[SV, stroke volume; DFP, diastolic filling period]

Of note, calculation of the SV using the thermodilution method is not accurate in patients with low cardiac output or significant tricuspid regurgitation. As in patients with AS, the valve area can also be calculated using the Hakki equation:

$$\text{MVA} = \text{CO} \div \sqrt{\text{mean gradient}}$$

In patients with a HR <75 bpm, the value above is divided by 1.35 to provide greater accuracy.

Mitral Regurgitation

Case Presentation

The patient is an 87-year-old man with prior history of diabetes, hypertension, hyperlipidemia, and chronic kidney disease (Stage IV, GFR 25 mL/min/1.73 m^2). He had undergone two prior coronary bypass graft operations, with recent angiography showing patent grafts to the left anterior descending, circumflex, and right coronary arteries. He noted worsening exertional dyspnea over the past 12 months, with recently increasing orthopnea and lower extremity edema. He had initially experienced relief with an increasing dose of diuretics and hydralazine, but his symptoms again worsened.

Physical examination revealed atrial fibrillation with a controlled heart rate of 80 bpm and BP 110/75 mmHg. The PMI was laterally displaced to the mid-axillary line, and there was a 3/6 systolic murmur heard best at the apex and

radiating to the axilla as well as the spine posteriorly. The JVP was elevated at 12 cm H_2O. TTE revealed severely depressed LV function (EF 25%) with moderate LV cavity dilation and moderate LA enlargement. There was severe, posteriorly directed mitral regurgitation due to MV annular dilation, apical displacement of the mitral leaflets, and restriction of the posterior mitral valve.

Given the patient's age, co-morbidities, and two prior open-heart surgeries, he was deemed an inoperable risk for surgical mitral valve repair. He therefore underwent percutaneous mitral valve repair using the MitraClip device (approximating the Alfieri stitch method of surgical repair), which provided a substantial reduction in his degree of MR and improvement in his clinical symptoms.

Epidemiology and Pathophysiology

Mitral regurgitation (MR) affects more than two million people in the United States [18]. Classification of MR is broadly defined by two groups: primary and secondary MR. Primary MR, which is a disorder of the valve itself, is most commonly due to myxomatous (degenerative) disease or mitral valve prolapse (MVP; Barlow's Disease) in the developed world and rheumatic disease in developing countries. Secondary MR is the result of a disordered left ventricular geometry and is usually referred to as "functional" or "ischemic" MR. In secondary MR, annular dilation, apical tethering of the MV leaflets, and/or excessive leaflet motion due to chordal avulsion or papillary muscle rupture lead to the regurgitant lesion.

Acute MR is most often caused by myocardial infarction that leads to papillary muscle rupture or chordal avulsion, supranormal contraction of the non-infarcted papillary muscle, or regional LV dysfunction. Similar to acute AR, it is a severe volume overload state that results in pulmonary edema and depressed cardiac output. Management requires urgent pharmacologic and mechanical afterload reduction and timely surgical referral. Chronic MR, over time, results in a volume overloaded state for the LV and leads to LV dilation and dysfunction, LA enlargement, atrial fibrillation, and pulmonary hypertension.

Physical Examination

A salient physical finding in patients with MR includes the classic high-pitched, holosystolic murmur heard at the apex with radiation to the axilla. If the MR is due to MV prolapse, the murmur may not start until mid-systole, after prolapse of the affected leaflet(s). In patients with severe, posteriorly directed MR (i.e., functional MR or patients with anterior leaflet prolapse), the murmur may also be appreciated by auscultation at the thoracic spine. With posterior prolapse, the regurgitant jet is directed anteriorly and may be best heard at the upper sternal border (similar to AS). The severity of the murmur does not correlate well with the severity of the MR, as other factors including LV cavity dilation and depressed cardiac output can diminish the murmur in the setting of severely decompensated disease. Similar to the murmur in AS, the sound is augmented by increasing afterload (i.e., handgrip) and diminished by reducing venous return (i.e., Valsalva maneuver).

The S1 sound is often diminished due to poor coaptation of the MV leaflets, and the S2 sound may be widely split due to a premature closure of the aortic valve (A2 component) in the setting of poor forward output. In patients with MV prolapse, a mid-systolic click may be appreciated at the time of maximum leaflet prolapse. With heart failure and a dilated LV, an S3 gallop may be also heard. The peripheral exam in severe MR often reveals a prominent upstroke and reflects the increased left ventricular ejection volume, similar to severe AR. In contrast to the pulse in AR, however, the pulse pressure with severe MR is normal.

Echocardiography

Echocardiography is used to quantify MR, evaluate the presence of valve pathology and define

the specific nature of the lesion, and evaluate LV size and systolic function. Quantification of MR is based on a number of parameters including color Doppler, continuous and pulsed-wave Doppler, and pulmonary venous flow pattern (Table 17.7) [19]. Color Doppler imaging can provide an overall impression of the degree of regurgitation based upon the visual estimation of the regurgitant jet in the LA. Slightly more quantitative methods include measurement of the vena contracta (thinnest portion of the regurgitant jet at the regurgitant orifice) and measurement of the regurgitant jet area (RJA) relative to the LA area.

Table 17.7 Echocardiographic determinants of mitral regurgitation severity

	Mild	Moderate	Severe
Color flow mapping			
RJA/LAA	<20%	20–40%	>40%
VC (cm)	<0.40	0.40–0.69	>0.70
ERO (cm^2)	<0.20	0.20–0.40	>0.40
RV (ml/beat)	<30	30–60	>60
Pulsed-wave Doppler			
Mitral E-wave velocity			>1.2 m/sec
PV flow pattern			Systolic blunting or reversal

RJA regurgitant jet area, *LAA* left atrial area, *VC* vena contracta, *ERO* effective regurgitant orifice, *RV* regurgitant volume, *PV* pulmonary vein

The proximal isovelocity surface area (PISA) method, as discussed previously in the evaluation of AR, provides the most precise echocardiographic estimation of MR. Briefly, the technique is based upon the idea that as blood converges toward a regurgitant orifice, velocity increases and forms a series of hemispheric shells with the same velocity (hence isovelocity). The velocity at a given shell can be set on the machine as the "aliasing velocity," and calculation of the area bounded by the shell (by measuring the radius) provides the flow at the surface of the shell. Since flow is constant (i.e., conservation of flow principle), the ERO can be calculated as in Fig. 17.7 using the color flow Doppler envelope and the continuous-wave (CW) Doppler tracing to measure MR velocity. If the MR velocity is assumed to be 5 m/sec, and the aliasing velocity set at 40 cm/sec, the PISA formula can be simplified as follows: ERO = $r^2/2$. The regurgitant volume can also be calculated using the

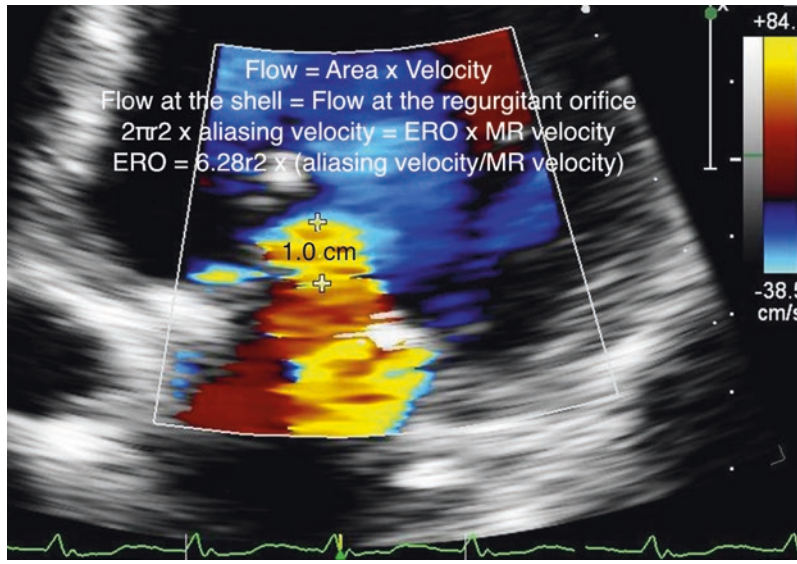

Fig. 17.7 Demonstration of the mitral regurgitation (MR) jet and calculation of the proximal isovelocity surface area (PISA). In this patient with an aliasing velocity set at 38.5 cm/sec and a MR velocity of 500 cm/sec (not shown), the simplified effective regurgitant orifice (ERO) calculation can be used ($r^2/2$), providing an ERO of 0.5 cm^2, which is consistent with severe MR. (Adapted with permission from Krishnaswamy et al., Coron Art Dis 2011)

following: $R_{vol} = ERO \times MR_{VTI}$ (MR_{VTI} is obtained by tracing the MR envelope on CW Doppler).

Pulsed-wave (PW) Doppler is used to interrogate the mitral inflow and stage diastolic function. In the setting of MR, assessment of the peak inflow velocity is useful in quantification. Severe regurgitation results in a higher LA–LV gradient and therefore a higher E-wave velocity during mitral inflow. Use of PW Doppler is also important to evaluate the pulmonary vein flow, specifically for the presence of systolic blunting or reversal in the pulmonary veins that signifies elevated LA pressure (assumedly due to severe MR).

Cardiac Catheterization

Invasive hemodynamic assessment in patients with MR is rarely necessary but may be performed when noninvasive testing is not definitive. In acute MR, the PCWP tracing (or direct LA measurement) demonstrates a large "v" wave due to the large volume of regurgitant blood into a low-compliance LA, and the amplitude of the "v" wave and the LV systolic pressure may be nearly equivalent (Fig. 17.8). It is important to keep this in mind during percutaneous balloon mitral valvotomy as an indicator of complications. The volume overload of the regurgitant lesion on the LV results in elevated LV pressures as well.

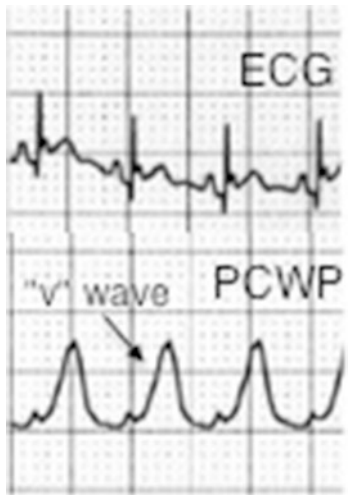

Fig. 17.8 Pulmonary artery catheter pressure tracing in the wedge position (PCWP) in a patient with acute severe mitral regurgitation due to papillary muscle rupture complicating acute myocardial infarction demonstrates a large v-wave

In patients with chronic MR, compliance of the LA increases over time (as does the LV in chronic AR). The "v" wave is therefore smaller than that seen with acute MR. The use of vasodilators in chronic MR produces a similar result. The LV responds to the chronic volume overload of MR as it does in chronic AR and compliance increases, resulting in a less drastic increase in LV pressures than in acute MR.

Ventriculography can also be used to assess the severity of MR. Grading of the regurgitation employs a similar scale as in AR: 1+ = brief LA opacification without LA enlargement; 2+ = moderate LA opacification less than LV opacification and without LA enlargement; 3+ = equal LA and LV opacification that clears over many cycles and with LA enlargement; and 4+ = immediate LA > LV opacification with pulmonary vein filling and LA enlargement. Caution should be exercised in performing ventriculography in patients with MR, in light of the contrast load that it requires in patients who may already be volume overloaded.

Review Questions

Q1. A 74-year-old man presented with exertional dyspnea and orthopnea. Echocardiography revealed a moderately thickened and calcified trileaflet aortic valve with severely restricted motion and an LVEF 20%. Results of interrogation of the AV were performed at rest and with infusion of dobutamine as follows:

Rest		*DBA*	
LVEF	20%	LVEF	25%
LVOT diameter	2.4 cm	LVOT diameter	2.4 cm
LVOT VTI	15.9 cm/sec	LVOT VTI	20.2 cm/sec
Calculated AVA	0.6 cm^2	Calculated AVA	0.9 cm^2

What is the appropriate next step?

(a) Refer for aortic valve replacement
(b) Refer for invasive hemodynamic study
(c) Medical management of LV dysfunction
(d) Refer for balloon aortic valvuloplasty

A1. C. This case demonstrates the diagnosis of "pseudo-AS," for which management of the underlying LV systolic dysfunction is appropriate. In patients with low-flow, low-gradient AS, provocative testing with DBA infusion may be helpful to distinguish true- and pseudo-AS. In this patient, the stroke volume (LVOT area x LVOT VTI) is 71 mL and at stress is 91 mL. This increase of >20% implies the presence of contractile reserve. The increase in calculated AVA of 0.3 cm^2 with stress provides evidence of improved AV leaflet excursion with higher SV; i.e., the "stenosis" is not fixed due to an intrinsic leaflet issue. Surgical intervention or valvuloplasty is not helpful in this setting. An invasive study is not necessary as the diagnosis is clear by echocardiography alone.

Q2. A 45-year-old woman with a history of rheumatic fever presents with worsening exertional dyspnea. Physical examination reveals a regular rate and rhythm. Cardiac auscultation reveals an opening snap and diastolic murmur heard at the apex. There is no lower extremity edema, and the JVP is appreciated at 5 cm above the sternum. Transthoracic echocardiography reveals a normal LVEF, doming of the anterior MV leaflet with restriction of the posterior MV leaflet, and a mean gradient across the MV of 7 mmHg. The estimated RVSP is 40 mmHg. What is the next step in management?

(a) Evaluate noncardiac causes of dyspnea
(b) Perform exercise echocardiography to evaluate the MV
(c) Refer for invasive cardiac catheterization to evaluate the MV
(d) Return for follow-up echocardiogram in 6 months

A2. B. This patient with a history of rheumatic fever presents with exertional dyspnea and a typical echocardiographic appearance of rheumatic mitral valve disease. The mean valve gradient is moderate at best, with a suggestion of borderline pulmonary hypertension (RVSP 40 mmHg). Given the patient's exertional symptoms, however, exercise echocardiography would be the next appropriate step in order to evaluate the MV gradient and pulmonary pressures with exertion. In this patient, TTE during stress revealed a mean MV gradient of 16 mmHg and RVSP of 65 mmHg. She subsequently underwent percutaneous balloon mitral valvuloplasty and was symptom-free with significant exertion afterward. Cardiac catheterization is considered to be less accurate in the evaluation of MS than echocardiography, and is therefore not yet indicated in this patient.

Q3. A 42-year-old man with bicuspid aortic valve seeks to establish a new cardiologist after many years of loss to follow-up. He does not take any medications. He feels well and exercises on a treadmill for 45 minutes 4 times per week. He has no exertional or positional dyspnea. On exam, his HR is 70 bpm and BP 115/50 mmHg. He has a holodiastolic murmur heard best at the left sternal border, and peripheral exam reveals bounding pulses with rapid collapse. TTE reveals normal LVEF 60% with LVIDd 7.2 cm and LVIDs 5.7 cm and a bicuspid aortic valve, and quantification of the degree of AR provides a vena contract of 0.7 cm, PHT 200 msec, and holodiastolic flow reversal in the descending aorta. What is the best next step?

(a) Routine clinical follow-up with TTE in 6 months
(b) Initiation of an ACE-inhibitor
(c) Referral for aortic valve surgery
(d) Exercise stress testing

A3. C. This patient with asymptomatic severe AR demonstrates LV cavity dilation (LVIDd >7.5 cm or LVIDs >5.5 cm), which is a criteria for aortic valve repair or replacement in patients with asymptomatic but severe AR (ACC/AHA Class IIa). For patients with severe AR and normal LV cavity size but without symptoms, follow-up echocardiography is indicated every 6 months (ACC/AHA Class I). Vasodilators are reasonable for symptomatic relief in patients with severe AR (Class IIa), but should not supersede definitive treatment in the setting of LV cavity dilation. Exercise stress testing may be helpful to distinguish whether or not the "asymptomatic" patient is truly asymptomatic (ACC/AHA Class

IIa), but the patient described here has LV cavity dilation and therefore symptoms are not necessary to make the recommendation for surgery.

Q4. A 67-year-old man with hypertension and hyperlipidemia presents with an inferior STEMI and undergoes primary percutaneous coronary intervention to a proximally occluded right coronary artery. The procedure is uneventful, and he is transferred to the cardiac ICU in stable condition. Fourteen hours later, he develops sudden hypotension and dyspnea. There are no new ECG changes. Which of the following would be expected of diagnostic testing:

(a) Large "v"-wave on a PCWP tracing
(b) LA > LV opacification within 1 cycle on a ventriculogram
(c) Pulmonary vein flow reversal during systole on TTE
(d) All of the above

A4. D. The patient above provides a classic presentation of mechanical complication after acute MI, in this case with severe MR due to papillary muscle rupture. Choices A–C all provide diagnostic evidence for severe MR. Appropriate management consists of emergent afterload reduction (using intra-aortic balloon counterpulsation and/or vasodilators if tolerated) and surgical referral for mitral valve surgery.

Q5. A 40-year-old man presents with worsening exertional dyspnea over the past 1 week, along with fevers to 102 degrees. He admits to regular intravenous drug use and claims to have had a "murmur" since childhood. His bedside echocardiogram suggests severe AR. What other diagnostic findings would be expected?

(a) Holodiastolic murmur at the left sternal border
(b) Bradycardia
(c) AR Pressure half-time <250 msec
(d) Systolic murmur resembling MR heard at the apex

A5. C. In acute AR, the rapid rise in LV pressure due to a noncompliant chamber results in rapid equilibration of aortic and LV pressures and results in a short pressure half-time. The hallmark diastolic murmur of AR may not be appreciated as easily in the acute setting for the same reason. Patients with acute AR are often quite tachycardic due to the poorly tolerated hemodynamic consequences of the lesion. The *Austin Flint* murmur of AR resembles the murmur of MS, and is thought to be due to premature closure of the anterior MV leaflet by the regurgitant AR jet.

Pulmonary Hypertension

18

Jordan D. Awerbach and Richard A. Krasuski

Introduction

The pulmonary circulation is normally a low-pressure, low-resistance, and highly compliant system. Pulmonary hypertension (PH) is a pathologic state characterized by an elevation in the mean pulmonary arterial pressure (mPAP). PH may occur as a primary process, though it is most often a complication of other chronic disease states, particularly heart failure and chronic lung disease. Globally, it is helpful to dichotomize PH into precapillary PH, or pulmonary arterial hypertension (PAH), and postcapillary PH, the so-called pulmonary venous hypertension (PVH). Patients may also present with a combination of both. Patients with PAH, regardless of etiology, share common pulmonary vascular changes that define this form of PH. Vasoconstriction and progressive endothelial dysfunction lead to pulmonary vascular remodeling that ultimately results in the obliteration of the pulmonary vasculature and increased pulmonary vascular resistance (PVR) [1].

Right heart catheterization (RHC) remains the gold standard for diagnosing PH and differentiating pre- from postcapillary forms of PH. Classification systems have evolved over time and currently recognize five major etiologies of PH (Table 18.1) [2]: Group 1, PAH; Group 2, PH owing to left-sided heart disease; Group 3, PH due to pulmonary disease or hypoxia; Group 4, chronic thromboembolic PH (CTEPH) and other pulmonary artery (PA) obstructions; and Group 5, PH due to multifactorial mechanisms. PH is hemodynamically defined by a resting mPAP of ≥25 mmHg. Previous definitions have also made reference to mPAP elevation during exercise (to >30 mmHg), but exercise-induced PH in patients with normal resting pressures remains a poorly characterized phenomenon, and recent guidelines have removed this from the definition [3, 4]. PAH is further defined by (1) a PVR >3 Wood units (Wu) and (2) a normal pulmonary capillary wedge pressure (PCWP) (≤15 mmHg).

Epidemiology of Pulmonary Hypertension

The global burden of PH throughout the world has become increasingly recognized [5]. Estimated the prevalence of PH in 2015 at 50–70 million individuals worldwide (about 1% of the global population). Left-sided heart diseases and chronic lung diseases are the most common causes in both industrialized and developing countries. However, the majority of PH is seen in the developing world, where associated diseases including schistosomiasis, rheumatic heart dis-

Table 18.1 World Health Organization classification system for pulmonary hypertension[a] [2]

Group 1: Pulmonary arterial hypertension
1.1 Idiopathic PAH
1.2 Heritable PAH
1.2.1 BMPR2
1.2.2 ALK-1, ENG, SMAD9, CAV1, KCNK3
1.2.3 Unknown
1.3 Drug- and toxin-induced
1.4 Associated with:
1.4.1 Connective tissue disease
1.4.2 HIV infection
1.4.3 Portal hypertension
1.4.4 Congenital heart diseases
1.4.5 Schistosomiasis
1′ Pulmonary veno-occlusive disease and/or pulmonary capillary hemangiomatosis
1″ Persistent pulmonary hypertension of the newborn (PPHN)
Group 2: Pulmonary hypertension due to left heart disease
2.1 Left ventricular systolic dysfunction
2.2 Left ventricular diastolic dysfunction
2.3 Valvular disease
2.4 Congenital/acquired left heart inflow/outflow tract obstruction and congenital cardiomyopathies
Group 3: Pulmonary hypertension due to lung diseases and/or hypoxia
3.1 Chronic obstructive pulmonary disease
3.2 Interstitial lung disease
3.3 Other pulmonary diseases with mixed restrictive and obstructive pattern
3.4 Sleep-disordered breathing
3.5 Alveolar hypoventilation disorders
3.6 Chronic exposure to high altitude
3.7 Developmental lung diseases
Group 4: Chronic thromboembolic pulmonary hypertension (CTEPH)
Group 5: Pulmonary hypertension with unclear multifactorial mechanisms
5.1 Hematologic disorders: chronic hemolytic anemia, myeloproliferative disorders, splenectomy
5.2 Systemic disorders: sarcoidosis, pulmonary histiocytosis, lymphangioleiomyomatosis
5.3 Metabolic disorders: glycogen storage disease, Gaucher disease, thyroid disorders
5.4 Others: tumoral obstruction, fibrosing mediastinitis, chronic renal failure, segmental PH

[a]Reproduced with permission of publisher [2]

ease, human immunodeficiency virus (HIV), and sickle cell disease are more commonly seen. PH in developing countries predominantly affects a much younger population, whereas it is primarily seen in older patients (above age 65) in industrialized countries.

PAH is overall a rare disease, although it has been the primary focus of most clinical investigation and treatment. Based on registry data primarily from Europe and the United States, the prevalence of PAH is around 12–15 cases per million [4, 6]. The majority of cases (40–50%) are idiopathic (iPAH) or are inheritable/familial forms. Twenty percent of sporadic cases of PAH and 80% of heritable PAH have been linked to mutations in the bone morphogenetic protein receptor type 2 (BMPR2) gene [7]. Presence of the BMPR2 mutation in patients with PAH is associated with increased mortality, and these patients typically present at a younger age with more severe disease [8]. Historically, iPAH commonly affected people in their fourth decade of life, but contemporary registries have demonstrated that the mean age of this population has increased to 50–65 years old [9]. Women are affected 3–4 times as often, though men diagnosed with iPAH have an overall worse prognosis [10]. Prior to the era of targeted PAH pharmacotherapies, long-term survival in iPAH was grim, with a median survival of 2.8 years and 1-, 3-, and 5-year survival rates of 68%, 48%, and 34%, respectively [11]. In the current treatment era, those rates have improved to 91%, 74%, and 65% for the same time intervals [12].

Additional important causes of PAH include connective tissue disease (CTD) and congenital heart disease (CHD). Approximately 15–25% of PAH is associated with CTDs. Systemic sclerosis is the most common cause of CTD-associated PAH in the majority of the world, and survival in patients with CTD-PAH is overall worse compared to those with iPAH [5, 12]. CHD-associated PAH accounts for approximately 10% of cases of PAH. The development of PAH in patients with CHD is generally due to the presence of a hemodynamically significant left-to-right (systemic-to-pulmonary) shunt exposing the pulmonary vascular bed to excessive blood flow and, in some cases, chronically elevated pressures. The risk of PAH developing in this population is related to both the chronicity of the shunt as well as its location, with lesions

distal to the tricuspid valve posing the greatest risk, as they permit the transmission of systemic blood pressures to the pulmonary vascular bed. Thus, PAH may also develop in patients with repaired CHD, particularly when the defect is corrected later in life. If CHD is unrepaired, PAH can progress and ultimately result in Eisenmenger syndrome, characterized by shunt reversal, cyanosis, and right heart failure. Interestingly, patients with Eisenmenger syndrome demonstrate better long-term survival in comparison with untreated iPAH patients, with a 77% 3-year survival [4].

Clinical Presentation

The suspicion for PH requires an astute clinician, especially in iPAH, where patients are comparatively younger and typically otherwise healthy. Many patients are often diagnosed years after the onset of symptoms [13]. Initial symptoms are often nonspecific and may be discounted by both the patient and their physician or attributed to other causes such as deconditioning. The clinician must also be proactive in screening for PAH in patients who have associated chronic illnesses, such as systemic sclerosis or HIV infection.

Dyspnea is the most common presenting symptom, seen in 60% of patients diagnosed with PAH [14]. Patients may also complain of fatigue and weakness early in the course of the disease. When untreated, symptom severity will progress as patients develop right heart dysfunction, and patients may present with syncope, arrhythmias, or overt heart failure [4]. The World Health Organization (WHO) functional classification (FC) schema provides one of the most powerful clinical tools for assessing disease severity and prognosis [4]. WHO FC I patients have no physical limitations. FC II patients are asymptomatic at rest but will experience symptoms with ordinary physical activities. FC III patients continue to be asymptomatic at rest but have marked limitations in physical activity. Patients who are FC IV are unable to carry out any physical activity without significant symptoms. They often have rapid progression of symptoms, may be symptomatic at rest, and have signs of right heart failure on exam; frank syncope may occur with exertion and helps define patients between FC III and IV as being FC IV. Patients who are FC IV have a poor prognosis, and when newly diagnosed generally require hospitalization and initiation of IV prostaglandins.

A measured 6-min walk distance (6MWD) performed in clinic provides an objective assessment of functional status. Using the modified Borg dyspnea scale (see Fig. 18.1 – below) to assess for patient effort and monitor oxygen saturation with noninvasive pulse oximetry may add additional prognostic value. Although baseline numbers provide predictive insight into survival, the significance of changes over time remains controversial. Patients who initially walk >440 m demonstrate improved 1-year survival, whereas those who walk <165 m have significantly worse outcome [15]. Formal exercise testing with measurement of oxygen consumption is also an independent predictor for survival and closely correlates with 6MWD.

Physical exam findings vary with disease severity, although most patients will have an

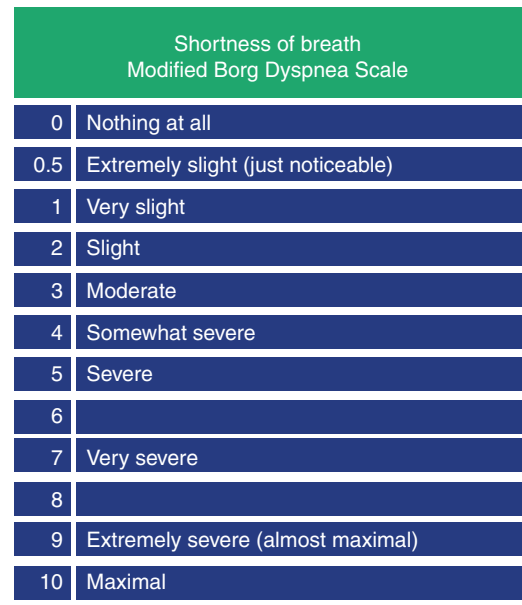

Fig. 18.1 The modified Borg scale has the potential to provide quick, easy, and rapid information about a patient's subjective state of dyspnea

accentuated P2 component of their second heart sound, even with mild disease. Additional auscultatory findings that become present with increasing right heart failure include the low-frequency holosystolic murmur of tricuspid regurgitation (TR), best heard over the left lower sternal border, and a right ventricular (RV) gallop (an S3 and/or S4 may be present). With increasing RV dilation, the patient will develop a palpable parasternal lift. Signs of fluid overload will also become evident with worsening RV failure, including jugular venous distension with prominent *a*- and *v*-wave pulsations associated with decreased RV compliance and worsening TR respectively. The lungs should be dry in isolated PAH; the presence of pulmonary edema suggests postcapillary PH is present, and an alternative diagnosis should be explored.

Noninvasive Testing in PH

The initial evaluation of patients with suspected PH typically involves multiple diagnostic modalities. Laboratory assessments are rarely helpful in the diagnosis of PAH, but may be important when other etiologies of PH, such as rheumatologic diseases, are suspected. Trending brain natriuretic peptide (measured as either BNP or NT-proBNP) values may be helpful to the clinician, as they are correlated with RV dysfunction and prognosis in patients with known PAH [4].

Chest radiography (CXR) is abnormal in 90% of patients presenting with PAH [4]. Right heart dilation, PA enlargement, and loss of distal pulmonary architecture with clear lung fields may all be seen on CXR [14]. A ventilation-perfusion (V/Q) scan should be performed in all patients with suspected PAH to rule out CTEPH, as patients with this disorder may be candidates for curative intervention (pulmonary thromboendarterectomy) or balloon pulmonary angioplasty. The sensitivity and specificity of V/Q scan for both diagnosing and excluding CTEPH approaches 95–100% [4, 16]. Computed tomography (CT) is often performed in patients with known or suspected underlying parenchymal lung disease. Pulmonary function testing (PFT) can elucidate underlying airway disease, such as chronic obstructive pulmonary disease (obstructive pattern) or interstitial lung disease (restrictive pattern). It is important to note, however, that the severity of lung disease as judged by PFTs is often poorly correlated with the presence or severity of PH [17]. A hint to the presence of PH itself is a low diffusing capacity (DLCO) that is out of proportion to the degree of lung disease suggested by the PFTs.

Transthoracic echocardiography should be performed in all patients with suspected PH. It is an excellent screening tool and can also be used assess the severity of PH. Quantifying right ventricular systolic pressure (RVSP) is most traditionally done by measuring the peak velocity of the TR jet, which provides an estimate of the RV systolic pressure (RVSP), a surrogate for pulmonary systolic pressure (in the absence of right ventricular outflow obstruction). There is a high probability of PH in the presence of a TR velocity > 2.8 m/s [4]. However, the absence of a measurable TR jet does not exclude PH and additional echocardiographic parameters can be helpful in this regard. These include dilation of the main PA, increased pulmonary regurgitant velocities, systolic flattening of the intraventricular septum, the presence of RV dilation and/or RV hypertrophy, and elevated right atrial pressure. Tricuspid annular plane systolic excursion (TAPSE) should be measured in all PH patients, with a distance <1.8 cm associated with increased mortality [18]. The presence of a pericardial effusion is an ominous sign in advanced PAH. The echocardiogram is also useful to evaluate for potential cardiac etiologies of PH, including significant valvular disease, left-sided heart failure (systolic and diastolic dysfunction), and the presence of an intracardiac shunt.

Cardiac magnetic resonance (CMR) can provide high-resolution structural information and with phase-contrast studies hemodynamic data as well. However, because of the limited availability and the high cost involved, this modality should not be used for screening.

Hemodynamic Evaluation

The cornerstone for the diagnosis of PH remains the RHC. Measurement of right heart and particularly PA pressures, cardiac output/cardiac index (CO/CI), PVR, and assessment of vasoreactivity are key elements for establishing diagnosis, collecting prognostic indicators, and assisting in the selection of therapy. RHC is recommended in all patients with PAH to confirm the diagnosis, evaluate severity of PH, and assess the need for PAH-specific drugs [4]. RHC is also recommended in patients diagnosed with PAH at 6–12 months surveillance intervals, 3–6 months after a change in therapy and when there is clinical deterioration [4]. There is often trepidation about performing RHC in patients with PAH, who are frequently viewed as being fragile. At experienced PH centers, cardiac catheterization is performed safely, and the risk of major complications is under 1% [19].

PH assessment is best performed in euvolemic states of low or normal CO. Transient high cardiac output states such as anemia, pregnancy, or sepsis will lead to elevated pulmonary pressures, but the PVR should remain normal. Current guidelines recommend that CO be measured by thermodilution, the reliability of which has been validated even in patients with low CO and severe TR [4, 20]. However, this method is prone to errors in measurement in the setting of intracardiac shunting. The direct Fick method is the gold standard for measuring CO, but is rarely performed today due to the cumbersome nature of directly measuring oxygen consumption (VO_2). The indirect Fick method has become the most widely accepted measure of CO; it is less reliable and results should be interpreted cautiously, particularly in patients who are severely obese [21].

We recommend performing a full oxygen saturation run to rule out CHD in all patients undergoing initial RHC for PAH. A left-to-right shunt should be suspected when the absolute PA saturation is >75% or if a step-up of >7% is seen between the superior vena cava (SVC) and PA. A shunt run should consist of measurements from the innominate vein, SVC, inferior vena cava (IVC), RA, RV, and PA. Both high and low SVC saturations should be obtained to identify the presence of anomalous pulmonary venous drainage to the SVC. Whenever a full saturation run is performed, it is important to recognize that the RA receives three different sources of blood return (SVC, IVC, and coronary sinus). The mixed venous saturation is thus estimated by adding three times the SVC saturation to the IVC saturation and dividing by four. Treatment decisions of which shunts benefit from repair and the timing of repair in the setting of PAH are beyond the scope of the chapter (see Chap. 20), but these patients should ideally be referred to cardiologists with expertise in managing adults with congenital heart disease.

The RA pressure waveform (and consequently the central venous waveform) of PH may have several distinctive features. A prominent *a*-wave is common when the RV diastolic pressure is elevated, and the normal *y*-descent may be attenuated reflecting reduced RV compliance. A prominent *v*-wave suggests the presence of significant TR and a fused *cv*-wave is sometimes seen. Severe elevation in mean RA pressure (>20 mmHg) has been associated with increased mortality [22]. Additionally, the expected decrease in RA pressure with inspiration may not occur in patients with severe PH and significant TR; on occasion RA pressure may even increase with inspiration creating confusion that pericardial disease (effusive or constrictive physiology) is present. Pulsus alternans in the RV and PA tracing can occasionally be seen in severe PH and suggests considerable RV dysfunction. It is characterized by alternating strong and weak beats, resulting from the altered Frank–Starling relationship and dyssynchrony of the noncompliant RV.

In normal adults the resting mPAP should not exceed 20 mmHg. PH is defined by a resting mPAP ≥25 mmHg. There remains uncertainty about patients with "borderline" mPAPs of 21–24 mmHg; these patients may simply be early in the disease process [23], though it is reasonable to suspect that future guidelines will lower the threshold of mPAP for defining PH. Previous definitions of PH also included a mPAP of >30 mmHg during exercise. However,

this has been removed from recent guidelines, as further understanding is needed to determine the best methodology for exercising these patients in the catheterization lab [4, 23]. Aging also plays a role in the degree of exercise-induced mPAP elevations; patients >50 years old may demonstrate significantly higher mPAPs, even with slight levels of exertion [23]. In general, however, severe elevations in mPAP (>45 mmHg) are typically only seen in patients with PAH and CTEPH.

Obtaining an accurate assessment of the PCWP is critical in patients with PAH. The PCWP allows for a direct measurement of mean LA pressure, a surrogate for the left ventricular end diastolic pressure (LVEDP) in the absence of mitral valve stenosis or pulmonary venous occlusive disease (PVOD). It is recommended that wedge pressures be sampled in several different segments of the pulmonary vasculature, preferably in the lower lobes of the pulmonary vasculature (West Zone 3). Zone 3 is the only location in the pulmonary circulation where one can be certain that the PA pressure is both greater than the pulmonary venous and pulmonary alveolar pressures, thus minimizing their contribution to the measured PA pressure. Multiple samples should also be obtained in patients with suspected or confirmed CTEPH; obstructive thrombi in some PA segments may lead to the erroneous interpretation of an elevated wedge pressure. An elegant way to document whether PAH is present is continuous recording of the PCWP and then the PAP after balloon deflation and careful withdrawal of the catheter (Fig. 18.2a, b). A significant step-up in the pressure waveform should be noted, resuming the PAP waveform almost immediately after deflation.

If the PCWP waveform has large v-waves, this suggests increased left atrial stiffness or possibly significant mitral regurgitation. In severe pulmonary hypertension, accurate measurement of PCWP may be difficult due to hybrid tracings resulting from incomplete seal of the balloon against the arterial wall. One must be careful not to overinflate the balloon or when performing repeat inflations and deflations in the wedge position, as these can cause rupture of the pulmonary artery, a rare but potentially fatal complication [23].

Measurement of the PCWP should take place during end-expiration (PCWP-exp), when the effects of intrathoracic pressure are minimized. This has been shown to be particularly important in obese and hypoxemic patients, who tend to generate larger intrathoracic pressure changes [23]. A mean pressure will typically be calculated by most cath lab software; however this represents a derived calculation measured over several seconds [24]. The discrepancies between the measured end-expiratory pressure and the digitally calculated mean pressure can be significant and lead to misclassification of patients with pre- and postcapillary PH, with potentially deleterious results (Fig. 18.3) [24]. If the PCWP is normal but clinical concern remains for impaired LV diastology, a small fluid bolus of 500 mL over 5–10 min can be safely administered to help unmask heart failure with preserved ejection fraction (HFpEF) [4, 23]. It is also possible that obtaining hemodynamics during exercise may help to uncover patients with diastolic heart failure, but this is not currently recommended for similar reasons as noted above for testing for PH with exercise [23]. If doubt exists about the accuracy of the PCWP measurement, direct measure of the LVEDP should be performed via retrograde crossing of the aortic valve.

PVR in the normal individual increases with age and decreases with elevations in cardiac output. PVR may be expressed either as Wood units (Wu; mmHg/L/min) or dynes (dyn/s/cm^{-5}),[1] with normal PVR being <1.1 Wu (88 dynes) [25]. PVR is calculated by dividing the transpulmonary pressure gradient (mPAP-PCWP) by the pulmonary blood flow (Qp), which is equal to CO in the absence of intracardiac shunting. A PVR >3 Wu is required for the definition of PAH. Pre- and postcapillary PH may coexist and can be difficult to distinguish clinically when seen together. When precapillary PH is present, the transpulmonary gradient will be higher, at least >12 mmHg, and often markedly elevated. The diastolic pressure

[1] Values given in Wu may be multiplied by 80 to convert to dynes.

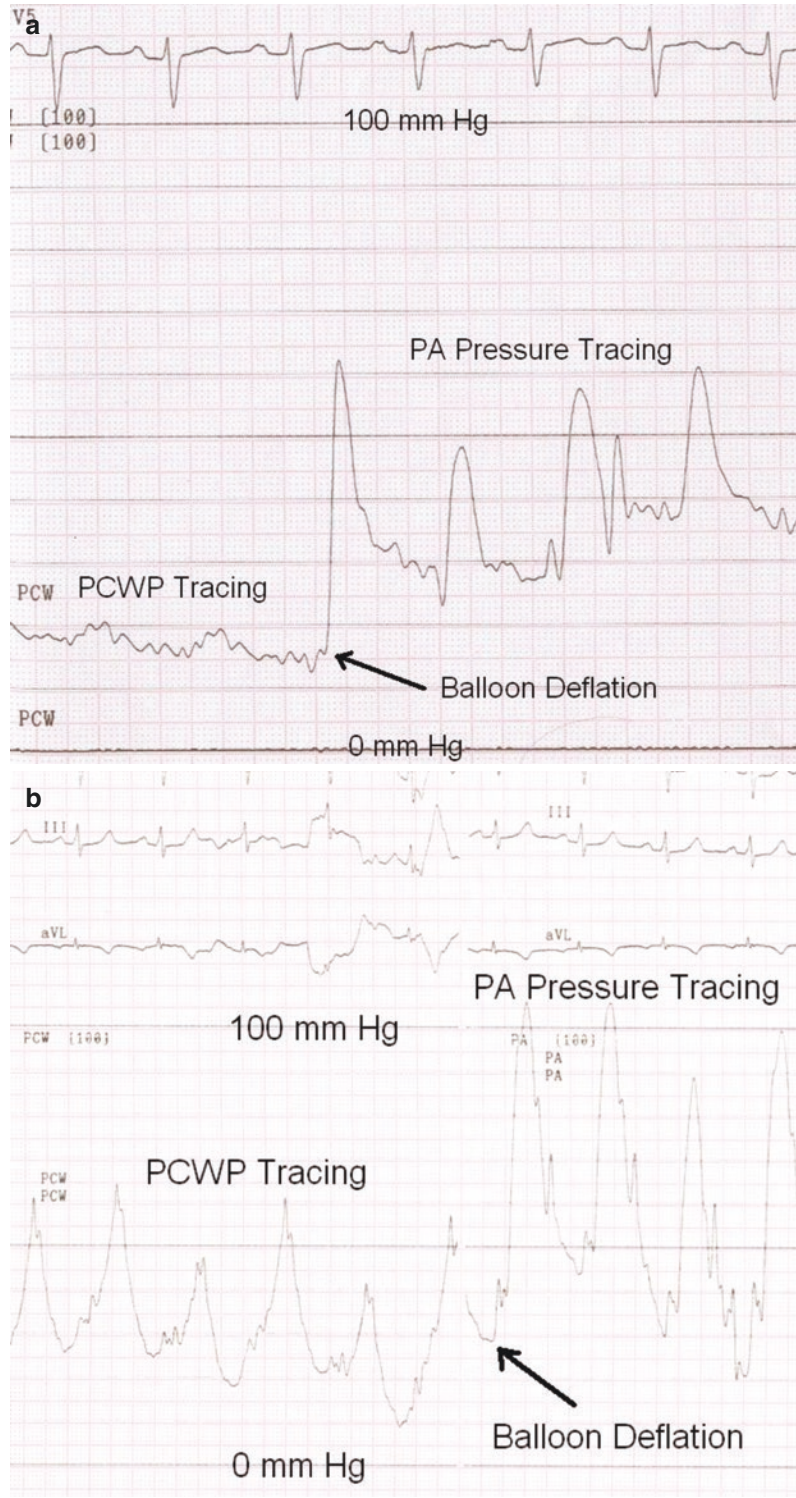

Fig. 18.2 (**a**) Deflation of the wedged pulmonary capillary balloon catheter results in a rapid increase in the pressure recordings identifying the pulmonary artery pressure. In this case the mPAP is >25 mmHg and PCWP is <15 mmHg consistent with a diagnosis of PAH. (**b**) Identification of pulmonary venous hypertension using continuous right heart pressure monitoring during acute balloon inflation and deflation. The PA pressure is elevated but the mPCWP is well in excess of 15 mmHg with large *v*-waves, reflecting the impact of severe mitral regurgitation in this case

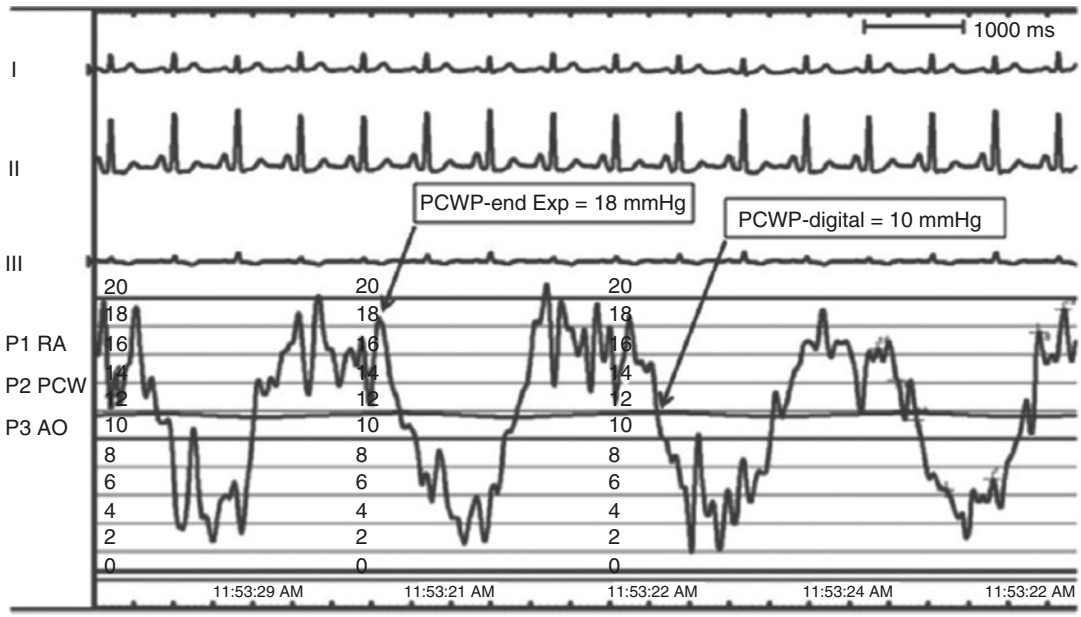

Fig. 18.3 This wedge tracing illustrates the respirophasic waveforms with the digitized means and the difference between PCWP–exp versus the automatically derived mean PCWP, thereby resulting in misclassification. (Reprinted with permission of publisher [24])

gradient (diastolic PAP – PCWP) is also very helpful. In pure postcapillary PH, this difference is typically close to 0, whereas a gradient ≥7 mmHg is consistent with the presence of precapillary PH.

All patients with suspected idiopathic, hereditary or drug-induced PAH should undergo pulmonary vasoreactivity testing as part of their initial RHC. Only a small minority of PAH patients (5–10%) will be vasoresponsive; however responders demonstrate a more favorable prognosis with a 5-year survival rate of 90% when treated with calcium channel blockers (CCBs) [26]. Responsiveness suggests the pulmonary vasculature has satisfactory amounts of vasodilatory reserve, likely representing an earlier stage of disease.

Inhaled nitric oxide (iNO) is most commonly used for vasoreactivity testing because of its specificity in targeting the pulmonary vasculature and neutral effects on coronary blood flow (intravenous prostacyclin and adenosine administration, alternative agents for vasodilatory testing, can reduce coronary blood flow). Also beneficial is the extremely short half-life of iNO, which is particularly important in the event a patient with masked LV diastolic failure or PVOD develops acute pulmonary edema. A substantial increase in the v-wave of the PCWP tracing during inhalation suggests that this may be occurring.

Unfortunately, the equipment used for the setup of iNO administration is cumbersome, and it requires the patient to wear a full facemask for delivery, which can be difficult to tolerate. Newer inhalation agents and smaller delivery devices are being developed (such as modification of the iNeb device to be able to deliver iloprost in a reusable circuit) that may be equally safe and at least as sensitive as iNO.

The maximal effect of iNO is obtained following 5–10 min of inhalation at 40 ppm, after which time the operator should repeat measurements of mPAP and PCWP, and collect PA and systemic saturations to reassess the cardiac output [27]. A positive response has most recently been defined as a reduction in mPAP by 10 mmHg to an absolute value of ≤40 mmHg with preserved CO. Although vasoreactivity testing has traditionally been used to identify patients with iPAH who may be candidates for CCB therapy, recent

studies have suggested that testing may also provide independent prognostic information that extends to other WHO Group I PH patients (PAH) and even those with non-Group I PH [28–30].

Our Approach to Hemodynamic Assessment of PH

1. Patients are taken to the catheterization laboratory in the fasting state and under minimal sedation (to prevent any adverse effect on oxygen saturation or CO).
2. Femoral venous and arterial access is obtained for the initial RHC and brachial, neck or femoral access (based on patient preference) for repeat assessments. If initiation of IV therapy is anticipated, neck access is preferred, as this facilitates leaving the right heart catheter in place after the procedure for more prolonged hemodynamic monitoring in an intensive care setting. In such cases radial access can be considered for left heart requirements. Arterial access permits measurement of the LVEDP if PCWP is questionable or grossly elevated. It also facilitates trouble-free arterial blood gas collection during the shunt run and provides for arterial pressure monitoring and arterial blood gas collection during AVT. It also allows for coronary angiography or ventriculography as necessary.
3. Ideally two transducers should be utilized – this facilitates monitoring of the pulmonary arterial and aortic pressures simultaneously during AVT.
4. A full oxygen saturation run is performed for the initial RHC. This includes innominate vein (or high SVC), SVC, IVC, RA, RV, PA, and aortic saturations. Saturations should immediately be reviewed and repeated if any measurements are questionable. The Fick CO should also be calculated at this time.
5. As the saturations are collected, pressures should be measured in each chamber as the catheter is advanced forward. Collected pressures include RA mean; RV systolic and diastolic; PA systolic, diastolic, and mean; PCWP systolic, diastolic, and mean; and aortic systolic, diastolic, and mean.
6. Measurement of the PCWP should be taken at end-expiration in West zone 3. If there is any question about the validity of the PCWP measurement or if the PCWP is unexpectedly >15 mmHg, measurement of the LVEDP should be performed.
7. Before AVT is performed, thermodilution CO should be performed if that modality is being utilized. At least three measures should be performed with individual results that do not vary more than 15%. If not the case, measures should be repeated until three measures that vary ≤15% have been collected.
8. AVT with iNO (or appropriate alternative agent) should be performed in all patients for whom initiation of advanced medical therapy for PAH is being considered. An increase in the PCWP during testing is generally a contraindication to use of these therapies. A positive response (decrease in mPAP of ≥10 mmHg to a mPAP ≤40 mmHg, without a decrease in CO) may permit initiation of calcium channel blocker therapy in iPAH. If this therapy is selected, very close follow-up is advised, as treatment failure is common.
9. Immediate communication of the results to the referring and treating physicians is essential for prompt recognition and initiation of therapy.

Treatment of PAH

A detailed discussion of the treatment of PAH is beyond the scope of this chapter. The goals of medical management are to achieve normal hemodynamics and a good quality of life – WHO FC I or II symptoms [31]. Treatment must be individualized to the patient and is best undertaken at centers with expertise treating PAH. Most patients will require diuretics to optimize volume status and may require supplemental oxygen to maintain saturations >90% [31]. Vasodilator testing responders should be started on high-dose CCBs (typically amlodipine, diltiazem, or nifedipine). There has been tremendous growth in the field of targeted PAH pharmacotherapies since IV epoprostenol was first approved in 1995. The major classes of PAH drugs currently include phospho-

diesterase type 5 inhibitors (PDE5), endothelin receptor antagonists (ERA), prostaglandins, guanylate cyclase stimulators, and selective prostacyclin IP receptor agonists. Lower-risk patients can be started on a single agent, though it is now common to initiate combination therapy with agents from different classes, particularly in higher-risk patients. Additionally, non-Group 1 patients with precapillary PH, including some with combined pre- and postcapillary PH, may derive benefit from these therapies [32, 33]. These uses should be considered off-label, however, and should be limited to carefully monitored clinical investigations. Ultimately, patients who progress despite advanced therapies may require lung or combined heart-lung transplant to survive.

Several interventional cardiology procedures may be considered to palliate patients with severe, medically refractory PAH and RV failure. Balloon atrial septostomy (BAS) creates an atrial-level right to left shunt that decompresses the RV and increases CO at the expense of worsening hypoxia. BAS has been shown to improve hemodynamics and functional capacity in the short term, although data on long-term survival benefits following the procedure are lacking [34]. The procedure should only be performed at experienced centers and is contraindicated in patients with a mean RA pressure > 20 mmHg or resting oxygen levels <85% on room air [4]. In 2013, Esch et al. [35] described the first-in-human experience, creating a transcatheter pulmonary-to-systemic shunt between the left pulmonary artery and descending thoracic aorta (Potts shunt). Surgical Potts shunts were previously utilized to palliate cyanotic congenital heart disease, but recent interest in their use in the pediatric and adult PAH populations is growing. The advantage of the Potts shunt over a BAS is that the former maintains fully oxygenated blood flow to the head and coronary arteries [34]. An emerging area of research is PA denervation via catheter-based ablation as a treatment of PAH. This is based on experimental evidence showing increased adrenergic signaling is present in patients with PAH and is linked to the development of pulmonary vascular disease and maladaptive RV remodeling [36]. A recent study of 66 patients with PH (39 with Group 1 PAH) demonstrated a >10 mmHg decrease in mPAP in 94% of patients immediately after the procedure, and sustained reductions in mPAP and improvements in CO and WHO FC at 1 year [37]. Though early data looks promising, extensive further studies will be necessary before this paradigm-shifting therapy can be approved.

Case Examples

Case 1

M.H. is a 53-year-old gentleman with scleroderma diagnosed 10 years ago and well-controlled essential hypertension who presented with complaints of worsening exertional dyspnea. A pulmonologist evaluated him 5 years ago and diagnosed him with mild interstitial lung disease. His fatigue and dyspnea had progressively worsened over the previous 3 months to the point of WHO FC III symptoms. There was no prior cardiac history.

His examination showed a JVP of 12 cm, a mildly prominent P2, a II/VI holosystolic murmur consistent with TR and 1+ peripheral edema. An echocardiogram revealed a dilated IVC, right heart enlargement, and mild RV systolic dysfunction with an estimated RVSP of 60 mmHg. There was grade 1 LV diastolic dysfunction; LA size was normal. He was taken to the cardiac catheterization laboratory where pressures included: mean RA 12 mmHg, RV 66/12 mmHg, PA 71/41 with a mean of 51 mmHg, PCWP of 41 mmHg, CI of 2.3 L/min/m^2 and a calculated PVR of 1.9 Wu. He was treated with diuretics by his physician but then developed hypotension and mild acute renal failure resulting in hospitalization.

After seeing the patient in consultation, we felt that the hemodynamics (suggesting PVH) did not match the clinical story (suggesting PAH). We then reviewed the hemodynamic tracings, which brought the measured PCWP into question (Fig. 18.4). It had been measured in only one position and the tracing suggested incomplete balloon occlusion of the PA. The patient begrudgingly agreed to repeat catheterization, where data revealed RA mean 8 mmHg,

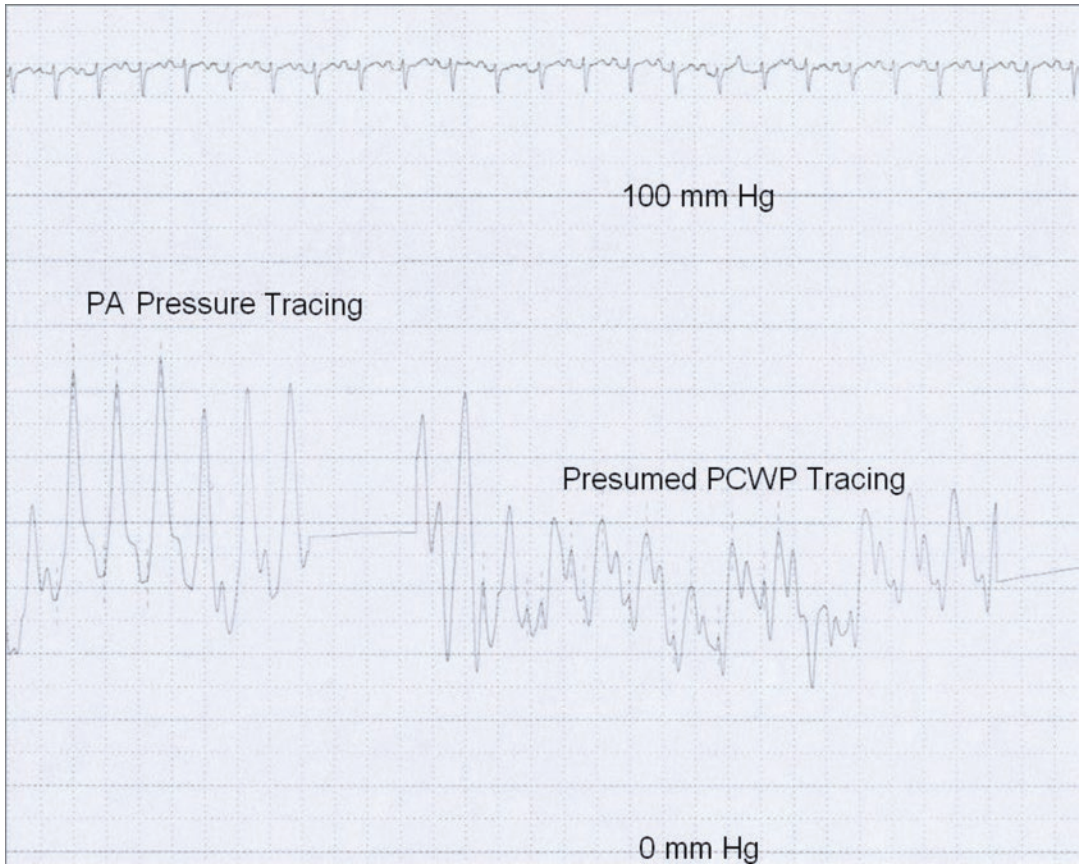

Fig. 18.4 Initial RHC in a patient with scleroderma that suggests the presence of PVH. There is limited respiratory variation in the PCWP tracing and the tracing appears to be a hybrid (fusion of PAP and PCWP waveforms) suggesting incomplete balloon occlusion of the pulmonary artery. These tracing were not consistent with the expected findings. In such cases multiple measurements should be obtained in different locations, and the LVEDP should then be measured for confirmation. This patient required repeat hemodynamic assessment to obtain proper measurements

RV 60/8 mmHg, PAP 60/33 with mean 40 mmHg, PCWP 12 mmHg, CI 2.2 L/min/m^2, and PVR 6.4 Wu (Fig. 18.5). LVEDP was also directly measured via retrograde left heart catheterization and was 11 mmHg. Vasodilatory testing was performed and resulted in a mPAP drop to 36 mmHg with stable PCWP pressure and CI and a decrease in PVR to 5.4 Wu. He was started on an ERA, and on follow-up he experienced a 50 m increase in 6MWD and had improved to WHO FC II.

This patient presents the dilemma of an RHC where data has not been properly collected. In cases like this, it is important to review the actual waveforms and assess if measurements were appropriately performed. In this case the initial RHC evaluated a hybrid PCWP waveform that grossly overestimated the PCWP. With repeat RHC and confirmation with measurement of the LVEDP, the appropriate diagnosis of PAH was made and proper therapy was initiated. Other techniques to ensure appropriate PCWP measurement include repeat measurements in both lung fields in different segments, assurance of appropriate respiratory variation in the tracing, collection of a wedge saturation (which should be ≥95%) and a small (2–3 cc), gentle injection of contrast dye, which should not be washed out until the balloon is deflated (Fig. 18.6).

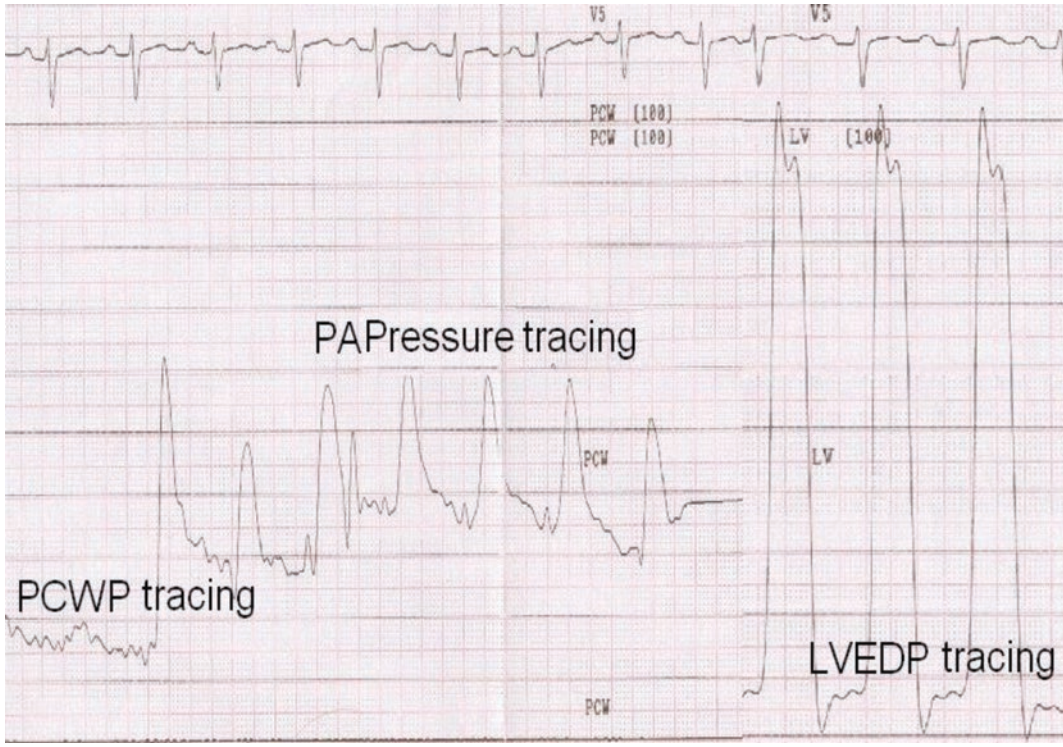

Fig. 18.5 Repeat RHC which indicates the presence of PAH (the expected finding given the clinical history). The LVEDP confirms that the PCWP is low in this case

Fig. 18.6 Gentle contrast injection into the right pulmonary artery under balloon inflation (pulmonary wedge angiogram). The tip of the balloon is highlighted by the arrow. Dye is seen filling a branch pulmonary artery proximal to the balloon and suggests incomplete occlusion. In such a case, a hybrid tracing would be present and would lead to an inappropriately high PCWP recording

Case 2

R.B. is a concerned 36-year-old gentleman who presented with progressive exertional dyspnea and fatigue that had significantly limited his ability to work in construction over the last few years. A recent echo suggested right-sided enlargement and borderline elevated RVSP. A bubble study was performed that suggested the presence of a patent foramen ovale (PFO). His right heart catheterization revealed mean RA pressure 10 mmHg, RV 40/9 mmHg, PA 40/18 with mean 25 mmHg, PCWP mean 12 mmHg, cardiac index 4.0 L/min/m^2, and PVR 1.3 Wu. O_2 saturation measurements were SVC 75%, IVC 76%, RA 89%, RV 88%, and PA 88% and a systemic saturation of 98%.

This case highlights the diagnostic capability of a properly performed shunt run. In this case there is a clear increase in saturation at the RA

level. A contrast injection was subsequently performed that showed an anomalous right upper pulmonary vein draining into the border of the SVC and RA and the presence of a right-to-left shunt in the superior septum. This was most consistent with a sinus venosus atrial septal defect and concomitant partial anomalous pulmonary venous return (PAPVR). It is important to recognize that PAPVR can also be present in isolation, and in such cases the echo bubble study may be negative. Performing a shunt run or at least SVC and PA saturations during RHC ensures that such a shunt will not be missed. The anomalous vein can be entered quite easily and safely (providing a careful technique using a flexible wire is utilized), and a gentle contrast injection can delineate its entry point into the heart (Fig. 18.7). A blood gas drawn in the vein should demonstrate a saturation ≥95%.

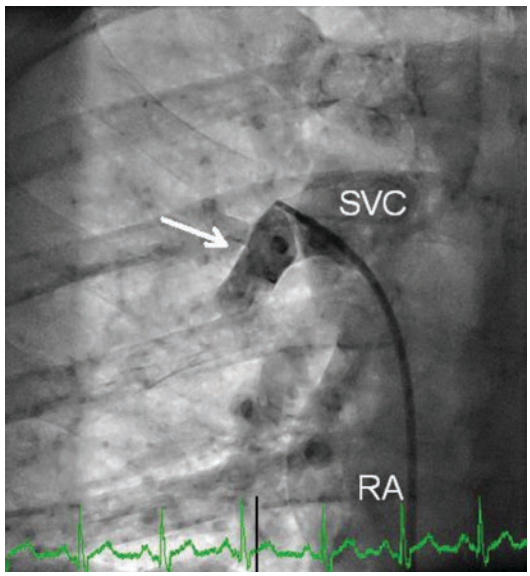

Fig. 18.7 Limited pulmonary vein angiogram (AP projection) of an anomalous right upper pulmonary vein performed via right femoral vein access (hand injection via end-hole catheter). The white arrow highlights the distal segment of the pulmonary vein which drains into the SVC at the RA junction. Samples drawn from this vein showed oxygen saturations >95%. A high CO at catheterization in the presence of right heart enlargement and a negative bubble study should prompt careful assessment for possible anomalous pulmonary venous return

A major clue to the presence of an underlying shunt is revealed in the cardiac index. Most patients with PH will have at least slightly reduced CO (if not grossly decreased). If the CO/CI is normal or high in a patient with echocardiographic evidence of right-sided enlargement (as it was in this case), a shunt is probable and should be carefully sought out. A PFO does not usually result in left-to-right shunting and would certainly not be expected to result in right heart enlargement. The patient in this case was referred to cardiac surgery and underwent successful repair. Repeat echocardiography has demonstrated normalization of his right-sided pressures and chamber sizes after repair.

Case 3

J.T. is a 66-year-old woman with multiple medical problems including advanced renal disease, dilated cardiomyopathy (LVEF~20%), and resultant severe mitral and tricuspid regurgitation. She was admitted to the coronary care unit for further management of worsening congestive heart failure and hemodynamic instability. On examination she was severely volume-overloaded and in respiratory distress with JVD above the angle of the jaw at 45° and a large cv wave. There was a prominent P2 present and a III/VI holosystolic murmur heart best over apex, a laterally displaced point of maximal impulse and a palpable RV heave. Lungs showed bibasilar rales and there was 2+ pitting peripheral edema.

Echo showed four chamber dilatation with severe mitral and tricuspid regurgitation. Estimated RV systolic pressure was 80 mmHg. RHC at the bedside revealed RA pressure 24 mmHg, RV 96/22 mmHg, PA 96/40 with mean 62 mmHg, mean PCWP 34 mmHg, CI 1.8 L/min/m^2, and PVR 10 Wood units. She was seen in consultation for possible initiation of pulmonary-selective therapies, and we instead recommended continued aggressive diuresis and afterload reduction with hydralazine and nitrates (baseline creatinine was 2.5 mg/dl) with the plan

for repeat hemodynamic assessment when stable.

RHC in the cath lab 10 days later showed RA pressure 15 mmHg, RV 73/15 mmHg, PA 73/28 with mean 44 mmHg, PCWP 16 mmHg, CI 1.5 L/min/m^2, and PVR 12.2 Wood units (Fig. 18.8). During inhalation of 40 ppm of nitric oxide, the PA pressure remained essentially unchanged (73/30 with mean 46 mmHg), but the pulmonary capillary wedge increased to a mean of 30 with v-waves to 65 mm Hg (Fig. 18.9). The team was instructed that the patient was not a candidate for selective pulmonary vasodilator therapy and surgical consultation for consideration of mitral and tricuspid valve repair was recommended.

This patient had long-standing RV dysfunction that likely arose from pulmonary venous hypertension consequent to high left-sided filling pressures from left ventricular dysfunction and mitral regurgitation. The PH in this case is therefore the offshoot of long-standing left heart disease and is likely compensatory to "protect" the left ventricle. AVT provides some insight into what would happen with pulmonary-selective therapy and the results suggest that the patient would be poorly tolerant of this therapeutic approach. In such cases this type of therapy could worsen her clinical course and precipitate decompensation and even death. Thorough assessment of hemodynamics in this case led to better understanding of the physiology and avoided a potential pharmacologic misadventure.

Pearls of Assessment of Pulmonary Hypertension

- Clinical suspicion for PH should remain high, especially in young patients with vague complaints such as dyspnea. Family and social history can provide important clues to a possible diagnosis.
- PAH is a diagnosis of exclusion, and patients must undergo a complete workup before a diagnosis of PAH is entertained. Secondary causes resulting in PVH are a far more common cause of PH.

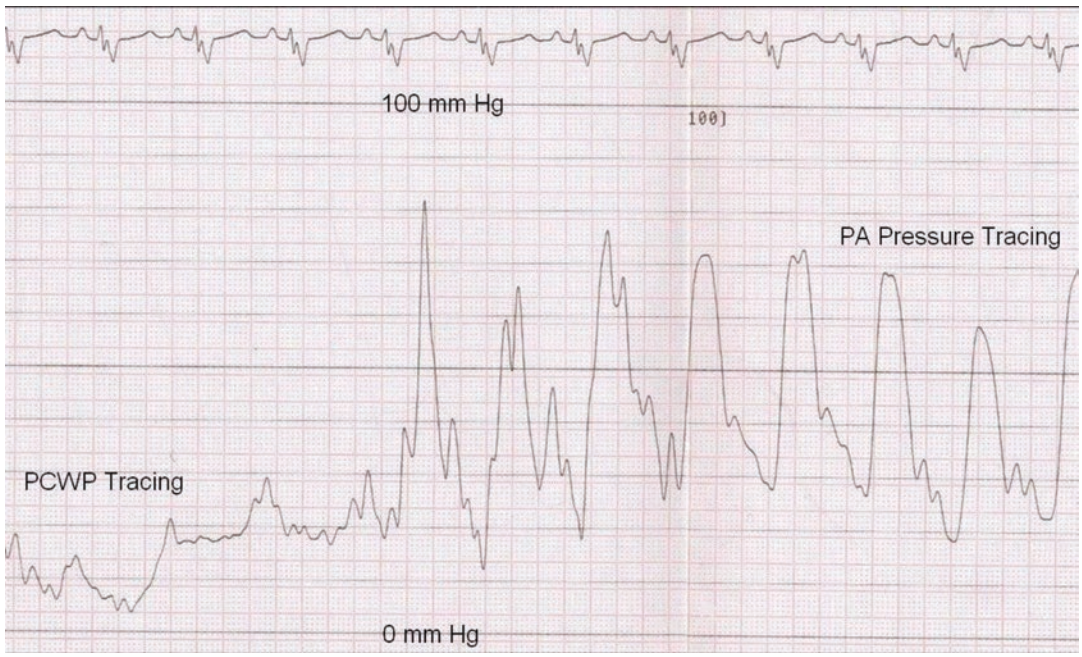

Fig. 18.8 Collected right heart catheterization waveforms in patient with heart failure and severe mitral regurgitation leading to pulmonary hypertension after aggressive diuresis. These suggest the presence of PAH and initially supported a potential role for selective pulmonary vasodilator therapy in this patient

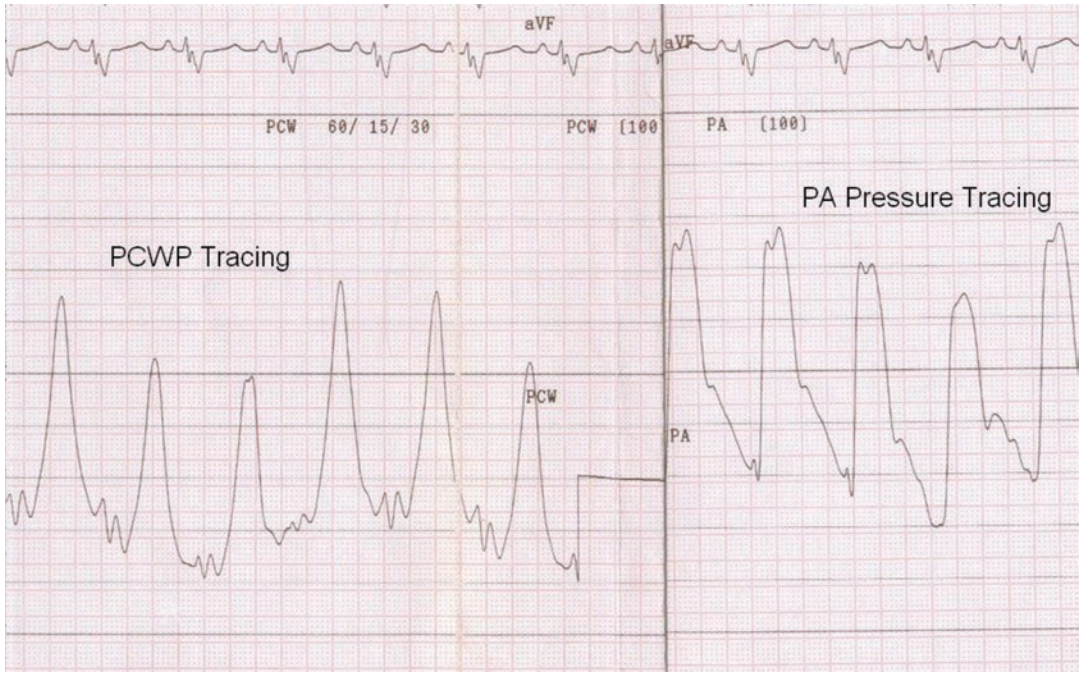

Fig. 18.9 Collected right heart catheterization waveforms during inhalation of 40 ppm of inhaled nitric oxide. Note the dramatic increase in mPCWP to ~30 mmHg and prominent *v*-waves to >65 mmHg. The PA pressure remained essentially unchanged (73/30 with mean 46 mm Hg) compared to baseline (Fig. 18.7). In this case acute vasodilator testing unmasked the left heart pathology leading to pulmonary venous hypertension in this patient

- The use of echocardiography is not adequate for evaluating mild to moderate PH. Only in severe PH does Doppler echocardiography provide reliable data for estimating RVSP. Echocardiography is essential for exclusion of left heart disease.
- The diagnosis of PAH can only be confirmed with RHC. Guidelines define PAH as mPAP >25 mmHg, PCWP ≤15 mmHg, and PVR >3 Wu in the absence of other causes of precapillary PH (e.g., CTEPH, chronic lung disease).
- Appropriate patients undergoing RHC should be further evaluated with vasodilator testing. This aids in selecting therapy and helps determine prognosis.
- Beware of hybrid tracings and confirm that an accurate PCWP measurement has been recorded. For patients in whom PCWP is not believed to be reliable, LVEDP should be directly measured.
- PCWP measurements should be taken at the end of the expiratory phase and in multiple PA segments to confirm accuracy, particularly in the setting of CTEPH or PVOD.
- Prognostic information and therapeutic decision-making are dependent on hemodynamics. Thus, appropriate techniques and proper and immediate interpretation are vital to performing RHC in patients with PH.
- Communication with referring and treating physicians is essential to streamline appropriate patient therapy in this very serious clinical disorder.

Review Questions

1a. A 46-year-old African American woman presents to clinic complaining of cough, lower extremity edema, and dyspnea on exertion over the last 3 months. Her medical history is significant for sarcoidosis diagnosed at 35 years of age and she has a 30-pack year history of smoking. Vitals are blood pressure 135/78 mmHg, pulse 87,

respiratory rate 20, and oxygen saturation 88% on room air. Her cardiac exam is notable only for a prominent P2. EKG shows sinus rhythm with right axis deviation. An arterial blood gas demonstrates a PO_2 of 49 mmHg and a PCO_2 of 35 mmHg. A chest x-ray demonstrates bilateral infiltrates, perihilar lymphadenopathy, and pulmonary vascular dilatation.

What is the best next step in the management of this patient?

A. PFTs
B. Transthoracic echocardiogram
C. CT angiography of chest
D. RHC
E. NT-pro-BNP

Answer C is correct. Although clinical suspicion for PH remains high, other more acute causes of hypoxemia must be ruled out. A CT scan can evaluate the lung parenchyma, which is likely to be abnormal, given this patient's history, and obtaining a contrasted angiography study will evaluate for acute pulmonary embolism or CTEPH as potential causes of hypoxia and PH, respectively. Subsequent evaluations with echocardiogram, PFTs, laboratory testing, and ultimately RHC are all appropriate if other workup is suggestive of PAH.

1b. The patient's CT scan shows the expected findings of sarcoidosis and no pulmonary embolism. An echocardiogram is obtained revealing an RVSP of 70 mmHg with enlargement of right-sided heart structures and normal left heart function. She desaturates to 83% on 6MWT and is only able to complete 280 m. RHC is scheduled.

Which of the following hemodynamics is most consistent with PAH?

A. mPAP 28 mmHg, PCWP 15 mmHg, CO 4.9 L/min, PVR 4.7 Wu
B. mPAP 40 mmHg, PCWP 26 mmHg, CO 5.2 L/min, PVR 2.7 Wu
C. mPAP 52 mmHg, PCWP 14 mmHg, CO 13.4 L/min, PVR 2.8 Wu
D. mPAP 18 mmHg, PCWP 12 mmHg, CO 5.5 L/min, PVR 1.1 Wu
E. mPAP 54 mmHg, PCWP 10 mmHg, CO 5.1 L/min, PVR 8.6 Wu

Answer E is correct. The hemodynamics for this patient are most consistent with the current guidelines for a diagnosis of PAH. Answer B is more indicative of postcapillary PH such as would be seen in patients with heart failure with preserved ejection fraction (HFpEF). The transpulmonary gradient is grossly elevated in answer C, but the CO is also grossly elevated suggesting the presence of an acute high output state such as sepsis or an intracardiac shunt. This patient should have a full saturation run performed to investigate the latter possibility more thoroughly. Answer D is consistent with completely normal hemodynamics. Answer A would have been correct if the PVR had not been calculated incorrectly. The actual PVR is (28–15)/4.9 = 2.7 Wu, which does not meet the formal criteria for PAH.

1c. Acute vasoreactivity testing with iNO at 40 ppm is performed. After 5 min, which of the following hemodynamics is most consistent with a positive response (baseline mPAP 54 mmHg, PCWP 10 mmHg, CO 5.1 L/min)?

A. mPAP 42 mmHg, PCWP 10 mmHg, and CO 5.1 L/min
B. mPAP 38 mmHg, PCWP 10 mmHg, and CO 5.6 L/min
C. mPAP 50 mmHg, PCWP 25 mmHg, and CO 4.9 L/min
D. mPAP 68 mmHg, PCWP 8 mmHg, and CO 4.8 L/min

Answer B is correct. The current definition of a positive test is a drop in mPAP $\geq$10 mmHg to an absolute value $\leq$40 mmHg with the CO remaining stable or increasing. Answer A shows a substantial drop in mPAP, but not to $\leq$40 mmHg. Answer C shows a slight drop in mPAP but also an increase in PCWP and slight decrease in CO. Her PVR calculates as (50–25/4.9) = 5.1 Wu, consistent with combined pre- and postcapillary PH with the predominant driver being left-sided diastolic dysfunction. Although some patients with combined pre- and postcapillary PH benefit from initiation of targeted PAH therapies, this patient's left-sided heart failure should first be optimized and RHC

then repeated to determine the best next steps. Answer E is illogical as the mPAP is not expected to rise, or the PWCP to fall, during vasodilatory testing.

2. A 45-year-old man undergoes RHC for suspected mild PAH. He weighs 80 kg, is 1.75 m tall and his body surface area is 1.97 m^2. His hemoglobin is 12.5 g/dL. Systemic saturation on arterial blood gas is 95%. A shunt run is performed. Which of the following would be most suspicious for PAH secondary to a congenital heart lesion?
   A. SVC saturation 75%, IVC saturation 77%, and PA saturation 74%
   B. SVC saturation 78%, IVC saturation 84%, and PA saturation 68%
   C. SVC saturation 70%, IVC saturation 74%, and PA saturation 72%
   D. SVC saturation 74%, IVC saturation 77%, and PA saturation 90%
   E. SVC saturation 69%, IVC saturation 72%, and PA saturation 71%

   Answer D is correct. The mixed venous saturation is estimated by (3 × SVC + IVC)/4. If the PA saturation is at least 7% greater than the mixed venous saturation, a shunt is highly likely. In answer D, the estimated mixed venous saturation is (3 × 74 + 77)/4 = 75% with a PA saturation of 90%. The pulmonary venous saturation (if not collected) is estimated at 95%. The degree of shunting can be calculated by dividing the Qp by the systemic blood flow (Qs). A rough estimate of the shunt can be calculated using the obtained saturations: (systemic-mixed venous saturations)/(pulmonary vein-PA saturations), which in this case yields a calculated Qp:Qs of (95–75)/(95–90) = 5:1, consistent with a large left-to-right shunt. None of the other choices show a step-up in saturation. The PA saturation in B must be incorrect as a step-down in saturation in the right heart is not possible. This saturation should be repeated ensuring to tap out any residual air bubbles from the syringe (which can lead to aberrant readings) before analysis.
3. A 44-year-old man with vasoresponsive iPAH has been stable on a regimen of 20 mg amlodipine daily for the past 3 years. He presents for follow-up and reports increasing dyspnea and fatigue over the last 3 months. He is comfortable at rest and able to perform some activities of daily living but has fatigue and light-headedness with repetitive actions such as brushing his teeth while standing up. On 6MWD, he desaturates to 83% after 50 m. One year ago, he desaturated to 92% after 100 m. What FC should he be classified as and what is the next step in the care of this patient?
   A. FC II: Change CCB therapy to verapamil or diltiazem
   B. FC III: Change CCB therapy to verapamil or diltiazem
   C. FC III: Repeat RHC for consideration of starting targeted PAH therapies
   D. FC VI: Change CCB therapy to verapamil or diltiazem
   E. FC VI: Admit to the hospital for initiation of IV prostacyclin therapy

   Answer C is correct. This patient presents with clinical worsening consistent with WHO FC III symptoms. It is important to note that the currently utilized definition of responsiveness was derived from a cohort of patients with iPAH with the goal of identifying patients who did well treated solely with CCBs [38]. In this cohort, only ~5% of patients did well with CCB monotherapy long-term. With the proliferation of targeted PAH therapies in the modern era, such a strategy is hard to justify. As such, the modern use of vasoresponsiveness helps to identify, by lack of a response, a high-risk cohort that may only benefit from the most aggressive of therapies. As such, this patient should undergo RHC and initiation of targeted PAH therapies should be considered. There is no evidence to suggest a benefit from switching to an alternative CCB agent as suggested in answers A, B, and D; verapamil is typically avoided in PAH patients out of concern for negative inotropic effects. Answer E is incorrect as the patient's FC is not yet at a VI. Although patients with FC VI often do require admission and initiation of IV prostacyclin therapy, an RHC should also be performed first and prior to a step-up in PAH therapy.

19 Acute Decompensated Heart Failure

Andrew D. M. Grant, Michael A. Hanna, and Mazen A. Hanna

Epidemiology of Acute Decompensated Heart Failure (ADHF)

Heart failure is estimated to affect 2% of the adult population. There are over one million hospitalizations for ADHF in the USA per year, and, among the Medicare population, it is the leading discharge diagnosis [1, 2]. About 25% of these patients present as de novo heart failure, and 75% present as an exacerbation of chronic heart failure. When not due to an arryhthmia or primary valvular disease, heart failure may arise in those with either reduced (≤40%), preserved (≥50%), or mid-range (40–50%) left ventricular ejection fraction [3, 4]. The inpatient mortality ranges from 3% to 25% depending on associated comorbidites and clinical characteristics [5]. The readmission rate at 30 days is a staggering 20–25% [6].

Hemodynamics of Decompensated Heart Failure

The hemodynamic perturbations in the syndrome of decompensated heart failure are characterized by elevated intracardiac filling pressures, normal or reduced cardiac output, and abnormalities in the systemic and pulmonary vascular resistance (PVR). Although there are syndromes in which the cardiac output is abnormally elevated, these will not be discussed in this chapter.

Intracardiac Filling Pressures

When volume overload (increased preload) and increased afterload occur, there is an elevation of left ventricular end-diastolic pressure from baseline (which may already be elevated). This leads to a rise in left atrial pressure and thus pulmonary capillary wedge pressure (PCWP). The elevation in the PCWP leads to passive *pulmonary hypertension* (pulmonary venous hypertension, WHO Group 2). Either volume overload or pulmonary hypertension (or both) leads to elevation of the right atrial pressure (RAP). The extent of pulmonary hypertension depends on the degree and chronicity of elevation of the PCWP and the degree of superimposed pulmonary vasoconstriction and vascular remodeling (see section "Vascular Resistance").

In patients with ADHF, PCWP is usually >22 mmHg and right atrial pressure >10 mmHg; such a patient is typically classified as "wet." In the average ADHF patient, a RAP >10 mmHg correlates to a PCWP >22 mmHg about 80% of the time [7–10]. In these "concordant" cases, PCWP

is usually about 2–2.5 times RAP. About 20% of the time, there is "discordance" in this relationship; one example is in patients with disproportionate RV failure in whom RAP is significantly elevated with a normal or only mildly elevated PCWP. The other example is when RAP is normal with a significantly elevated PCWP as one may see in acute left-sided heart failure without volume overload or a very noncompliant LV with high resting filling pressure despite euvolemia. These are important hemodynamic concepts to understand as they may affect management.

Cardiac Output

Cardiac output is a product of stroke volume and heart rate (see Chap. 4). Stroke volume is determined by preload (filling pressure), myocardial contractility, and afterload (mainly systemic vascular resistance). In patients with ADHF, a decrease in cardiac output is more likely due to low stroke volume but occasionally can be due to an inappropriately low heart rate. It is important to note that in the majority of cases of ADHF, the cardiac output remains normal. Low cardiac output, as measured by Fick or thermodilution (we more often use the Fick method at our institution), occurs in a minority of patients who have advanced heart failure or excessively low filling pressures due to overdiuresis. Arbitrarily, a cardiac index (cardiac output/body surface area) of <2.2 is considered low, and such a patient is typically classified as "cold" while a patient with a cardiac index >2.2 is classified as "warm [11]." A patient with a low cardiac index may be compensated and have no signs or symptoms of low perfusion at rest; thus, it is important to consider the overall clinical picture in addition to the calculated cardiac index when deciding treatment options and prognosis.

When evaluating a patient with ADHF, it is useful to categorize the patient according to the estimation or measurement of left-sided filling pressures and cardiac output. The classification scheme shown in Fig. 19.1 is a simple and efficient way to clinically categorize patients and help guide appropriate treatment strategies.

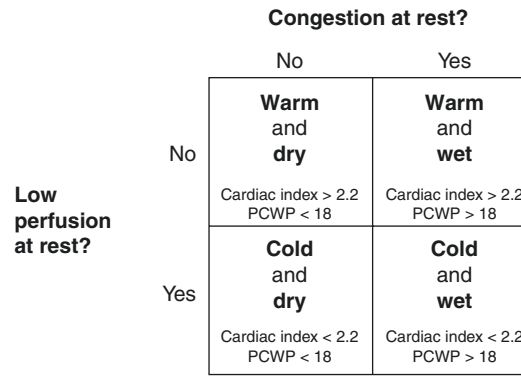

Fig. 19.1 Hemodynamic profiles in patients with left-sided heart failure

Vascular Resistance

Systemic vascular resistance (SVR) is measured as the difference between mean arterial pressure and right atrial pressure divided by cardiac output. Classically, in ADHF, SVR is high as a result of an increased level of vasoconstricting neurohormones such as norepinephrine, angiotension II, and endothelin. However, in the contemporary era in which treatment with agents that block the renin angiotensin aldosterone system (ACE inhibitors/angiotensin receptor blockers/angiotensin receptor blocker + neprilysin inhibitors) and beta blockers is common, the SVR can be normal or sometimes even low. Patients with right-sided heart failure and renal insufficiency are more likely to have normal or low SVR. Knowing the blood pressure and/or the SVR is important with respect to determining treatment options.

Pulmonary vascular resistance (PVR) is measured as the difference between mean pulmonary artery pressure and PCWP (left atrial pressure surrogate) divided by cardiac output. It is important to note that in some patients, in addition to passive pulmonary hypertension due to elevated left atrial pressure, there is an additional component of pulmonary arterial vasoconstriction, raising pulmonary vascular resistance and thus further raising pulmonary artery pressure (pulmonary arterial hypertension). Long-standing elevation of PCWP can also lead to pulmonary vascular remodeling. This component of pulmonary vascular resistance

cannot be reversed by acutely lowering PCWP or with the use of pulmonary vasodilators. Reversal of pulmonary vascular remodeling can be accomplished by long-term consistent lowering of left atrial pressure (e.g., correction of mitral stenosis, left ventricular assist device placement). Patients with an elevated PVR that cannot be reversed have a worse prognosis.

Hemodynamic Evaluation of Decompensated Heart Failure

There are many ways to evaluate hemodynamics in heart failure. The initial and most practical strategy is starting with the clinical history and the physical examination (H&P). Further important hemodynamic information can be gleaned from echocardiography. The most invasive and accurate way to assess hemodynamics is with right heart catheterization using a pulmonary artery catheter, which is reserved for special situations.

Clinical Assessment

The H&P, together with a chest X-ray and basic labs, provides the majority of the hemodynamic information needed to treat patients with acute decompensated heart failure (ADHF). The shortcomings of an H&P are important to acknowledge however, and some of these will be highlighted as we discuss each of the clinical cases at the end of the chapter.

Clinical Estimation of Filling Pressures

Using the H&P, experienced clinicians can estimate, with reasonable accuracy, the intracardiac filling pressures [12, 13]. Some of the important signs and symptoms of elevated filling pressures are outlined in Table 19.1. Symptoms of elevated right atrial pressure, depending on the degree and chronicity, include abdominal bloating and discomfort, early satiety, and RUQ pain that can mimic an abdominal etiology. Signs of elevated right atrial pressure include lower extremity edema, hepatomegaly, and, in advanced right heart failure, ascites. However, the most reliable sign of elevated right atrial pressure is elevation of the jugular venous pressure (JVP), and depending on the skill of the examiner, the right atrial pressure can be reliably assessed at the bedside in most heart failure patients. Indeed, patients with elevation of right atrial pressure may have no edema or ascites, and the only sign may be elevated jugular venous pressure. It is in these patients that congestion is often missed and the patient is incorrectly assumed to be euvolemic.

Table 19.1 Symptoms and signs of elevated intracardiac filling pressures

	↑ RA pressure	↑ PCWP
Symptoms	Leg swelling	Dyspnea at rest or on exertion
	Abdominal bloating	Orthopnea
	Early satiety	PND
	Nausea, anorexia	Positional cough
	RUQ pain	
Signs	Elevated JVP[a]	S_3gallop
	Ascites	+ Abdominojugular reflux
	Enlarged/tender liver	Rales[b]
	Lower extremity edema[c]	

[a]Most specific and sensitive sign of elevated RA pressure and may often be the only sign
[b]Rare in chronic heart failure
[c]Nonspecific and can be due to venous insufficiency, DVT, calcium channel blockers, etc.

Elevation of left atrial pressure/PCWP pressure leads to symptoms of exertional/resting dyspnea, dry cough (worse in the recumbent position), orthopnea, and paroxysmal nocturnal dyspnea. In fact, orthopnea and particularly paroxysmal nocturnal dyspnea are the most specific symptoms of elevated PCWP. The physical exam finding that is most specific for an elevated PCWP (in the absence of mitral stenosis) is an S3 gallop; however, it is not a sensitive finding as most patients with an elevated PCWP do not have an S3 gallop. One of the best clues that a heart failure patient has an elevated PCWP is elevation in the jugular venous pressure. This is because elevated right

Table 19.2 Signs and symptoms of low cardiac output

Symptoms	Fatigue
	Decreased memory/mentation
	Lightheadedness
Signs	Cool extremities
	Sleepy/obtunded
	Narrow pulse pressure
	Oliguria

atrial pressure is predictive of an elevated PCWP in most chronic heart failure patients (see section "Intracardiac Filling Pressures").

Clinical Estimation of Cardiac Output

Estimating cardiac output is more difficult at the bedside [12], but there are several clues to low cardiac output (see Table 19.2). General fatigue, impaired mentation, cool extremities, low urine output, and increased lactate level are useful clues. An objective measure is to calculate the "proportional pulse pressure" which is the systolic blood pressure minus the diastolic blood pressure divided by the systolic blood pressure. A proportional pulse pressure <25% suggests a cardiac index of <2.2 [11].

Echocardiography

The echocardiogram is an important tool in the assessment of heart failure. In patients presenting with a new diagnosis, it is essential in establishing the mechanism of heart failure (preserved versus reduced ejection fraction or valvular etiology; see Chap. 6). Performing a baseline echocardiogram is given a Class I (should be performed) recommendation in patients with a new diagnosis of heart failure according to the ACC/AHA guidelines [14]. For patients with an acute exacerbation of chronic heart failure, it is not always necessary to obtain an echocardiogram. This is particularly true when there is an obvious precipitant for the change in clinical status. When the patient is critically ill or the symptomatic decline is precipitous, the echocardiogram can exclude new structural abnormalities. This is given a IIa (reasonable to perform) recommendation by the ACC/AHA guidelines [14] and has been shown to provide reliable estimates of invasive hemodynamics in this setting [15].

Echo Assessment of Filling Pressures

The measured size of the inferior vena cava (IVC) and its changes with respiration is traditionally used to estimate right atrial pressure [16]. Using this method, there is an assumption that there is continuity between central veins and the right atrium, the same assumption used in interpreting the jugular venous pressure as a reflection of right atrial pressure. Patients with an IVC measuring ≤2.2 cm in diameter that collapses by 50% or more with a sniff are designated as having a low RA pressure (assigned a value of 3 mmHg for the purposes of calculations). Patients with a distended IVC that does not collapse with sniff are designated as having a high RA pressure (15 mmHg). Patients with intermediate findings are assigned an RA pressure of 8 mmHg [16]. An example of this technique is given in Case 3.

Echocardiographic estimation of left ventricular end-diastolic pressures is a continued area of active investigation. The ratio of early diastolic inflow velocity across the mitral valve (E) to the early peak velocity of the mitral valve annulus (E′) has been shown to have a reasonably good correlation with LVEDP [17, 18]. This technique is used in a semiquantitative fashion. An E:E′ ratio of <8 suggests a normal LVEDP. An E:E′ ratio of >15 suggests an LVEDP of greater than 15 [17]. The E:E′ ratio was shown to be less predictive among patients with advanced heart failure admitted to the ICU [19]. Research is underway to find more consistent and precise echocardiographic predictors of LVEDP.

Echo Estimation of Pulmonary Pressures

The most well-accepted means of estimating pulmonary pressures with echocardiography is to

calculate the pressure gradient across the tricuspid valve using the peak velocity of the tricuspid regurgitation jet [16]. Using a simplified Bernoulli equation, the pressure gradient between the right ventricle and the right atrium can be estimated as $P=4v^2$. This is also discussed in detail in Chap. 6, and an example will be reviewed in Case 3.

Echo Assessment of Cardiac Output

Stroke volume (and therefore cardiac output) can be estimated by echocardiography, although it requires several important assumptions be made [20]. The technique for making this estimation is as follows (see also Chap. 6).

The Doppler profile of flow through the LV outflow tract is a graph of velocity vs. time. Taking the integral of this curve gives a unit of distance. When this distance is multiplied by the surface area of the left ventricular outflow tract (LVOT), the resulting number (a volume) is the stroke volume. The LVOT area can be estimated by using 2D echo measurements of its diameter in long axis and then assuming that it is a circle. Although this method is not frequently employed, it should yield a reasonably accurate estimate of stroke volume and therefore of cardiac output (when multiplied by heart rate).

Right Heart Catheterization

Right heart catheterization remains the gold standard for measuring many of the hemodynamic parameters important in the management of heart failure. As noninvasive methodology has improved, however, there are now fewer situations in which this information is necessary [14]. Additionally, a large randomized study showed no benefit to the routine use of a pulmonary artery catheter to manage patients with ADHF in terms of the combined endpoint of mortality and days outside of hospital at 6 months [21].

Right heart catheterization should be considered in a patient who is refractory to initial therapy, whose volume status and cardiac filling pressures are unclear, who has clinically significant hypotension (typically SBP <80 mmHg) or worsening renal function during therapy, or who is being considered for cardiac transplant and needs assessment of the degree and reversibility of pulmonary hypertension and PVR [14, 22]. This latter issue will be discussed further in Case 3.

In each of Cases 1–3, pressures in the right atrium (RA) and pulmonary artery (PA) as well as PCWP as derived from right-heart catheterization are displayed. RA pressure and PCWP are commonly used clinically as descriptors of right and left ventricular "preload" respectively (see Chapter 1). The PA pressure is reported as systolic PA pressure/diastolic PA pressure (mean PA pressure). The cardiac index, as estimated using the Fick principle (see Chap. 4), is also shown. The cardiac index is calculated by dividing the cardiac output by the patient's body surface area. This factor in the size of the patient which is clearly important as normal cardiac output varies with size.

Implantable Hemodynamic Monitoring

There has been recent interest in the use of implantable hemodynamic monitoring systems in the management of heart failure. The CardioMEMS HF system (St. Jude Medical), approved by the FDA in 2016, is a small device implanted in a branch of the pulmonary artery allowing for continuous monitoring of PA pressure. A large randomized clinical trial using this device in patients with chronic NYHA III heart failure demonstrated a reduction in heart failure hospitalizations [23].

General Principles of Management

The majority of patients who present with ADHF are congested and have elevated filling pressures. The central goal of therapy is to decongest the patient and optimize filling pressures to normal or near normal levels. This is most effectively

achieved with the use of an intravenous loop diuretic. In instances of diuretic resistance, combining a loop diuretic with a thiazide, amiloride, and/or spironolactone can be highly effective. If this approach is not successful, as can be the case in advanced renal dysfunction, ultrafiltration may be considered [24, 25].

To further optimize hemodynamics, vasodilators which reduce filling pressures can be used in conjunction with diuretics. Vasodilators, in addition to lowering filling pressures, improve cardiac output by reducing afterload, decreasing functional mitral regurgitation (and thereby increasing forward cardiac output), and reducing wall stress [26–28]. The patients who benefit the most from vasodilators are those with elevated blood pressure and high SVR. It is important to note, however, that a patient with "normal" blood pressure may still have an elevated SVR and benefit from vasodilator therapy. Both "wet and warm" and "wet and cold" patients may be treated with vasodilators.

Intravenous vasodilators used in heart failure are nitroprusside, nitroglycerin, and nesiritide. The vasodilator of choice at our own institution is nitroprusside, which should be administered in an ICU setting with hemodynamic monitoring using a right heart catheter and, in most instances, a blood pressure cuff (as opposed to an arterial line). This is well tolerated and the incidence of cyanide or thiocyanate toxicity is extremely rare to nonexistent [29, 30]. A mean arterial pressure of approximately 65 mmHg is targeted, but this depends on the patient and may need to be higher if renovascular or coronary artery disease is present or suspected, or if the patient is chronically hypertensive with an altered renal autoregulatory threshold. Excessive or overexuberant vasodilation with decrease in blood pressure beyond the renal autoregulatory threshold often leads to decreased renal perfusion, worsening renal function, and should be avoided. Once patients have clinically and hemodynamically improved on intravenous vasodilators, they may be transitioned to an oral vasodilator regimen of either ACE inhibitors, the combination of hydralazine and isosorbide dinitrate, or a combination of all three agents [31].

Intotropic therapy (milrinone or dobutamine) should be reserved for low output states associated with hypotension and end-organ hypoperfusion [32]. The typical patient has advanced systolic dysfunction, a low proportional pulse pressure, cool extremities, and worsening renal function despite adequate filling pressure (need to rule out hypovolemia) and is unresponsive to or intolerant of intravenous vasodilators. These patients constitute no more than 5% of the total ADHF population. Inotropes can also be used as palliative therapy for end-stage heart failure or as a bridge to transplantation.

It is important to note that inotropes increase myocardial oxygen consumption by increasing heart rate and myocardial contractility and can precipitate atrial and ventricular arrhythmias as well as myocardial ischemia. In contrast to dobutamine, milrinone has a long half-life (2.5 h) and is renally excreted, and the dose should be adjusted for renal function. Also, given that milrinone is a more powerful vasodilator, hypotension is more common with this agent and therefore should be used with caution or even avoided when the systolic blood pressure is <90 mmHg. In the setting of background beta blocker therapy, dobutamine will be ineffective unless used in high doses, and milrinone is favored [33, 34]. In rare circumstances, vasopressors are used (dopamine, norepinephrine, vasopressin), when the patient is vasodilated with a low SVR and profound hypotension.

In patients who are managed on a telemetry floor without invasive monitoring, the goal of therapy is to normalize intravascular volume as reflected by relief of edema and normalization of the jugular venous pressure (<8 cmH_2O). When this is achieved, most patients will no longer have orthopnea or dyspnea. Signs of overdiuresis consist of orthostatic decrease in blood pressure and worsening renal function. A common clinical error is incorrectly assuming euvolemia has been achieved when edema has resolved yet unrecognized elevation of the jugular venous pressure persists. By the same token, one may have normalized the jugular venous pressure and achieved intravascular euvolemia but may still have residual edema due to low albumin, venous

insufficiency, or drug side effect (e.g., calcium channel blockers) and wrongly assumed to be intravascularly volume overloaded.

In patients managed with hemodynamic monitoring with a right heart catheter, vasodilator therapy (both intravenous and oral) and diuretics are "tailored" to certain hemodynamic goals. Typically a PCWP of ≤16 mmHg, an RA pressure of ≤8 mmHg, and an SVR of about 1000–1200 dyn are targeted. A common misconception that patients with dilated dysfunctional ventricles require higher filling pressures to maintain cardiac output based on the Starling curve has been dispelled by data showing that most of these patients can maintain and even improve cardiac output with normal or near normal PCWP [30, 35]. As far as RA pressure goals, patients with primarily RV failure may require a higher RA pressure than 8 mmHg to maintain cardiac output and renal perfusion. It has been shown that patients with very elevated RA pressure can have worsening renal function on the basis of renal venous congestion. By lowering RA pressure with diuretics and vasodilators, the kidney is "decongested" or decompressed and renal function often improves [36–38] (see Fig. 19.2).

The goal of cardiac index is usually >2.2, but one has to acknowledge that using the Fick equation, oxygen consumption is estimated and not measured and that up to a 20% variation in cardiac output can be seen [39]. Thus, targeting a specific number per se is simplistic, and the entire clinical picture needs to be considered (e.g., a patient with a cardiac index of 1.8 who with normal PCWP feels well may not need further intervention). Although cardiac output frequently improves, the cardiac output is not the primary target of therapy, rather the reduction of the filling pressures [40]. The general principles of management for the different presentations of heart failure are shown in Fig. 19.3.

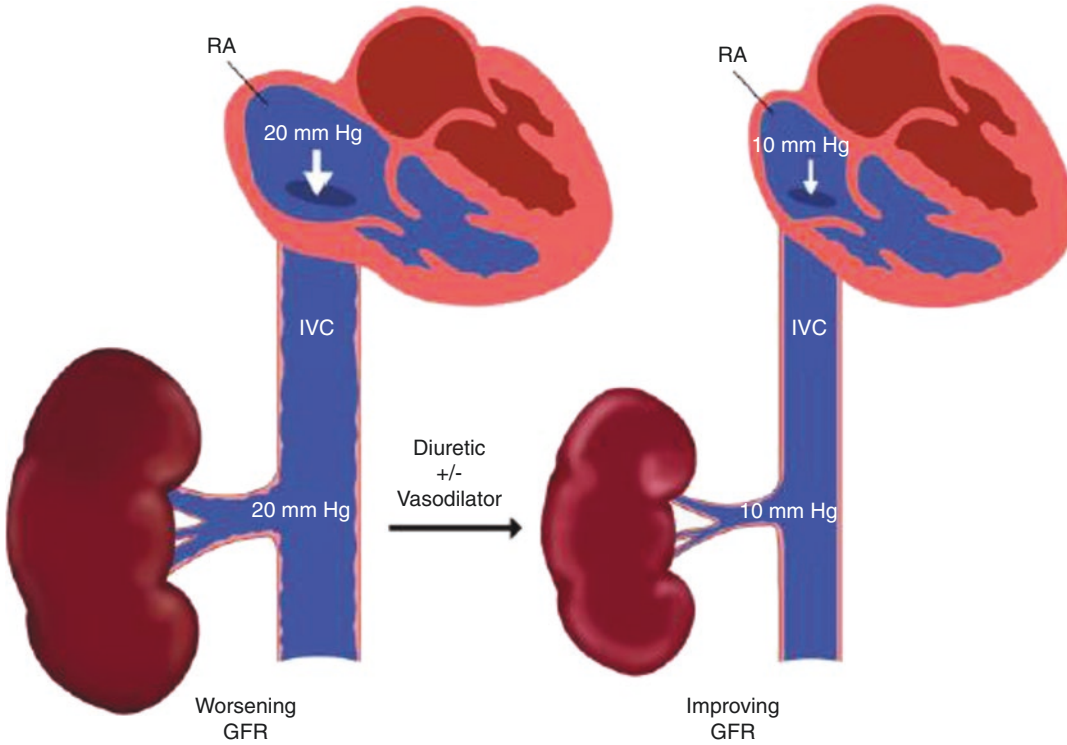

Fig. 19.2 Renal venous congestion: increased right atrial pressure leading to elevated pressure in the IVC and thus the renal vein (especially when coupled with low mean arterial pressure) can lead to worsening renal function by "congesting the kidney." Decreasing right atrial pressure and thus the renal venous pressure can lead to improved renal function

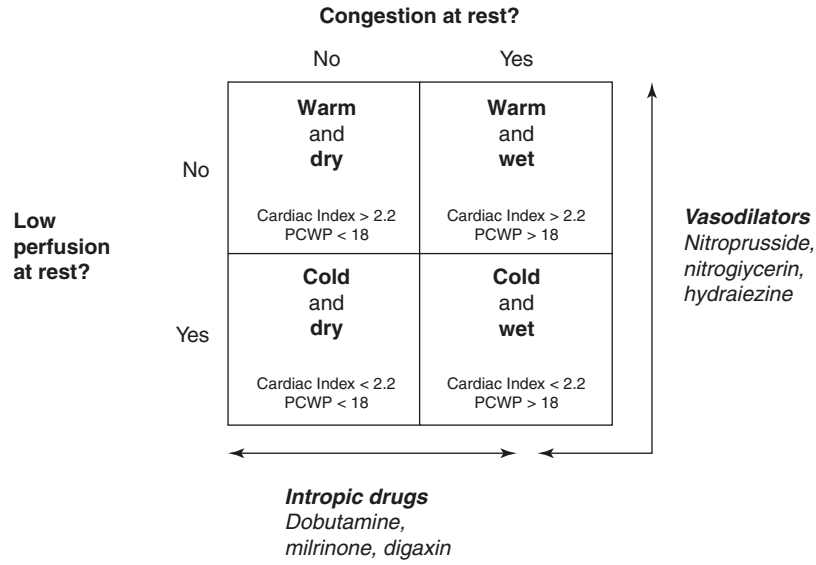

Fig. 19.3 Treatment paradigm in patients with left-sided heart failure

Clinical Presentations of Acute Heart Failure

Case 1

A 46-year-old male with a history of diabetes and hypertension presents with sudden onset of retrosternal chest pain. He is brought by emergency medical services to the hospital where he is found to have an elevated jugular venous pressure, bilateral rales, and edematous and well-perfused extremities. His electrocardiogram reveals ST segment elevation in the inferior leads (ECG leads II, III, and aVF). He is transferred to the cardiac catheterization laboratory but becomes dyspneic and hypoxic lying flat on the table. On examination, his HR is 90 bpm and BP measures 130/90 mmHg. His oxygen saturation is 93% on a high-flow oxygen mask.

A left heart catheterization is performed. The right coronary artery is found to be completely occluded, and the patient undergoes successful angioplasty and stenting to the vessel with good results. A pulmonary artery catheter is placed yielding the following hemodynamics:

RA	PA	PCWP	Cardiac index
12	38/25 (30)	24	3.2

Fig. 19.4 Case 1: left ventricular pressure tracing

A sample from his left heart catheterization is shown in Fig. 19.4. The LVEDP is elevated and correlates closely with the PCWP obtained with right heart catheterization. An echocardiogram is performed which demonstrates severe akinesis of

the inferior wall from base to apex. The overall left ventricular systolic function is described as mildly decreased. Right ventricular function is reported as normal.

Case 1: Hemodynamic Assessment

This is an example of so-called "warm and wet" heart failure (based clinically on his JVP, lower extremity edema and warm extremities, and hemodynamically on an elevated PCWP with a cardiac index in the normal range). Occlusion of the right coronary artery led to systolic and diastolic dysfunction of the left ventricle. This resulted in elevation of the left-sided filling pressures with pulmonary edema.

The orthopnea and hypoxia suggested an acute rise in PCWP. The relationship between PCWP and clinical signs of pulmonary congestion has been well characterized in patients with acute myocardial infarction. The onset of pulmonary congestion generally occurs at a PCWP between 18 and 20, and acute pulmonary edema generally correlates with a PCWP of greater than 30 [41]. These data have been challenged, however [42], and were collected prior to the use of reperfusion techniques such as fibrinolysis and primary percutaneous coronary intervention.

In this case, the importance of echocardiography was to confirm that the main problem was a left ventricular wall motion abnormality and not acute mitral regurgitation, which can be a mechanical complication of inferior myocardial infarction. Suspicion was low for this patient as such cases generally present with cardiogenic shock. However, a high index of suspicion is important. Another known complication of inferior myocardial infarction can be right ventricular infarction. This occurs in some patients when there is proximal occlusion of the right coronary artery but would generally be manifested by an elevated JVP and hypotension without pulmonary congestion. The right heart catheterization provided accurate measurement of cardiac output which has important prognostic implications [43].

In this case, the underlying cause of left ventricular dysfunction is acute coronary occlusion. This is best treated by promptly opening the culprit vessel (here with emergent PCI) in efforts to improve contractility by restoring flow to the compromised ischemic myocardium. Diuretic therapy was also provided to facilitate reduction of volume overload and clearance of pulmonary edema. This is generally considered to be a mainstay of the treatment of decompensated heart failure with increased RA pressure and PCWP. The patient was treated with intravenous furosemide with excellent response. After several days, he no longer required supplemental oxygen, and clinical and radiographic evidence of pulmonary congestion had improved.

Case 2

A 19-year-old G_1P_1 female presents to the emergency department with profound fatigue and right upper quadrant discomfort. Two weeks prior, she gave birth to a healthy baby boy via an uncomplicated vaginal delivery. Since the delivery, she has noticed gradual progression of tiredness to the point where she is no longer able to carry out basic activities of daily living and is short of breath at rest. There is no orthopnea or leg swelling but occasional paroxysmal nocturnal dyspnea. She complains of a dull aching discomfort in the right upper quadrant of her abdomen.

On examination, she is tachycardic with a HR of 120 bpm and BP of 106/88 mmHg. Her extremities are warm. The JVP is elevated to 8 cm above the sternal angle at 60°. The chest is clear to auscultation. In addition to loud first and second heart sounds, a prominent S3 is heard. There is right upper quadrant abdominal tenderness with no rebound tenderness or guarding. A chest X-ray is performed and shows an enlarged cardiac silhouette. An ECG shows sinus tachycardia with low voltages and a nonspecific ST abnormality. Labs are notable for elevated liver enzymes.

Echocardiography shows severe left ventricular dysfunction with an LVEF of 10%, moderate mitral regurgitation, and moderate right

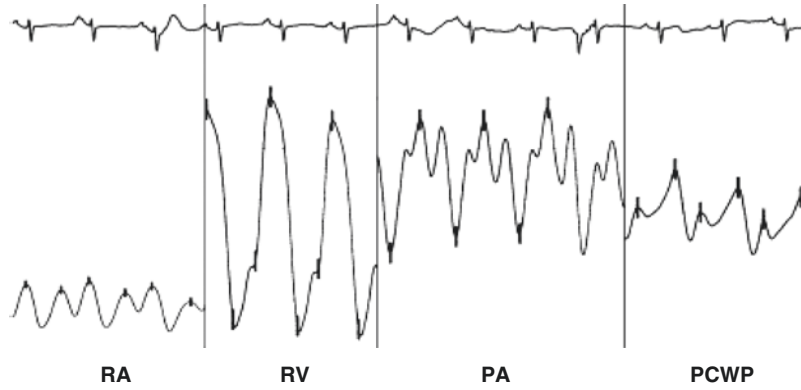

Fig. 19.5 Case 2 sample hemodynamic tracings: Pressures were recorded with the catheter positioned in the right atrium (RA), right ventricle (RV), and pulmonary artery (PA) as well as with pulmonary capillary "wedging" (PCWP). The following pressures were noted: RA mean pressure of 10 mmHg (normal, 0–8 mmHg); RV, pressure of 46/10 mmHg (normal 15–30/0–8 mmHg); PA, pressure of 46/30 mmHg (normal 15–30/4–12 mmHg); and PCWP, mean pressure of 32 mmHg (normal 1–10 mmHg)

ventricular dysfunction. She is given a presumptive diagnosis of a peripartum cardiomyopathy. She is admitted to a heart failure intensive care unit and a pulmonary artery catheterization is performed. Samples from the tracings are seen in Fig. 19.5. Note the somewhat exaggerated waveforms on the section of the tracing labeled pulmonary artery, a commonly encountered artifact.

Her reported hemodynamics are as follows:

RA	PA	PCWP	Cardiac index
10	46/30 (35)	32	2.0

Case 2: Hemodynamic Assessment

This is a case of a patient with so-called "cold and wet" heart failure. The cardiac index is reduced, and both the RA pressure and the PCWP are increased. When accompanied by findings of impaired end-organ function, this state would be termed cardiogenic shock (see Chap. 14). For this patient, there is no clinical evidence of a low perfusion state, such as hypotension, decreased level of consciousness, cool extremities, or renal failure.

The right upper quadrant pain and elevated liver enzymes reflect passive congestion of the liver. The physical examination disclosed an elevated JVP which corresponds to the elevated RA pressure. Note that there were no rales on chest examination and only minimal pulmonary edema on chest X-ray. These findings may have led the clinician to suspect that PCWP was not elevated. Unfortunately, such findings of elevated PCWP are frequently not present among chronic heart failure patients when the time-course of the decompensation is gradual. In such cases, pulmonary lymphatic drainage is enhanced and sufficient to prevent the accumulation of interstitial edema in the lungs. The finding of an S3 should definitely steer the clinician in the right direction, however. The low cardiac output was not recognized at the bedside due to the lack of cool extremities, altered mentation, and low urine output underscoring the insensitivity of these findings [12, 44]. However, if one calculates the proportional pulse pressure in this patient (106–88/106), a value of 17% is obtained suggesting a low cardiac index of <2.2 (see section "Clinical Estimation of Cardiac Output") [11].

The presence of a significant resting sinus tachycardia is ominous however. It suggests that the patient is compensating for a reduced stroke volume by increasing heart rate to maintain cardiac output.

The echocardiogram was crucial in confirming that severe biventricular dysfunction was the cause of the heart failure syndrome. The right heart catheterization was performed because of a concern that the patient was potentially unstable

and needed invasive monitoring. In this case, the right heart catheterization also shows mild elevation in pulmonary artery pressure. The calculated pulmonary vascular resistance (see Chap. 12 for more details) is normal at 1.0 Wood unit:

$$\text{PVR} = \frac{(\text{Mean PA pressure} - \text{PCWP})}{\text{Cardiac output}}$$

$$\text{PVR} = \frac{35-32}{3*} = 1$$

*Cardiac index of 2.0 corresponded to cardiac output of 3 L/min because of body surface area of 1.5 m^2.

This suggests that the patient's pulmonary hypertension is passive and there is no element of pulmonary vasoconstriction or pulmonary vascular remodeling.

The patient was treated with diuretic therapy, ACE inhibitors, and digoxin and observed carefully in an ICU setting. *Beta blockers should not be initiated in such a patient until they become euvolemic and hemodynamically stable*. She was discharged from the hospital 7 days later. Over the next 6 months, the patient was followed closely as an outpatient and had dramatic improvement in symptoms and complete resolution of LV dysfunction. She was advised to avoid pregnancy in the future due to the high risk of recurrent heart failure.

Case 3

A 58-year-old male is referred to a specialized heart failure clinic for evaluation. He has been followed for several years for a non-ischemic dilated cardiomyopathy with severe limitation of his exercise tolerance. His physician sends him for evaluation for the possible need for heart transplantation due to end-stage heart failure. When questioned, he reports that over the past 3 weeks, he has had worsened symptoms of weight gain and leg swelling. These symptoms began after he had started taking a nonsteroidal anti-inflammatory drug for arthritis. On examination, his HR is 90 bpm and his BP measures 98/70 mmHg. He is grossly edematous with pitting edema of both legs as well as scrotal edema. His JVP is elevated with prominent *v* waves. Auscultation of the chest reveals normal breath sounds with no rales or wheeze. On examination of the precordium, there is a loud pulmonic component of the second heart sound and an S3 gallop.

Echocardiography shows severe left ventricular dysfunction with an LVEF of 10% and moderate mitral regurgitation. Severe right ventricular dysfunction is also noted. The estimated RVSP by echocardiography is 88 mmHg (see Fig. 19.6).

The patient is admitted to the hospital, and a right heart catheterization is performed with the following results:

RA	PA	PCWP	Cardiac index
19	88/44 (59)	39	1.5

Case 3: Hemodynamic Assessment

This is another case of so-called "cold and wet" heart failure with reduced cardiac output and elevated right- and left-sided filling pressures. Note again that the patient was not hypoxic and auscultation of the chest did not reveal rales despite a very high PCWP. In contrast to the previous case, the pulmonary hypertension is severe with pulmonary artery pressures approaching the systemic pressures. The loud pulmonic component of S2 is consistent with these high pressures, although it is not a sensitive finding.

The calculated pulmonary vascular resistance is very high (see calculations below) suggesting that there is a pulmonary arterial component to the pulmonary hypertension that would not be immediately reversed if the PCWP was lowered.

$$\text{PVR} = \frac{(\text{Mean PA pressure} - \text{PCWP})}{\text{Cardiac output}}$$

$$\text{PVR} = \frac{59-39}{2.5} = 8 \text{ Wood units}$$

Note how closely the PA pressure was estimated by the transthoracic echocardiogram. Studying the parasternal short-axis images from the echocardiogram also gives us some idea of the relative left- and right-sided intracardiac pressures (Fig. 19.7). The flattened configuration of the interventricular septum during both systole

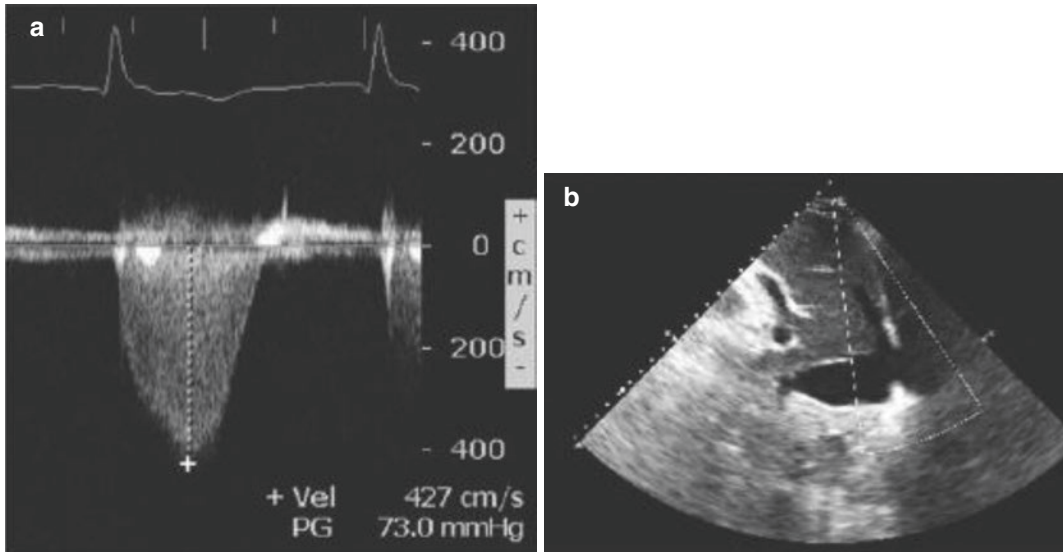

Fig. 19.6 Case 3: estimation of pulmonary artery systolic pressure by echocardiography. Peak velocity of the tricuspid regurgitation jet is 4.27 m/s (**a**) – this suggests a gradient from the RV to the RA of ~73 mmHg. [RV to RA gradient = $4v^2 = 4 \times (4.27)^2 = 72.9$ mmHg. The IVC is dilated (**b**) with a diameter of 2.8 cm and less than 50% variation with respiration – these findings suggest an RA pressure of 15 mmHg. Estimated peak pulmonary artery pressure is 88 mmHg (assuming no pulmonary valve stenosis) (73 + 15 = 88)

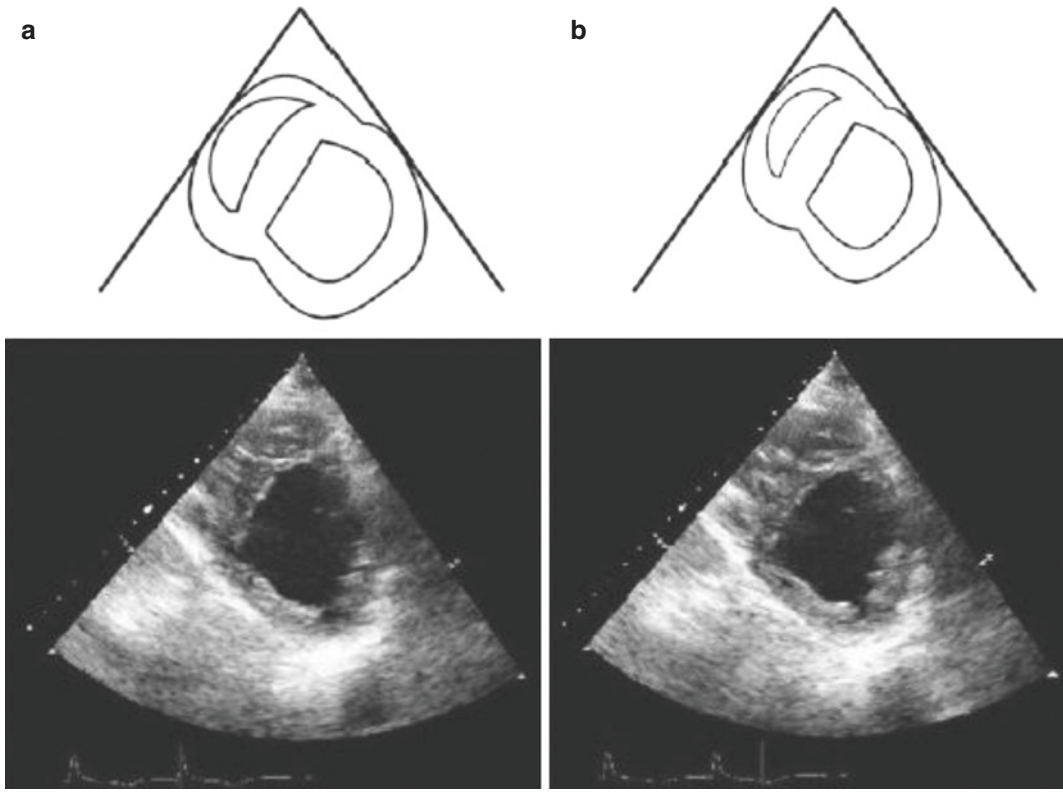

Fig. 19.7 Case 3: parasternal short-axis echo images showing pronounced flattening of the interventricular septum during diastole (**a**) which is still present during systole (**b**). This produces a "D-shaped appearance" of the left ventricle as emphasized in the cartoon above. Severe left ventricular dysfunction is suggested by the minimal change in area of the left ventricular cavity

and diastole suggests that the pressure in the right ventricle (and hence the pulmonary artery) is very high during both systole and diastole.

The patient was treated with inotropic therapy using milrinone, as well as a continuous infusion of furosemide. He was felt to have advanced heart failure, but his high pulmonary vascular resistance precluded heart transplantation because of the risk that the transplanted heart would develop acute right ventricular failure. He underwent placement of a left ventricular assist device which functions as an additional mechanical pump that reroutes blood from the left ventricle into the aorta. With this intervention, he had a dramatic improvement in symptoms and exercise tolerance as well as a marked reduction in PCWP and pulmonary artery pressure.

Pearls of Assessment

- The history and physical examination provide the majority of the hemodynamic information required to manage acute decompensated heart failure.
- No single symptom or sign is perfectly sensitive or specific for the diagnosis of acute decompensated heart failure.
- The most reliable sign of elevated right atrial pressure is elevation of the jugular venous pressure.
- Paroxysmal nocturnal dyspnea is a specific symptom for elevated PCWP.
- Transthoracic echocardiography is an important means of establishing the mechanism of newly diagnosed heart failure and of excluding new structural problems as the trigger for heart failure exacerbation.
- Echocardiography is not needed in routine heart failure exacerbations when a cause for decompensation is clear.
- Need for right heart catheterization is being obviated by noninvasive means of estimating hemodynamic parameters in most situations.
- Right heart catheterization in acute decompensated heart failure is indicated when volume status and cardiac filling pressures are unclear and clinically significant hypotension or worsening renal function during therapy occurs and for the evaluation of pulmonary vascular resistance.

Review Questions

1. A patient with known chronic systolic heart failure is admitted with acute decompensated heart failure. The patient has orthopnea and paroxysmal nocturnal dyspnea. On exam, the jugular venous pressure (JVP) is elevated and estimated to be 10 cm above the sternal angle while the patient is seated upright. Auscultation reveals an S3 gallop. Which of the following suggests an elevated pulmonary capillary wedge pressure (PCWP)?
   A. Orthopnea
   B. S3 gallop
   C. Elevated JVP
   D. All of the above
   Answer D
   Orthopnea and paroxysmal nocturnal dyspnea are the most specific symptoms for elevated PCWP. Although an S3 gallop is not sensitive, it is the most specific sign of left ventricular filling pressure. Elevated jugular venous pressure, although directly estimates right atrial pressure, is a surrogate for elevated PCWP in the vast majority of cases.
2. A patient admitted with decompensated heart failure undergoes right heart catheterization. The right atrial pressure is 5 mmHg, the pulmonary capillary wedge pressure is 10 mmHg, and the cardiac output is 4.0 L/min with cardiac index 1.9 L/min/m^2.
   This is an example of:
   A. Warm and wet heart failure
   B. Warm and dry heart failure
   C. Cold and wet heart failure
   D. Cold and dry heart failure
   Answer D
   The cardiac output of 4 L/min is close to normal. However, this patient has a large body surface area, and his calculated cardiac index is low. The PCWP and RA pressure are both in the normal range.

3. A 72-year-old male presents to the emergency department with a 2-week history of progressive shortness of breath with orthopnea and paroxysmal nocturnal dyspnea. On exam, he has peripheral edema and an elevated JVP at 12 cm above the sternal angle while seated upright. A prominent third heart sound is heard. The patient has inspiratory rales to the mid lung zones bilaterally. A chest X-ray confirms the presence of pulmonary congestion with vascular redistribution, Kerley B lines, and small bilateral pleural effusions.

   The most appropriate next study to assess this patient's etiology of heart failure and hemodynamics is:

   A. 2D echocardiogram with Doppler
   B. Right heart catheterization
   C. Computed tomography with IV contrast
   D. Magnetic resonance imaging

   Answer A

   Echocardiography is a noninvasive, readily available and relatively inexpensive tool for evaluation of left ventricular function, valvular disease, and hemodynamics. It is recommended as a first-line investigation for patients with a new diagnosis of heart failure.

4. The following are all appropriate indications for use of a pulmonary arterial catheter in heart failure except:

   A. Distinction of pulmonary edema related to heart failure from other causes of hypoxia in a critically ill patient in the intensive care unit
   B. Assessment of a patient in shock when intracardiac filling pressures cannot be adequately estimated by noninvasive means
   C. Monitoring of response to beta blocker therapy on routine annual follow-up
   D. Measurement of pulmonary pressures and calculation of pulmonary vascular resistance prior to planned heart transplantation

   Answer C

   For reasons discussed in the section on hemodynamic assessment, the use of pulmonary artery catheters in heart failure should be limited to certain scenarios such as those outlined in answers A, B, and D.

5. A patient admitted with decompensated heart failure undergoes right heart catheterization. The right atrial pressure is 10 mmHg, and the pulmonary arterial pressures are 59/32 mmHg with a mean of 40 mmHg. The pulmonary capillary wedge pressure is 34 mmHg, and the cardiac output is 4.0 L/min.

   The pulmonary pressure in this case could be described as:

   A. Normal – no evidence of pulmonary hypertension
   B. Elevated on the basis of pulmonary venous hypertension
   C. Elevated on the basis of pulmonary arterial hypertension
   D. Representing a mixture of pulmonary venous and pulmonary arterial hypertension

   Answer B

   A pulmonary pressure in this range is clearly abnormal. Determining the extent to which these pressures are elevated due to elevated left-sided pressures alone hinges on the calculation of the pulmonary vascular resistance. The pulmonary vascular resistance calculates out to be 1.5 Wood units, which is within the normal range. This suggests that if the LVEDP could be brought down to normal (with diuresis for example), the pulmonary pressures would become normal. This is the definition of pulmonary venous hypertension.

Intracardiac Shunts

20

Olcay Aksoy, Alper Ozkan, and E. Murat Tuzcu

Introduction and Epidemiology of the Disease State

In the normal circulation, deoxygenated blood comes into the right heart and passes through the pulmonary circulation to become oxygenated. Then oxygenated blood goes through the left heart to the systemic circulation. An abnormal communication between two heart chambers resulting in an intracardiac (IC) shunt may take place from systemic to pulmonary circulation (left to right) or from pulmonary to systemic circulation (right to left) or may be bidirectional. In this chapter, we review the evaluation and treatment of intracardiac shunts.

While congenital heart diseases are the most common causes of intracardiac shunts, acquired pathologies may also result in IC shunts. Left to right (L → R) shunt in postmyocardial infarction VSD and right to left (R → L) shunt in platypnea-orthodeoxia syndrome (POS) are two examples of acquired IC shunts.

Detection, localization, and quantification of intracardiac shunts are clinically important in the management of IC shunts and can be performed using noninvasive and invasive techniques. Noninvasive techniques include transthoracic or transesophageal echocardiography, cardiovascular magnetic resonance (CMR), and radionuclide tests. Invasive techniques apply catheter insertion and selective blood sampling of oxygen saturation to diagnose and quantify IC shunts.

Noninvasive Assessment of Intracardiac Shunts

Transthoracic echocardiography (TTE) is a safe, reproducible, and relatively inexpensive method that is widely used in the assessment of intracardiac shunts. Transesophageal echocardiography (TEE) is an excellent tool for defining the anatomy of IC shunts and provides additional information; however, its incremental value in shunt assessment is limited. Magnetic resonance imaging (MRI) allows precise measurement of cardiac volumes and flows yielding accurate IC shunt calculations.

Echocardiographic Assessment of Intracardiac Shunts

Echocardiography has been the primary diagnostic tool and plays an essential role in providing

A. T. Askari, A. W. Messerli (eds.), *Cardiovascular Hemodynamics*, Contemporary Cardiology,
https://doi.org/10.1007/978-3-030-19131-3_20

morphologic assessment and hemodynamic evaluation in congenital heart disease. TTE permits comprehensive anatomic information regarding the location and the size of the defect. TEE may be needed as a complementary imaging tool particularly in lesions located posteriorly and in patients who will undergo percutaneous or surgical intervention. Color flow Doppler plays a critical role in the detection and localization of IC shunts as well as in determining the direction of shunting—though the sensitivity of echocardiographic evaluation with color Doppler or 2D imaging only is limited. The use of contrast echocardiography with agitated saline together with Valsalva maneuver will increase right atrial pressure and may allow for increased sensitivity when diagnosing intracardiac shunting, when a patent foramen ovale is present. If microbubbles from agitated saline injected from a peripheral vein is seen to enter the left heart chambers within 3 beats; this is consistent with an intracardiac communication between right and left chambers of the heart. If there is delayed appearance of microbubbles in the left chambers (>5 beats), this is associated with intrapulmonary shunting. TEE and transcranial Dopplers with microbubble administration have also enhanced the detection of shunts not otherwise visualized by TTE techniques [1].

In addition to the detection of shunts, echocardiographic techniques can also provide quantification of the degree of shunting. Pulmonary blood flow (Q_p) to systemic blood flow (Q_s) ratio can be calculated using Doppler and 2D echocardiography.

Comprehensive evaluation of a patient with IC shunt is not limited to the detection and quantification of the shunt flow. It also involves the evaluation of the associated abnormalities and secondary findings. For example, in a patient with ASD, the evaluation of right atrial and right ventricular size and septal motion and for other associated anomalies such as anomalous pulmonary venos return is as important as the quantification of the defect.

The hemodynamic significance of intracardiac shunts can be evaluated based on volumetric flow calculations using cross-sectional area (CSA) and velocity time integral (VTI) across the outflow tracts of both ventricles. Pulmonary flow (Q_p) equals systemic flow (Q_s) in the absence of shunt. Formulas are used to calculate volumetric flow with two important assumptions. The first assumption is blood flow has a uniform pattern and constant velocity. The second assumption is that the shape of the outflow tract is circular.

Flow formula is as follows:

$$Q = \mathrm{CSA} \times \mathrm{VTI}$$

(Q = flow, CSA = cross-sectional area, VTI = velocity time integral)

CSA is calculated based on circular shape assumption:

$$\mathrm{CSA} = \pi \times r^2$$

(π = pi constant, which is 3.14; r = radius of the outflow tract)

For the pulmonary flow, the formulas are as follows:

$$Q_p = \mathrm{CSA}_{\mathrm{RVOT}} \times \mathrm{VTI}_{\mathrm{RVOT}}$$

$$Q_p = \pi \times \left(\frac{\text{RVOT Diameter}}{2} \right)^2 \times \mathrm{VTI}_{\mathrm{RVOT}}$$

$$Q_p = \pi \times \frac{\left(\text{RVOT Diameter}\right)^2}{4} \times \mathrm{VTI}_{\mathrm{RVOT}} \quad \text{with} \left(\frac{\pi}{4} = 0.785 \right)$$

$$Q_p = 0.785 \times \left(\text{RVOT Diameter}\right)^2 \times \mathrm{VTI}_{\mathrm{RVOT}}$$

For the systemic flow, the formula would be simplified as follows:

$$Q_s = 0.785 \times \left(\text{LVOT Diameter}\right)^2 \times \text{VTI}_{\text{LVOT}}$$

After simplification, the formula of Q_p/Q_s is

$$\frac{Q_p}{Q_s} = \frac{\left(\text{RVOT Diameter}\right)^2 \times \text{VTI}_{\text{RVOT}}}{\left(\text{LVOT Diameter}\right)^2 \times \text{VTI}_{\text{LVOT}}}$$

See the example in Fig. 20.1. (Q_p = pulmonary flow; Q_s = systemic flow; RVOT = right ventricle outflow tract; LVOT = left ventricle outflow tract).

Potential Source of Errors and Pitfalls

Precise measurements of LVOT and RVOT diameters require appropriate site selection. LVOT diameter should be measured at the level of the aortic annulus during systole in parasternal long axis view of the LV, whereas RVOT is measured at the level of pulmonary valve annulus in parasternal short axis view (see Fig. 20.1). It is important to note that CSA is calculated as if it is a perfect circle even though the shape of the outflow tracts change throughout the cardiac cycle as these are dynamic structures. Positioning of

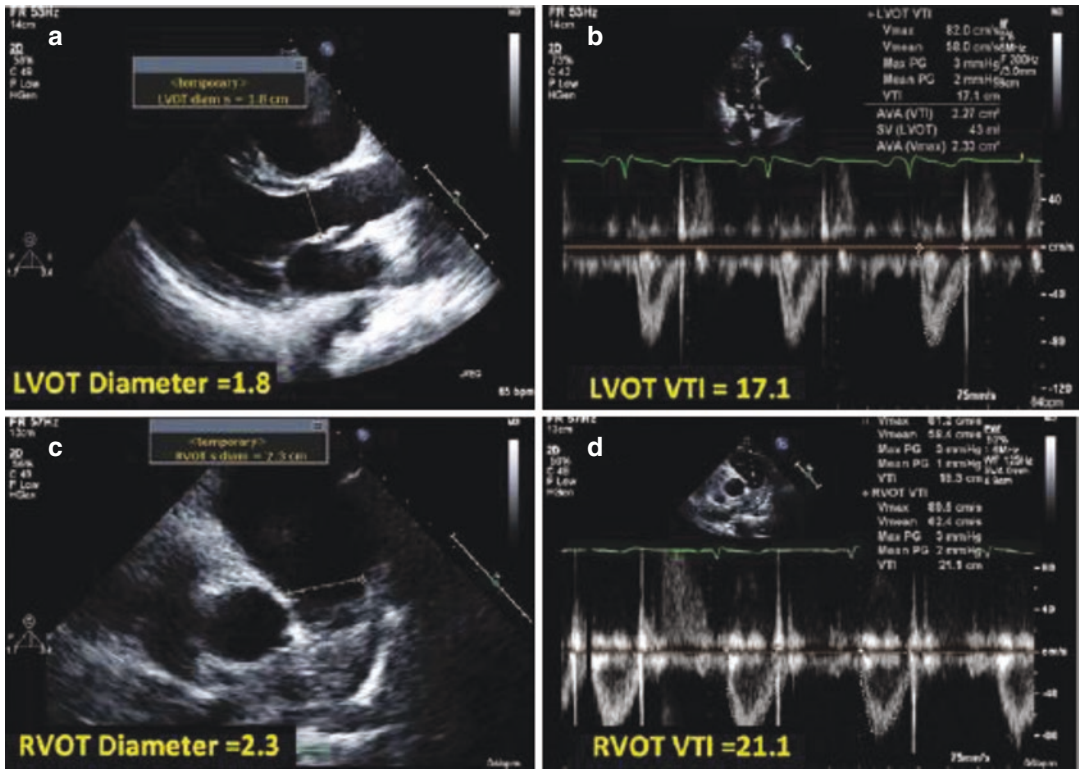

Fig. 20.1 Quantification of IC shunts using transthoracic echocardiography. Systemic stroke volume or flow (Q_s) can be calculated by using CSA of LVOT, which is derived by LVOT diameter at the end of systole (**a**), and LVOT VTI (**b**) pulmonary stroke volume or flow (Q_p) can be measured using CSA of RVOT, which is derived by RVOT diameter at the end of systole (**c**) and RVOT VTI (**d**)

$$\frac{Q_p}{Q_s} = \frac{\text{CSA RVOT} \times \text{VTI RVOT}}{\text{CSA LVOT} \times \text{VTI LVOT}}, \quad \frac{Q_p}{Q_s} = \frac{3.14 \times (2.3/2)^2 \times 21.1}{3.14 \times (1.8/2)^2 \times 17.1}, \quad \frac{Q_p}{Q_s} = \frac{87.6}{43.5} = 2.$$

CSA cross-sectional area, *LVOT* left ventricle outflow tract, *VTI* velocity time integral, and *RVOT* right ventricle outflow tract

sample volume of pulsed wave Doppler signals should be obtained at the levels where RVOT and LVOT diameters were measured. Optimal Doppler signals must be acquired for accurate velocities and VTI. Respiratory variations can affect the position of PW sample location or Doppler velocities.

Many other pitfalls such as arrhythmia, heart rate variability, and presence of valvular heart disease in particular aortic and mitral regurgitation may also complicate shunt assessment. A small error in the diameter measurement is magnified in the calculation of cross-sectional area translating into large errors in flow calculations.

Assessment of Intracardiac Shunt with Cardiovascular Magnetic Resonance

Although echocardiography provides the clinician with an initial screening tool for the assessment shunts, cardiovascular magnetic resonance (CMR) has become a complementary tool for the noninvasive evaluation of the size and morphologic features of the congenital cardiac defects. MRI provides not only the exact visualization of cardiac anatomy but also allows accurate and reproducible quantification of IC shunts. Studies have demonstrated that MRI measurements of IC shunts correlate with those obtained by invasive methods in children [2–5] as well as in adults [5] using different MRI applications [6, 7]. Volumetric MRI and phase contrast cine MRI are the commonly used protocols for the assessment of IC shunt. With these techniques, ventricular stroke volume can be calculated for each ventricle with short axis and/or four chamber views (Fig. 20.2). In the absence of significant valvular regurgitation or ventricular septal defect (VSD), the ratio of the RV to LV stroke volumes yields the Q_p/Q_s ratio. Velocity-encoded (VENC) cine MR is another application for the measurement of IC shunt [6]. Each voxel has its own velocity across the vessel in the gray scale images. Flow can be estimated using the cross-sectional area of the vessel and integrated into the velocity of the blood at the same level. Magnitude images provide an accurate measurement for the cross-sectional areas of the vessel, and phase cine MR images offer reliable quantification for mean flow velocity [3] (Fig. 20.3a, b).

MRI has many advantages when compared to other noninvasive imaging modalities. Unlike echocardiography, MR allows visualization of vascular structures in addition to cardiac chambers. It is possible to make reliable and reproducible measurements of blood flow velocities and assess stenotic and regurgitant valvular lesions by CMR. These can be accomplished with much less subjectivity compared with echocardiography. In contrast to radionuclide technique or cardiac computed tomography (CT), MR does not have any ionizing radiation. In addition to the accurate quantification of IC shunts, MRI is a promising technique for the guidance of transcatheter closure of congenital heart defects [8]. After the closure of such defects, MRI can clearly show the anatomic location of the device and can quantify its effectiveness [9–11]. However, MRI requires more patient compliance, and a comprehensive MR exam takes time and is relatively expensive. Many stents, devices, and vascular filters are MR compatible. Whereas implantable cardiac devices have previously been considered as absolute contraindications, MRI-conditional and MRI-safe pacemakers are now available.

Other Noninvasive Imaging Modalities

Radionuclide techniques can also be used for the assessment of IC shunt. Radionuclide scintigraphy can be considered as an alternative noninvasive method for the quantification of IC shunt and evaluation of LV function in patients with post-MI VSR [12].

Cardiac CT can provide comprehensive anatomic information in the assessment of congenital cardiac defects. Although cine CT makes some hemodynamic measurements possible such as cardiac output, quantification of IC shunts with CT has not been well established.

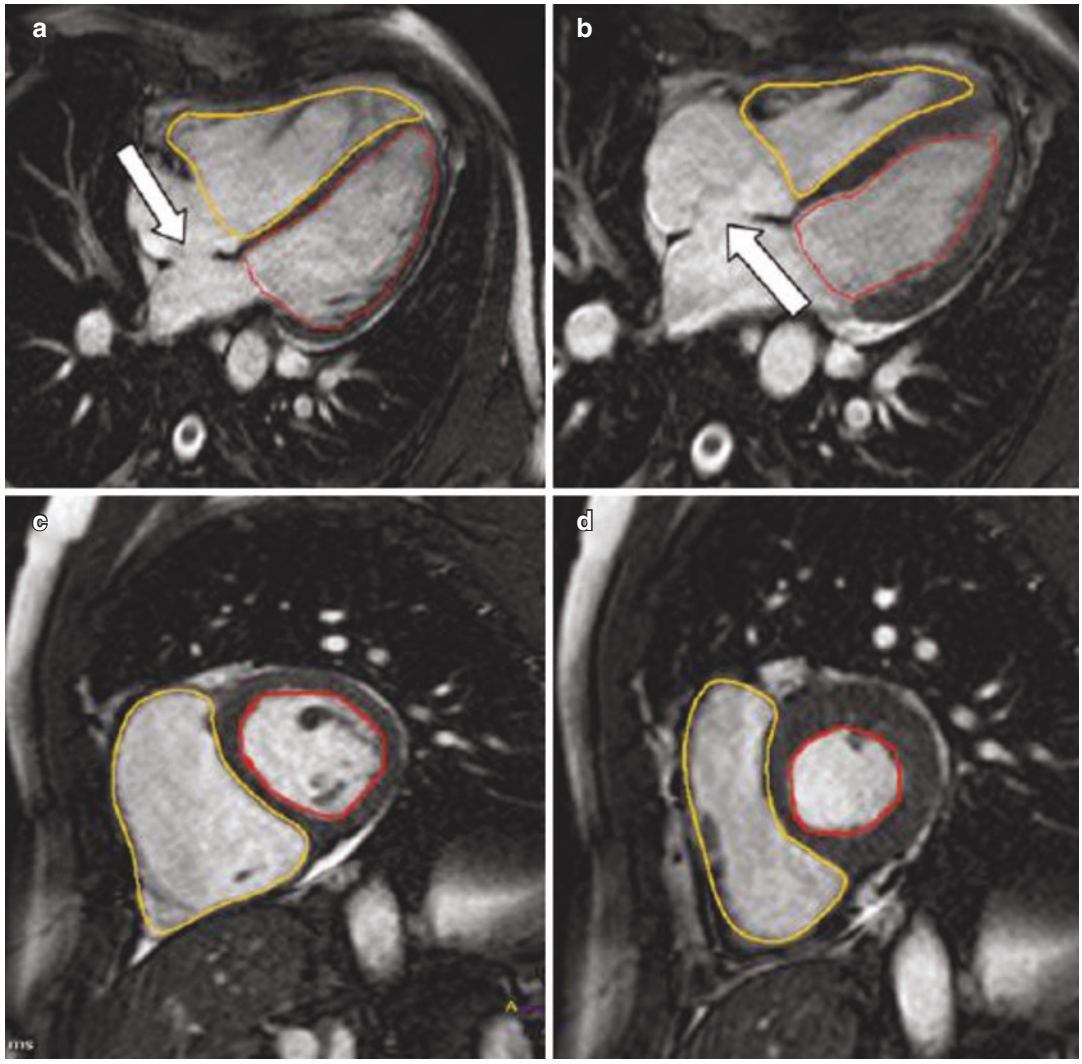

Fig. 20.2 Volumetric method for the quantification of IC shunt. Diastolic (**a**) and systolic (**b**) four chamber cine MR images of both ventricles demonstrate moderately dilated RV with normal systolic function. Diastolic (**c**) and systolic (**d**) short axis cine MR images of both ventricles. The ratio of the RV to LV stroke volumes gives shunt ratio (Q_p/Q_s). LV EDV = 194 cm^3; LV ESV = 102 cm^3; LV SV = 92 cm^3; LV EF = 48%, RV EDV = 289 cm^3; RV ESV = 124 cm^3; RV SV = 165 cm^3; and RV EF = 57%. Shunt ratio can be therefore calculated for this ASD case (*white arrows* show the defect); Q_p/Q_s = 165/92 = 1.8 (ASD atrial septal defect, EDV end diastolic volumes, ESV end systolic volumes, LV left ventricle, RV right ventricle)

Invasive Quantification of Intracardiac Shunts

IC shunts have been calculated using various invasive methods. Indocyanin dilution and/or dye curve technique have been used in the past. Contrast angiography provides qualitative evaluation and localization of the shunts but is not suitable for precise shunt quantification. The widely used invasive technique is the oxymetric study, which is based on blood sampling from different locations in the circulation.

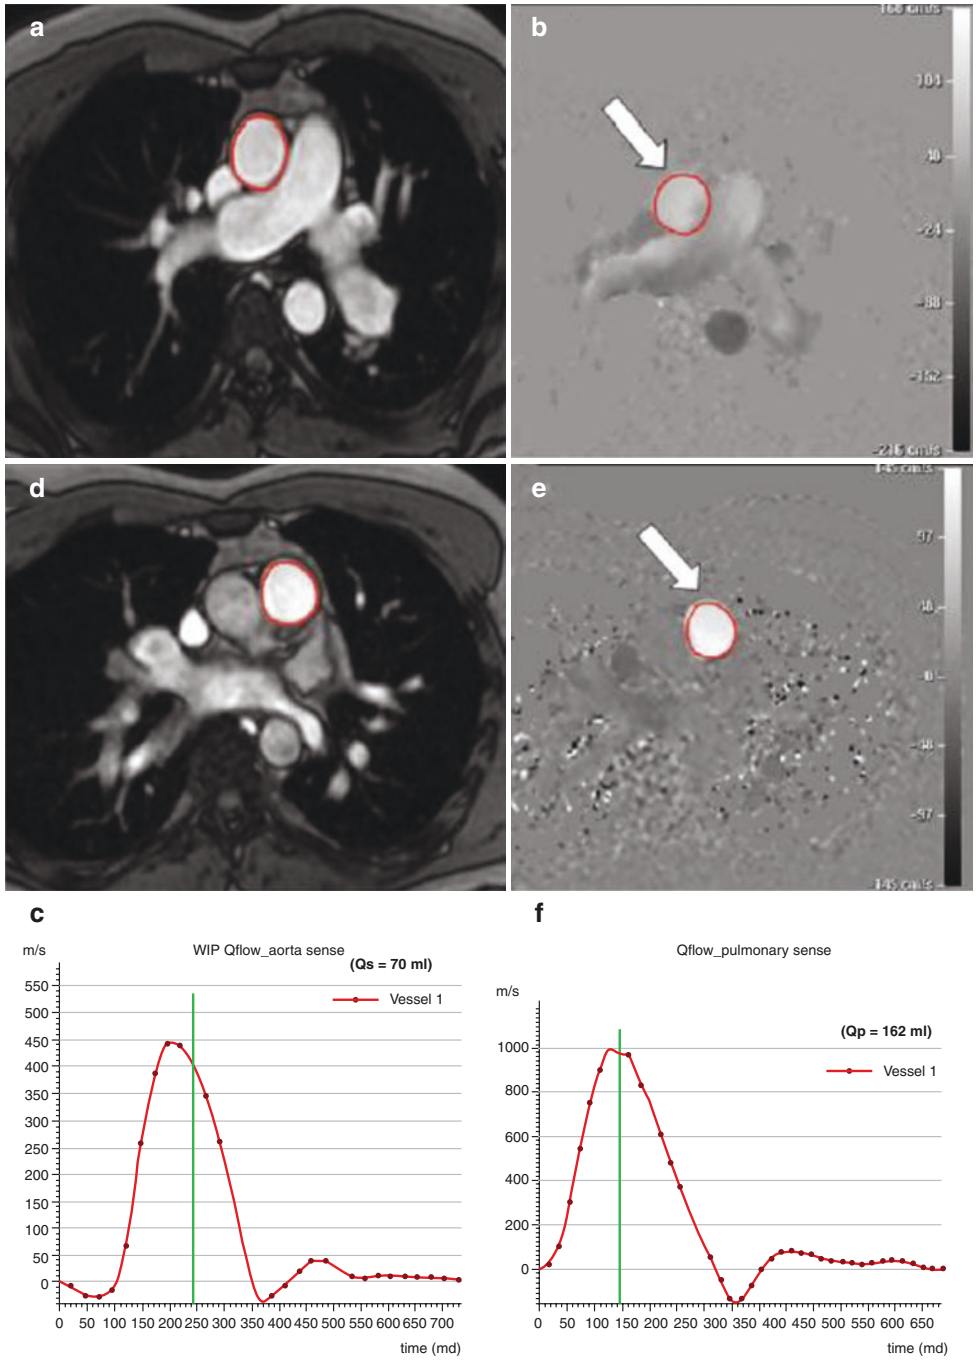

Fig. 20.3 (**a**–**c**) Velocity-encoded (phase contrast) cine MR imaging for the quantitation of systemic flow (Q_s). (**a**) Magnitude image of the ascending aorta for the measurement of cross-sectional area of the vessel. The plane is positioned at the level of the bifurcation of the main pulmonary artery. (**b**) Phase contrast image perpendicular to the ascending aorta (*white arrow*). (**c**) Through-plane velocity mapping creates flow vs. time curves. The area under the curve represents stroke volume of the ascending aorta (Q_s), which was measured 70 mL/beat for this case. (Q_s = 70 mL). (**d**–**f**) Phase contrast cine MR imaging for the quantitation of pulmonary flow(Q_p). (**a**) Magnitude image of the main pulmonary artery. (**b**) Phase contrast image perpendicular to the main pulmonary artery (*white arrow*). (**c**) Through-plane velocity mapping demonstrates flow vs. time curves across the main pulmonary artery. The area under the curve represents stroke volume of the pulmonary artery (Q_p), which was calculated 162 mL/beat for this case. The shunt ratio was therefore calculated Q_p/Q_s = 162/70 = 2.2, which indicates significant left to right shunting

Oxygen Saturation Run

Knowledge of basic principles of Fick's method is fundamental to understanding how IC shunts are calculated in catheterization laboratory.

Blood Sampling

Blood samples should be obtained after a "steady state" of heart rate, respiratory rate, and blood pressure is reached on room air if tolerated by patient. A large hole catheter should be used for easy blood draw. It should be kept in mind that very rapid aspiration or a faulty connection may allow the entry of microbubbles into the syringe, resulting in erroneously increased O_2 saturation and overestimation of Q_p [13]. Sites for blood sampling must be carefully chosen depending on the underlying pathology (Fig. 20.4) Blood sampling procedure should be completed within 5–10 min (or at the same time that oxygen consumption is calculated) in order to minimize the variability in oxygen consumption. After each sample is obtained, the catheter must be cleared with a saline flush. Obtaining blood samples from distal to proximal during catheter "pull-back" from pulmonary artery (PA) is more practical. If possible, the patient should not be receiving supplemental oxygen greater than 30%, as the increased dissolved O_2 in the right heart might cause increased pulmonary flow resulting in overestimation of the shunt ratio.

Variability of oxygen measurements and oxygen content should be taken into account during the sampling process, particularly in the right-sided heart chambers. In a study with 980 patients [14] without shunting, differences of O_2 saturation were found between SVC and RA, RA and PA, and SVC and PA, 3.9 ± 2.4%, 2.3 ± 1.7%, and 4.0 ± 2.5%, respectively. In another study [15], 102 adults without left to right shunt were assessed in order to find the limits of normality of O_2 content differences. The outcomes were from right atrium to mixed venous, right ventricle to right atrium, and pulmonary artery to right ventricle, 0.5 mL/dL, 0.6 mL/dL, and 0.9 mL/dL, respectively.

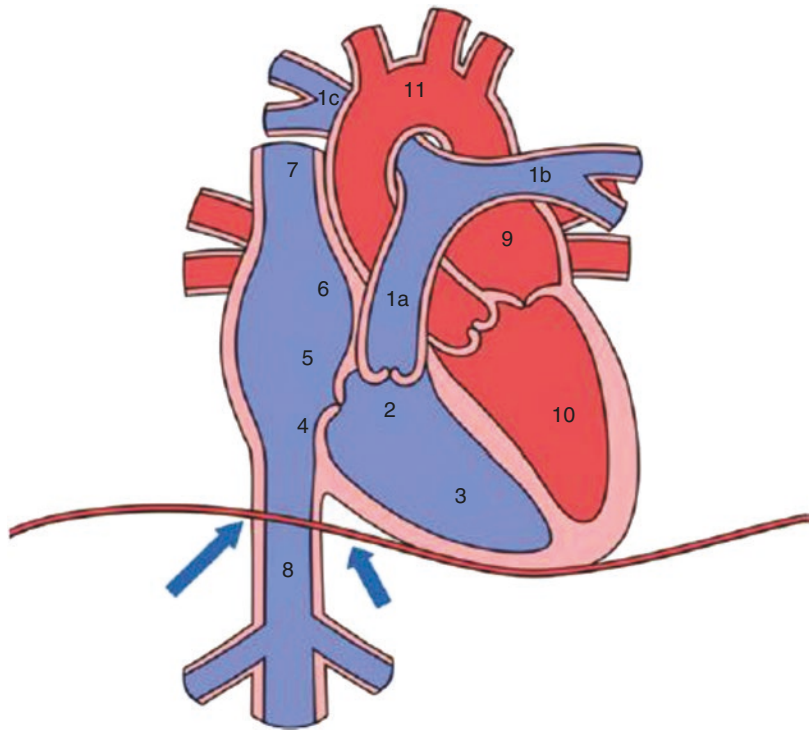

Fig. 20.4 Exact localization for the blood sampling in oxymetric run study. *1a* main pulmonary artery, *1b* left pulmonary artery, *1c* right pulmonary artery, *2* right ventricular outflow tract, *3* right ventricle, *4* low right atrium, *5* mid right atrium, *6* high right atrium, *7* superior vena cava, *8* inferior vena cava (sample should be obtained just below the diaphragm (*blue arrows*); hepatic vein must be taken into account while obtaining inferior vena cava blood), *9* left atrium, *10* left ventricle, *11* aorta or femoral artery

Mixed Venous Oxygen Saturation

In the normal circulation, deoxygenated blood is mixed in the pulmonary artery (PA). However, in the setting of left to right shunt, the site of mixed venous blood would vary according to the location of the lesion. Unfortunately, there is no practical way to measure mixed venous oxygen (MVO_2) because the various sources of MVO_2 (superior vena cava, inferior vena cava, coronary sinus) have different amounts of blood with varying saturations. As a general rule, blood samples should be obtained proximal and distal to the lesion and blood from the chamber(s) proximal to the shunt site is used for MVO_2 measurement. For instance, in the case of patent ductus arteriosus (PDA), arterial blood mixes with venous blood at the pulmonary artery at the level of the aorta. Thus, venous samples should be taken from RV, which is the proximal chamber to the shunt site. In patients with a ventricular septal defect, RAO_2 saturation can represent MVO_2 site. In the case of an atrial septal defect, the location where the arterial shunt mixes with venous blood is not constant. Different formulas are used for the calculation of MVO_2. The most commonly used formula in the estimation of MVO_2 is ((3 × SVC + 1 × IVC)/4) [16]. Other formulas may also be considered for an estimation of MVO_2 as follows:

$$\begin{bmatrix} = \dfrac{\left(\left(1\times \mathrm{SVC_{Sat}}\right)+\left(2\times \mathrm{IVC_{Sat}}\right)\right)}{3} \\ \mathrm{MVO_2} = \dfrac{\left(\left(2\times \mathrm{SVC_{Sat}}\right)+\left(3\times \mathrm{IVC_{Sat}}\right)\right)}{5} \end{bmatrix}$$

where MVO_2 = mixed venous oxygen saturation, SVC_{Sat} = superior vena cava saturation, and IVC_{Sat} = inferior vena cava saturation [15, 17].

Calculation of Shunt Size "Pulmonary to Systemic Flow Ratio (Q_p/Q_s)"

In the absence of a shunt, pulmonary blood flow (Q_p) is equal to the systemic blood flow(Q_s). Q_p/Q_s ratio is calculated based on Fick's principle as follows:

$$\text{Cardiac output} = \frac{\text{Oxygen consumption}}{\left(\text{Arterial } O_2 - \text{Venous } O_2\right)\times \text{Hemoglobin concentration}\times 1.36\times 10}$$

Since the pulmonary circulation occurs between pulmonary veins and pulmonary artery, the formula is adapted as follows:

$$Q_p = \frac{\text{Oxygen consumption}}{\left(\mathrm{PVO_2} - \mathrm{PAO_2}\right)\times \text{Hemoglobin concentration}\times 1.36\times 10}$$

where Q_p = pulmonary blood flow, PVO_2 = pulmonary vein oxygen saturation, and PAO_2 = pulmonary artery oxygen saturation.

Systemic circulation takes place between the aorta and the point where the venous blood is assumed to be fully mixed. Therefore, the formula corresponds to:

$$Q_s = \frac{\text{Oxygen consumption}}{\left(\mathrm{AoO_2} - \mathrm{MVO_2}\right)\times \text{Hemoglobin concentration}\times 1.36\times 10}$$

where Q_s = systemic blood flow, AoO_2 = aortic or systemic arterial oxygen saturation, and MVO_2 = mixed venous oxygen saturation).

These formulas can be simplified to calculate Q_p/Q_s as follows:

$$\frac{Q_p}{Q_s} = \frac{(AoO_2 - MVO_2)}{(PVO_2 - PAO_2)}$$

For right to left or bidirectional shunts:

Effective pulmonary blood flow must be calculated. The net difference of systemic flow to shunt flow should be considered as effective pulmonary flow.

Clinical Utility of the Shunt Ratio in Practice

Shunt ratio (Q_p/Q_s) can help clinicians to better understand the hemodynamic importance of the IC shunt and is clinically very important in decision-making about the requirement of possible intervention. If the ratio is less than 1.5, it generally indicates a "small lesion," a ratio of 1.5–2.0 indicates "likely to require intervention," and a ratio of 2 or more is usually considered to be "severe." Nevertheless, each case should be evaluated individually with its clinical presentation, and shunt ratio should be determined within the clinical context of the disease state. If there is inconsistency between invasive and noninvasive measurements, symptoms attributable to shunt defect, possible associated congenital abnormalities, as well as measurement pitfalls should be carefully reviewed. Secondary findings such as the quantification of chamber enlargement or ventricular function can also help in decision-making.

Review Questions

Q1—A 30-year-old woman presented with dyspnea on exertion. Echocardiographic examination revealed enlargement of right-sided heart chambers with an increased pulmonary flow. Left to right shunt was detected by color flow Doppler assessment in the interatrial septum. Which one of the following echocardiographic measurements is *not* necessary for the quantification of atrial shunt in this patient?

A. Diameter of LVOT
B. Diameter of RVOT
C. Diameter of defect
D. RVOT VTI
E. LVOT VTI

Q2—In which of the following congenital heart diseases, volumetric MRI measurement is *not* an appropriate method for the quantification of the intracardiac shunt?

A. Muscular type VSD
B. Secundum type ASD
C. Patent ductus arterious
D. Partial anomalous pulmonary venous return
E. Aorticopulmonary window

Q3—Which one of the following formulas can be used to estimate mixed venous blood (MVO_2) saturation during cardiac catheterization?

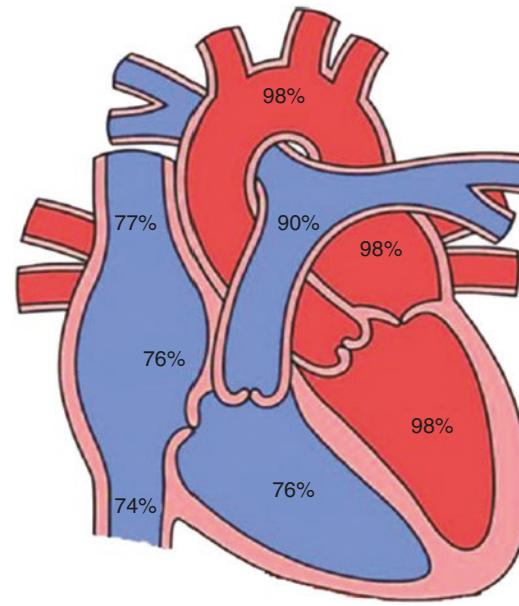
A. $MVO_2 = \frac{(3\times SVC_{sat} + 1\times IVC_{sat})}{4}$

B. $MVO_2 = \frac{(SVC_{sat} + IVC_{sat})}{2}$

C. $MVO_2 = \frac{(2\times SVC_{sat} + 3\times IVC_{sat})}{5}$

D. $MVO_2 = SVC_{sat}$

E. All of the above



Q4—A 16-year-old patient underwent cardiac catheterization for further investigation with the suspicion of congenital heart disease. Her hemoglobin level is 13 g/dL and calculated O_2 consumption is 190 mL/min. According to the saturation run study results, shown below, which is the correct diagnosis?

A. Muscular type VSD − Q_p/Q_s = 1.5
B. Ostium primum type ASD − Q_p/Q_s = 2.8
C. Ostium secundum type ASD − Q_p/Q_s = 2.8
D. Patent ductus arteriosus − Q_p/Q_s = 2.8
E. Patent ductus arteriosus − Q_p/Q_s = 1.5

Q5—A 36-year-old man who was diagnosed secundum type ASD with left to right shunting. Calculated Q_p/Q_s ratio was reported as 2.1 with right atrial and ventricular enlargement. There was no associated significant valvular abnormality and he was still on normal sinus rhythm (68 beats/s). He was complaining of palpitations and exertional dyspnea and referred to you for further investigation and treatment. The following oxygen saturations were measured in catheterization room while the patient was breathing 21% oxygen room air O_2 cont; IVCsat: 69%, SVCsat: 73%, PAsat: 80%, femoral artery sat: 98%.

What would you do for the next step in the evaluation of this patient?

A. Invasive Q_p/Q_s ratio cannot be calculated with these data; hemoglobin and cardiac output should have been reported.
B. Echocardiographic shunt ratio indicates significant left to right shunting with an enlargement of right-sided heart chamber, which is enough for the decision on closure of this ASD.
C. Room oxygen level is not enough; oxymetric study should be repeated while the patient is breathing 80% oxygen.
D. Invasive Q_p/Q_s indicates significant left to right shunt so the defect should be closed as soon as possible.
E. Invasive Q_p/Q_s indicates nonsignificant left to right shunt; therefore, the patient should be treated medically and must be closely monitored.

Answers of the Questions

A1—The correct answer is C.

Echocardiography is the primary tool for the assessment of congenital heart disease. Although echocardiography can provide sizing of the defect, it is not required in the quantification of shunt ratio. The defect size, however, cannot give an idea about the shunt ratio. Small lesion can be associated with small shunt ratio, whereas big lesions can be complicated by Eisenmenger physiology with right to left or bidirectional shunting.

A2—The correct answer is A.

Gradient echo cine MR can provide comprehensive volumetric assessment for both ventricles. The shunt volume can be easily calculated as net difference between LV and RV stroke volumes. In the setting of VSD, however, IC shunt occurs at the ventricular level and quantification of Q_p/Q_s is impossible using this method. On the other hand, if there is severe valvular regurgitation, due to substantial back flow into the atria, stroke volumes can be underestimated.

A3—The correct answer is E.

Although the most common formula is (3 × SVC + IVC)/4, in the estimation of saturation MVO_2 blood**,** other formulas can be considered.

A4—The correct answer is D.

The diagnosis is PDA with L → R shunt. O_2 step up can be clearly seen in the main pulmonary artery. Hence, we can easily calculate Q_p/Q_s using simplified formula, which is

$$\frac{Q_p}{Q_s} = \frac{\left(AoO_2 - MVO_2\right)}{\left(PVO_2 - PAO_2\right)}$$

$$\frac{Q_p}{Q_s} = \frac{\left(98-76\right)}{\left(98-90\right)} = \frac{\left(22\right)}{\left(8\right)} = 2.75$$

Step-by-step approach for the assessment of intracardiac shunt quantification:

Step 1: Compute oxygen content for main locations

$$\text{Arterial oxygen content} = 0.98 \times 1.36 \times 13 \times 10 = 173$$
$$\text{Pulmonary vein oxygen content} = 0.98 \times 1.36 \times 13 \times 10 = 173$$
$$\text{Pulmonary artery oxygen content} = 0.90 \times 1.36 \times 13 \times 10 = 160$$
$$\text{Mixed venous oxygen content} = 0.76 \times 1.36 \times 13 \times 10 = 134$$

(As this is a PDA case, RVsat can represent MVO_2)

Step 2: Compute systemic flow (Q_s)

$$\frac{190}{173-134} = 4.87$$

Step 3: Compute pulmonary flow (Q_p)

$$\frac{190}{173-160} = 14.6$$

Step 4: Compute Q_p/Q_s

$$\frac{14.6}{4.87} = 3$$

A5—The correct answer is B.

Invasive oxymetric measurement of the Q_p/Q_s ratio is 1.5, which is inconsistent with echocardiographic shunt ratio. This is not an uncommon situation in daily practice. Although Q_p/Q_s ratio is clinically very important in decision-making, if there is strong clinical suspicion or laboratory evidence of a significant shunt (this patient is symptomatic and TTE revealed right-sided heart chamber enlargement), then the defect should be closed. On the other hand, it should be kept in mind that atrial shunts can easily be affected by ventricular filling patterns such as compliance or stiffness and might be underestimated in the setting of severe tricuspid regurgitation or atrial fibrillation.

Hemoglobin and oxygen contents are not exactly necessary for an estimation of Q_p/Q_s ratio. Because same parameters are used in the denominator and nominator of the equations, simplified method can be used practically.

Shock

21

Jose Mariano T. Tan and Michael P. Brunner

Epidemiology of Shock

Shock is a pathophysiological state characterized by inadequate tissue oxygenation. It is a life-threatening condition that may lead to cellular death and vital organ dysfunction. Common clinical manifestations of shock include tachycardia, hypotension, oliguria, and confusion. Laboratory tests often demonstrate signs of end-organ damage such as acute liver or kidney injury, metabolic acidosis, and lactic acidosis.

There are four major categories of shock: cardiogenic, hypovolemic, distributive, and obstructive shock. However, it is important to note that these major categories of shock are not mutually exclusive and combinations with other form(s) of shock may occur.

Cardiogenic shock (CS) is often depicted as shock due to pump failure. The primary disorder in CS is low cardiac output due to intrinsic cardiac dysfunction. It is often a complication of myocardial infarction, but it may also be due to arrhythmia, congestive heart failure, or a primary valvular disorder. CS is estimated to complicate 3–8% of cases of acute myocardial infarction [1–3]. The mortality rate associated with CS in patients with acute myocardial infarction historically approached 80% [1]. Due to contemporary strategies in the management of acute coronary syndrome, the adjusted mortality rate ranges from 45 to 66% [4].

Hypovolemic shock is shock due to hemorrhagic or nonhemorrhagic volume loss. It is often related to traumatic injury, gastrointestinal bleeding, vomiting, or diarrhea. The incidence of hypovolemic shock varies depending on its underlying etiology.

The most common etiology of *distributive shock* is sepsis, a dysfunctional systemic response to an infection. Every year, 1.6 million patients are diagnosed with sepsis in the United States [5]. In its severe form, septic shock may ensue. The mortality associated with severe sepsis and septic shock is estimated to be 14.7–29.9% [6]. These figures are likely underestimated as severe sepsis and septic shock often occur concomitantly with other leading causes of mortality including pneumonia, urinary tract infection, gastrointestinal tract infection, skin infection, and malignancy.

The primary disorder in *obstructive shock* is low cardiac output due to extrinsic cardiac dysfunction. The incidence of obstructive shock varies according to its etiology which includes pulmonary embolism, cardiac tamponade, and tension pneumothorax.

Clinical Presentation of Shock: A Case-Based Approach

Understanding the pathophysiology associated with each category of shock is essential in performing an appropriate clinical assessment and guiding appropriate therapy. Examples of different conditions associated with each major category of shock are listed in Table 21.1. The following cases are examples from each category of shock.

Case 1: Cardiogenic Shock

A 55-year-old male with hypertension, dyslipidemia, and a family history of coronary artery disease presents to the emergency department

Table 21.1 Etiologies of shock

Cardiogenic[a]	**Distributive**
Myopathic	Sepsis; pancreatitis
Acute myocardial infarction	Pancreatitis
Left ventricular failure	Anaphylaxis
Right ventricular failure	Bacterial toxins
Acute myocarditis	Acidosis
Idiopathic cardiomyopathy	Adrenal crisis
Restrictive/constrictive cardiomyopathy	Myxedema coma
Stress-induced (Takotsubo) cardiomyopathy	Iatrogenic
Acute heart transplant rejection	Neurogenic insult
Iatrogenic (negative inotropic or vasodilatory medications)	Post-resuscitation syndrome
Post-cardiac arrest	Post-cardiopulmonary bypass
Mechanical	**Hypovolemic**
Ventricular septal rupture	Hemorrhagic
Ventricular Free Wall rupture	Trauma
Hypertrophic obstructive cardiomyopathy	Gastrointestinal bleeding
Dynamic left ventricular outflow tract obstruction	Ruptured hematoma
Atrial myxoma	Hemorrhagic pancreatitis
Traumatic	Fractures
Valvular	Ruptured aortic aneurysm
Papillary muscle/chordal rupture	Acute aortic dissection
Acute mitral regurgitation	Plasma extravasation related
Prosthetic valve obstruction	Systemic inflammatory response
Severe aortic regurgitation	Sepsis
Critical aortic stenosis	Major surgery
Severe mitral stenosis	Pancreatitis
Arrhythmic	Major surgery
Tachycardia	Fluid loss related
Sustained ventricular tachycardia	Dehydration
Ventricular fibrillation	Severe burns
Bradycardia	Emesis
High-grade AV block	Diarrhea
Complete heart block	Diaphoresis
	Insensible losses
	Inadequate fluid intake
	Obstructive
	Cardiac tamponade
	Pulmonary embolism
	Pulmonary hypertension
	Tension pneumothorax

[a]*Causes that may complicate acute myocardial infarction are italicized*

with severe substernal chest pain and shortness of breath. Initial vital signs demonstrate tachycardia and hypotension. A third heart sound (S3) is auscultated. He has inspiratory rales in both lung bases, and his internal jugular vein is appreciated above the clavicle in an upright position. His extremities are cool, mottled, and cyanotic. An electrocardiogram reveals ST segment elevation across the anterior precordial leads.

This case describes a patient with CS caused by acute myocardial infarction. CS is a clinical condition in which inadequate tissue perfusion is the consequence of intrinsic cardiac dysfunction. It is characterized by a reduction in cardiac output despite adequate filling pressures. Causes of CS include myopathic, mechanical, valvular, and arrhythmic processes (Table 21.1). The criteria typically used to define CS include systolic blood pressure less than 90 mmHg for at least 30 min or the need for a vasopressor or mechanical circulatory support to maintain a systolic blood pressure greater than 90 mmHg; pulmonary capillary wedge pressure greater than 15 mmHg; and cardiac index less than 2.2 L/min/kg/m^2 [7].

Tachycardia, hypotension, oliguria, confusion, cyanosis, and cold extremities typically characterize the clinical presentation of CS. Tachycardia occurs in an effort to maintain cardiac output when the stroke volume is reduced. Oliguria and confusion are the result of poor tissue perfusion. Cool, mottled, and cyanotic extremities are manifestations of peripheral vasoconstriction.

Peripheral pulses are often diminished in CS due to decreased pulse pressure (*pulsus parvus*). In a failing left ventricle, the strength of every other beat may alternate, a phenomenon known as *pulses alternans*. Delayed pulses (*pulsus tardus*) may be seen in cardiogenic shock in the setting of severe aortic stenosis.

CS due to left ventricular failure may present with pulmonary congestion; patients may complain of orthopnea and paroxysmal nocturnal dyspnea (PND). Examination may demonstrate bilateral inspiratory rales, S3 gallop, and laterally displaced apical impulse due to left ventricular dilatation. Chest radiography may demonstrate cardiomegaly, pulmonary vessel cephalization, Kerley B lines, and parenchymal edema. If right ventricular failure is also present, evidence of venous congestion may be observed including jugular vein distention, hepatojugular reflux, and bilateral lower extremity edema.

Of note, a significant proportion of patients in the SHOCK (SHould we emergently revascularize Occluded Coronaries in cardiogenic shocK?) trial had no pulmonary congestion [8]. Neither auscultation nor chest radiograph detected pulmonary edema in 28% of patients.

Right ventricular infarction complicates up to half of all transmural inferior-posterior myocardial infarctions [9]. Patients with hemodynamically significant right ventricular infarction classically present with hypotension, clear lung fields, and jugular venous distention. Right ventricular failure may be associated with a holosystolic tricuspid regurgitation murmur at the left lower sternal border, jugular venous distension, liver engorgement, pulsatile liver, and peripheral edema. Patients with patent foramen ovale and acute right ventricular infarction may present with profound hypoxia due to decreased compliance in the infarcted right ventricle and right-to-left shunting.

Mechanical complications of acute myocardial infarction may result in CS and can sometimes be evident on physical exam. Acute mitral regurgitation, tricuspid regurgitation, and ventricular septal rupture are associated with holosystolic murmurs. However, if there is rapid equalization of pressure in the atria and ventricles, acute regurgitant lesions may not cause a significant murmur. Prominent jugular *v*-waves suggest severe tricuspid regurgitation. Jugular cannon *a*-waves suggest complete heart block. Ventricular free wall rupture will frequently result in fulminant cardiac tamponade (see section "Case 4: Obstructive Shock").

In CS, a compensatory increase in systemic vascular resistance (SVR) typically occurs through peripheral vasoconstriction in an effort to maintain tissue perfusion. However, this classic paradigm has been challenged. Data from the SHOCK trial demonstrated that many patients with CS instead have low systemic resistance, similar to patients with septic shock [10]

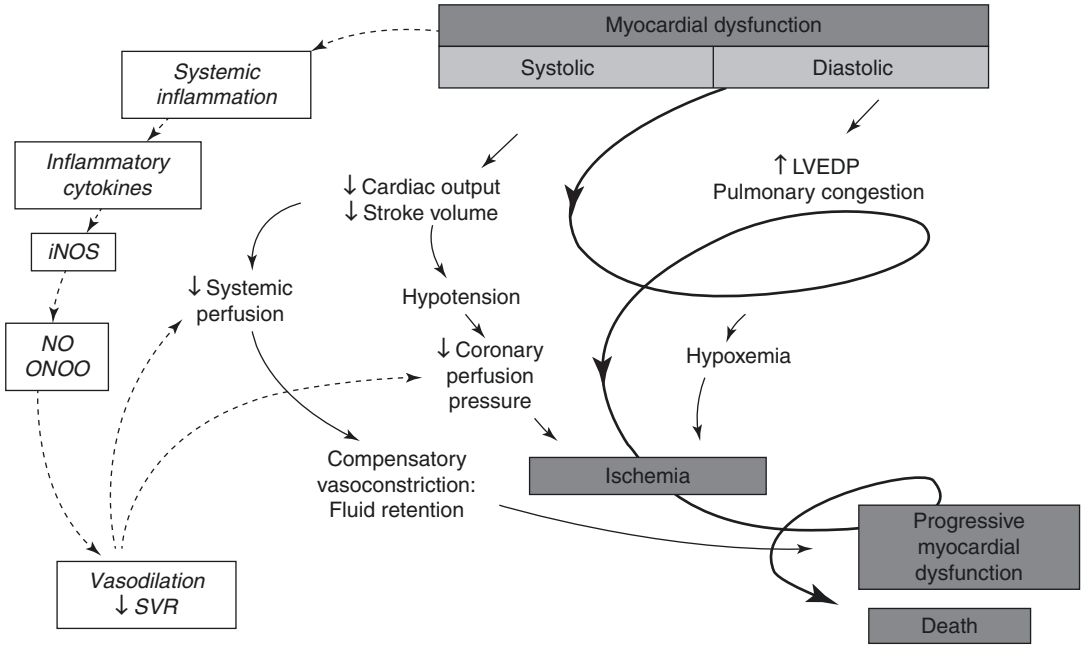

Fig. 21.1 Expansion of the pathophysiological paradigm of cardiogenic shock to include the potential contribution of inflammatory mediators. LVEDP left ventricular end-diastolic pressure; NO nitric oxide; iNOS inducible nitric oxide synthase; ONOO− peroxynitrite; SVR systemic vascular resistance. (Reprinted with permission from Hochman and Ohman [26])

(Fig. 21.1). It has been postulated that a systemic inflammatory response-like syndrome with a low SVR may be encountered in up to one-fifth of patients with acute myocardial infarction complicated by CS [11].

The clinical presentation can be utilized to risk-stratify patients with acute myocardial infarction complicated by CS. Killip described a case series of 250 patients presenting to an academic university intensive care unit with myocardial infarction [12]. He divided the patients into four classes according to the clinical presentation. Class I had no clinical signs of heart failure; class II presented with basilar rales and/or S3 gallop and/or elevated jugular venous pressure; class III had frank pulmonary edema; and class IV had cardiogenic shock. Reported mortality was 6%, 17%, 38%, and 67% for each class, respectively.

Current mortality with reperfusion therapy is dramatically lower than that observed in the original observation. However, Killip Class II, III, and IV continue to identify a high-risk subset of patients.

Therapeutic measures for CS often need to be implemented before invasive hemodynamic data are available. The clinical presentation may guide the most effective therapy. For example, patients with a clinical presentation consistent with myocardial infarction require urgent revascularization. A profile consistent with left ventricular failure may require inotropic or vasoactive agents and/or mechanical circulatory support in the form of an intra-aortic balloon pump, percutaneous left ventricular assist device, or extracorporeal membrane oxygenation. Patients with findings consistent with right ventricular infarction may require rapid fluid resuscitation and/or percutaneous right ventricular assist device placement.

Case 2: Hypovolemic Shock

A 25-year-old male patient presents shortly after a gunshot wound to the abdomen. He has experienced profound bleeding. He is tachycardic, hypotensive, and confused. Neck veins are

flat and lung fields are clear. The mucus membranes and skin are dry. Extremities are cool and clammy. He has a large drop in blood pressure and is more tachycardic when changing from supine to standing position.

The second case describes a patient with hypovolemic shock related to traumatic hemorrhage. Hypovolemic shock is characterized by inadequate intravascular volume. Etiologies are generally related to hemorrhage, plasma extravasation, or fluid loss (see Table 21.1). Hemorrhagic etiologies include trauma, gastrointestinal bleeding, ruptured hematoma, hemorrhagic pancreatitis, fracture, and ruptured abdominal aortic aneurysm. Etiologies related to plasma extravasation include systemic inflammatory response, major surgery, and severe pancreatitis. Fluid loss may be due to severe burns, emesis, diarrhea, diaphoresis, other insensible losses, and inadequate oral intake.

Hypotension, tachycardia, confusion, oliguria, and cold extremities typically characterize the clinical presentation of hypovolemic shock. Cardiac output generally falls as a result of decreased ventricular preload. Compensatory tachycardia and an increase in SVR, mediated by peripheral vasoconstriction, occur in an effort to improve tissue perfusion. Increased sympathetic activity may cause narrow pulse pressure and diaphoresis. Peripheral vasoconstriction results in cool, mottled, and cyanotic extremities.

The clinical history will generally suggest the underlying etiology. However, clinical findings may overlap with cardiogenic shock. A key difference is that the intracardiac filling pressure is adequate or elevated (PCWP greater than 15 mmHg) in CS, whereas it is generally low in hypovolemic shock due to inadequate intravascular volume. In hypovolemic shock, the lung fields are generally clear, and there is no evidence of jugular venous distension or peripheral edema.

The physical diagnosis of hypovolemia has been systematically reviewed in adults [13]. The most helpful physical findings include severe postural dizziness or a postural pulse increment of at least 30 beats/min, a systolic pressure decrement of at least 20 mmHg, or a diastolic pressure decrement of at least 10 mmHg for measurements obtained 2 min after assuming an upright posture (orthostasis). Supine hypotension and tachycardia were frequently absent, even after up to 1150 mL of blood loss [13]. In patients with vomiting, diarrhea, or decreased oral intake, the presence of a dry axilla supports the diagnosis of hypovolemia. In adults, the capillary refill time and poor skin turgor have no proven diagnostic value.

Case 3: Distributive Shock

An 80-year-old female with recurrent urinary tract infection presents with fever, tachycardia, hypotension, decreased urine output, and confusion. She is diaphoretic and has foul smelling urine. Her neck veins are flat and the lung fields are clear. The extremities are warm and hyperemic. Capillary refill is brisk. Her hypotension does not improve despite aggressive fluid resuscitation.

This third case describes a patient with distributive shock related to severe sepsis. Inappropriate vasodilation, decreased SVR, hypotension, and poor tissue oxygenation characterize distributive shock. Etiologies of distributive shock include systemic inflammatory response syndrome, severe sepsis, bacterial toxins (e.g., staphylococcal toxic shock), anaphylaxis, adrenal insufficiency, myxedema coma, neurogenic insult, post-resuscitation syndrome, and post-cardiopulmonary bypass (see Table 21.1).

Septic shock is the most common presentation of distributive shock. Septic shock is defined by sepsis-induced hypotension that persists despite adequate fluid resuscitation (20–30 mL/kg starch or 40–60 mL/kg saline or PCWP 12–20 mmHg) [14].

Clinical presentations of distributive shock vary by etiology but are generally characterized by tachycardia, hypotension, oliguria, confusion, and warm, well-perfused extremities. Compensatory tachycardia, oliguria, and confusion are manifestations of poor tissue perfusion. Warm and hyperemic extremities with brisk capillary refill time are the result of inappropriate

vasodilatation and decreased SVR. The cardiac output is typically elevated in distributive shock and may manifest as bounding pulses. The lungs are typically clear, and there is no jugular venous distension or peripheral edema.

Patients with severe sepsis and shock may have fever or hypothermia, diaphoresis, and rigors. Findings associated with an infectious process (e.g., pneumonia) may be present. Tachypnea is common and occurs in an effort to compensate for severe metabolic acidosis caused by elevated lactate. Hoarseness, stridor, wheezing, pruritus, flushing, hives, and abdominal pain may accompany anaphylactic shock. Hypothermia, hypoventilation, and somnolence are associated with myxedema coma (severe hypothyroidism). Profound orthostatic hypotension and skin hyperpigmentation may be presenting signs of adrenal insufficiency. Although most patients with distributive shock present with tachycardia, patients with neurogenic shock may have bradycardia due to sympathetic denervation.

Case 4: Obstructive Shock

A 65-year-old female patient with metastatic breast cancer presents with dyspnea and palpitations. Although she is tachycardic, her heart sounds seem distant. Her initial blood pressure is 80/50 mmHg. Her internal jugular vein is distended, but her breath sounds are clear to auscultation. Careful examination of her blood pressure demonstrates an exaggerated dissipation of Korotkoff sounds during inspiration. She has no leg edema and has not observed any recent fever, bleeding, vomiting, or diarrhea. Chest radiography revealed cardiomegaly with no significant parenchymal disease.

The fourth case is representative of obstructive shock due to cardiac tamponade. In the setting of breast cancer, pericardial metastasis is suspected. Classic findings of cardiac tamponade include distant, muffled heart sounds, jugular venous distension, and hypotension. Ventricular interdependence, manifested by an inspiratory drop in blood pressure (*pulses paradoxus*) greater than 10 mmHg, may also be observed.

Other causes of obstructive shock include tension pneumothorax and pulmonary embolism. Tension pneumothorax may be accompanied by dyspnea with tympany and decreased breath sounds in the affected hemithorax. Pulmonary embolism may be associated with cough, hemoptysis, and limb asymmetry in the context of prolonged immobilization. Both may present with desaturation.

Diagnostic Evaluation of Shock

The etiology of shock can often be determined using data acquired from the medical history, physical examination, basic laboratory evaluation, and radiographic findings. However, additional diagnostic tests may be needed in the optimal assessment and management of shock. Intra-arterial pressure monitoring, echocardiography, and pulmonary artery catheterization are frequently utilized diagnostic modalities.

Brachial cuff measurements are often inaccurate in states of shock. Intra-arterial pressure monitoring provides a continuous assessment of the blood pressure and heart rate and allows for safe and effective titration of vasoactive medications.. Additional data may also be obtained by assessing the arterial waveform. Further, the pulse pressure (systolic blood pressure − diastolic blood pressure) may be helpful in differentiating various shock states.

The 2004 American College of Cardiology/American Heart Association (ACC/AHA) guidelines for the management of patients with ST segment elevation myocardial infarction state that intra-arterial pressure monitoring should be performed (class I indication) for severe hypotension (systemic arterial pressure less than 80 mmHg), during the administration of vasopressor and/or inotropic agents, and for cardiogenic shock [15]. Although the 2016 ACC/AHA guideline does not make any reference to intra-arterial pressure monitoring, it continues to be employed frequently for the same indications. Potential complications of intra-arterial pressure monitoring include pain, infection, hematoma, arterial obstruction, and arterial embolus.

Echocardiography is an invaluable tool in the assessment of shock. It may help determine the etiology of shock and guide management. Echocardiography can be utilized to assess left and right ventricular function and can detect tamponade, restrictive/constrictive physiology, severe valvular regurgitation or valvular stenosis, ventricular septal or free wall rupture, and proximal aortic dissection. Echocardiographic findings of a clot-in-transit and right ventricular dysfunction may suggest the presence of a hemodynamically significant pulmonary embolism.

Echocardiography using agitated saline is a sensitive diagnostic modality for detecting intracardiac and pulmonary vascular shunting. Hemodynamic parameters such as central venous pressure, pulmonary artery pressure, and left ventricular end-diastolic pressure can be estimated using conventional echocardiographic methods.

The pulmonary artery catheter can be valuable in determining the etiology of shock and may help in guiding management. Data obtained from the pulmonary artery catheter includes central venous pressure, right atrial pressure, right ventricular pressure, pulmonary artery pressure, and pulmonary capillary wedge pressure. Obtaining a mixed venous oxygen saturation permits the calculation of the cardiac output, cardiac index, and systemic venous resistance. Furthermore, important diagnostic information may also be determined by analyzing the pressure waveforms.

The hemodynamic data gathered with a pulmonary artery catheter can be utilized to titrate vasopressor therapy, assess hemodynamic effects of changes in mechanical ventilation (e.g., positive end expiratory pressure), and guide fluid resuscitation. In addition, the data may help differentiate between cardiogenic and noncardiogenic pulmonary edema when a trial of diuretic and/or vasodilator therapy has failed.

Pulmonary artery catheterization may aid in determining if pericardial tamponade is present when clinical assessment is inconclusive and echocardiography is not available. Findings of cardiac tamponade include diastolic equalization of pressures and blunted y descent of the arterial waveform (see Chap. 15). Other uses of pulmonary artery catheterization include assessment of valvular heart disease severity and reversibility of pulmonary vasoconstriction in patients being considered for heart transplant. An oximetry run may also be performed using a pulmonary artery catheter. This is important in the investigation of cardiac shunts, which may occur as a complication of myocardial infarction.

Despite its potential advantages, pulmonary artery catheterization has not been shown to broadly improve patient outcomes. Its use is therefore controversial and is not favored in some centers. Whether the lack of benefit on important outcomes is a result of the severity of illness in the patients for whom the use of this tool is contemplated, or a result of incorrect interpretation and use of the data obtained, is a debated topic. It is important to note that the Evaluation Study of Congestive Heart Failure and Pulmonary Artery Catheterization Effectiveness (ESCAPE) trial showed no significant difference in endpoints of mortality and days out of hospital in the management of congestive heart failure refractory to standard medical therapy [16]. However, this trial demonstrated that the use of the pulmonary artery catheter for this group of patients was safe.

In ESCAPE, the addition of pulmonary artery catheterization to careful clinical assessment was associated with a higher frequency of adverse events but did not affect overall mortality and hospitalization. Adverse events included implantable cardioverter-defibrillator firing, cardiogenic shock, ischemia/angina, pulmonary artery catheter infection, myocardial infarction, stroke or ischemic attack, cardiac arrest, and infection. The only individual event that was statistically different (p value < 0.05) between the groups was pulmonary artery catheter infection (p value $= 0.03$).

The external validity of the findings of the ESCAPE trial has been debated [17]. Many of the registry patients did not get randomized into the trial because pulmonary artery catheterization was deemed necessary for management by a study investigator. Subsequently, only patients with clinical equipoise in whom physicians were comfortable managing heart failure decompensation with or without hemodynamic monitoring were included in the study. As such, the study is not applicable to the critically ill heart failure

patients who are often considered for pulmonary artery catheterization.

The routine use of pulmonary artery catheterization in intensive care units is also controversial. A 2005 meta-analysis of 13 randomized trials including over 5000 critically ill patients showed that the use of pulmonary artery catheters was not associated with benefit or increased mortality [18]. However, the meta-analysis included patients who were critically ill from a wide variety of causes.

There have not been any randomized studies aimed at directly evaluating the utility of pulmonary artery catheters in patients presenting with CS. There were 2968 patients with cardiogenic shock enrolled in the Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Coronary Arteries (GUSTO-1) trial. Mortality among patients (n = 995) managed with PA catheters (45.2%) was less than that among patients (n = 1406) not managed with PA catheters (63.4%) [19].

A potential limitation of pulmonary artery catheter hemodynamic monitoring is that many physicians do not know how to correctly interpret findings from the device [20]. A 31-question multiple-choice exam was administered to 496 medical doctors at 13 different institutions to assess their knowledge and understanding of the use of the pulmonary artery catheter and interpretation of data derived from it. The examination was given unannounced at general meetings in the departments of medicine, anesthesiology, and surgery. The mean score was 67%; almost half of the responders (47%) could not read a pulmonary capillary wedge pressure from a clear tracing.

The 2013 ACCF/AHA guidelines for the management of heart failure provide guidance for appropriate pulmonary catheter use in hemodynamic assessment [21]. It is a class I indication to use pulmonary artery catheter monitoring to guide therapy in patients with respiratory distress or clinical evidence of impaired perfusion when intracardiac filling pressures cannot be determined by clinical assessment. The guidelines also state that pulmonary artery catheters "can be" useful (class IIa indication) in acute heart failure with persistent symptoms despite seemingly appropriate adjustments of standard therapies if fluid status, perfusion, systemic vascular resistance, or pulmonary vascular resistance is uncertain. Similarly, pulmonary artery catheters can be useful in the setting of renal dysfunction, vasoactive agent use, or mechanical circulatory support. The 2017 ACC/AHA/HFSA Focused Update of the aforementioned guideline did not provide additional guidance on the use of pulmonary artery catheterization.

Routine invasive monitoring of hemodynamics is not recommended in normotensive patients with acute decompensated heart failure responding appropriately to therapy [21]. Potential complications of pulmonary artery catheter use include infection, right bundle branch block, ventricular tachycardia, pulmonary artery rupture, and pulmonary infarction. Over time, pulmonary artery catheters tend to soften and migrate distally, leading to spontaneous wedging even when the balloon tip is not inflated.

Hemodynamic Assessment of Shock

A fundamental understanding of the hemodynamics of shock is critically important. The etiology of shock may not be evident despite the data acquired from the medical history, physical examination, basic laboratory evaluation, and radiographic findings. Hemodynamic data can help diagnose the correct etiology of shock and guide appropriate management.

Systemic tissue perfusion (blood pressure) is determined by the cardiac output (CO) and SVR. Similar to Ohm's law, whereas electrical current through a circuit is directly proportional to the potential difference across the circuit and inversely proportional to the resistance, cardiac output (CO) is directly proportional to the blood pressure difference across the systemic circulation (mean arterial pressure [MAP] − mean right atrial pressure [mean RAP]) and inversely proportional to SVR. Therefore [CO = (MAP − mean RAP)/SVR].

Cardiac output can be measured with a pulmonary artery catheter by utilizing either the Fick method or thermodilution technique (see

Table 21.2 Hemodynamic patterns classically associated with different categories of shock

	RA (mmHg)	RV (mmHg)	PA (mmHg)	PCWP (mmHg)	CI (L/min/kg/m^2)	PP (mmHg)	HR (bpm)	SVR (dynes)	SVO_2 (%)
Normal values	<6	<25/0–12	<25/0–12	<6–12	>2.5	40–50	60–100	800–1600	70
Cardiogenic	↑	↑	↑	↑ (>15)[a]	↓ (<2.2)	↑↓	↑	↑[b]	↓
Distributive	↑↓	↑↓	↑↓	↑↓	↑[c]	↑	↑[d]	↓	↑↓[e]
Hypovolemic	↓	↓	↓	↓	↓	↓	↑	↑	↓

RA right atrium, *RV* right ventricle, *PA* pulmonary artery, *PCWP* pulmonary capillary wedge pressure, *CI* cardiac index, *PP* pulse pressure, *HR* heart rate, *SVR* systemic vascular resistance, *SVO_2* mixed venous oxygen saturation

[a]In the SHOCK trial, 28% of patients had no auscultatory or radiographic evidence of pulmonary edema suggestive of elevated PCWP

[b]A systemic inflammatory response-like syndrome with a low SVR may be encountered in up to one-fifth of patients with acute myocardial infarction complicated by cardiogenic shock

[c]Cardiac output can be reduced in distributive shock due to myopathic processes such as severe acidosis or when preload is decreased because of inadequate intravascular volume

[d]Patients with neurogenic shock may have bradycardia due to sympathetic denervation

[e]SVO_2 is generally increased in sepsis due to poor oxygen utilization

Chap. 4). Different categories of shock can be discriminated using the calculated cardiac output. Whereas cardiac output is low in cardiogenic shock and hypovolemic shock, it is generally elevated in distributive shock (Table 21.2). However, cardiac output can also be reduced in distributive shock due to myopathic processes such as severe acidosis or when preload is decreased because of inadequate intravascular volume.

Systemic vascular resistance (SVR) can be calculated if the blood pressure, right atrial pressure, and cardiac output are known. The drop in arterial pressure across the systemic circulation divided by cardiac output is equal to SVR. [SVR = [MAP − mean RAP]/CO]. The units for SVR are mmHg/mL/m^2 (Woods units) and are typically multiplied by 80 to convert to dynes/cm^5 (dyn). Pulmonary vascular resistance can be calculated by substituting the drop in pressure across the systemic circulation with that of the pulmonary circulation (mean pulmonary artery pressure − mean pulmonary capillary wedge pressure). SVR is reduced in distributive shock but is generally elevated in CS and hypovolemic shock [22].

Mixed venous oxygen concentration (SVO_2) may help differentiate shock from its different categories. In distributive shock related to sepsis, SVO_2 is generally elevated because the mitochondria are unable to utilize oxygen appropriately. As a result, there is a higher than expected venous oxygen saturation. In other states of shock, SVO_2 is generally low.

Elevated pulmonary capillary wedge pressure (greater than 15 mmHg) has classically been used to distinguish CS from noncardiogenic causes of shock. However, in the SHOCK trial, 28% of patients had no auscultatory or radiographic evidence of pulmonary edema to suggest elevated PCWP [8]. Severe sepsis can cause myocardial depression and may elevate left-sided pressures as well. CS related to right ventricular infarction may be associated with marked hypotension, low cardiac output, and shock despite a normal pulmonary capillary wedge pressure.

The intra-arterial pressure waveform can help differentiate various shock etiologies. Pulse pressure equals the difference between systolic and diastolic blood pressure and is normally 40–50 mmHg (Fig. 21.2). The pulse pressure is a reflection of the stroke volume and the strength of each ventricular contraction.

In patients with CS related to left ventricular failure, the pulse pressure is reduced (see Fig. 21.3). A narrow pulse pressure, defined as a pulse pressure <25% of the systolic blood pressure, has a sensitivity and specificity of 91% and 83% for a cardiac index of <2.2 L/min/m^2 [23]. Other causes of narrow pulse pressure include profound intravascular volume loss, cardiac tamponade, and aortic stenosis.

Fig. 21.2 Normal aortic waveform

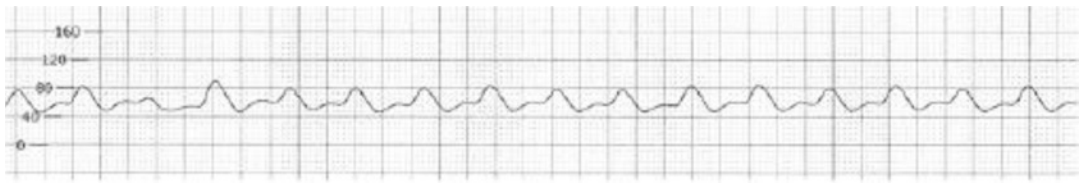

Fig. 21.3 Example of narrow pulse pressure in a patient with cardiogenic shock

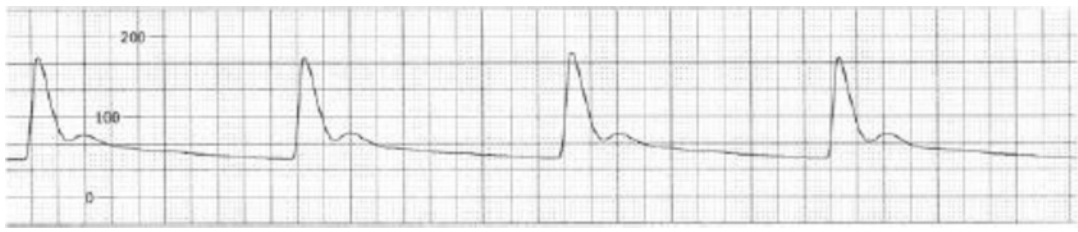

Fig. 21.4 Example of wide pulse pressure in a patient with complete heart block

Fig. 21.5 Example of narrow pulse width in a patient with acute aortic dissection

Widened pulse pressure is a physiological response to exercise and can be seen pathologically with atherosclerosis, aortic insufficiency, complete heart block, aortic dissection, arteriovenous fistula, fever, anemia, thyrotoxicosis, pregnancy, and elevated intracranial pressure (see Fig. 21.4).

The pulse width is also a reflection of stroke volume. Patients in shock with normal or hypercontractile ventricles often have aortic waveforms with narrow pulse widths but normal pulse pressures. Both noncardiac (e.g., anaphylaxis and severe sepsis) and cardiac (e.g., tamponade, acute mitral regurgitation, post-myocardial infarction ventricular septal defect, and aortic dissection) etiologies of shock may be associated with narrow pulse widths. A narrow pulse has a spike appearance with a dicrotic notch that appears low (see Fig. 21.5).

Pulsus alternans occurs when there is an alternating rise and fall in systolic pressure

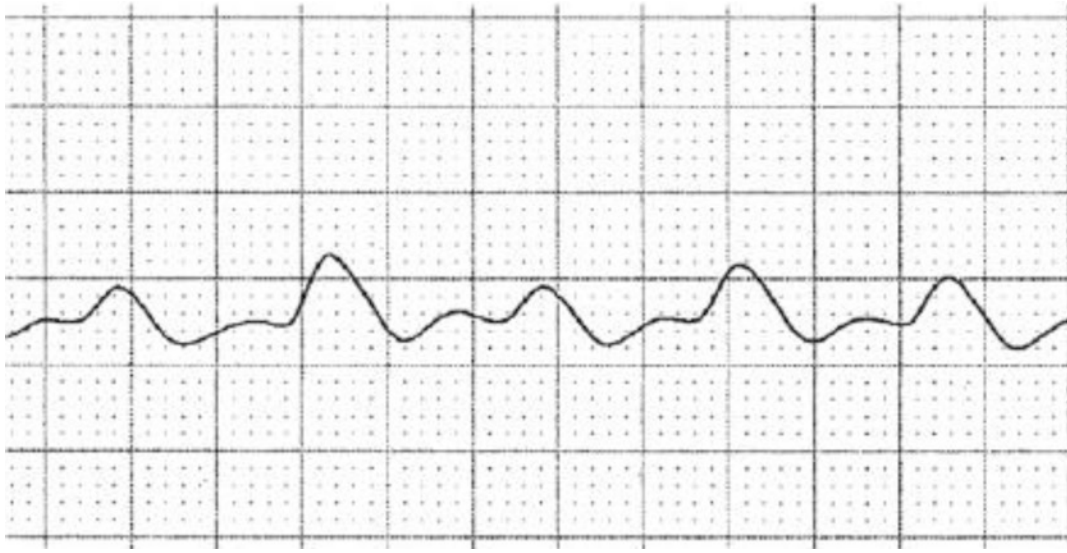

Fig. 21.6 Example of pulses alternans in a patient with advanced left ventricular failure

from beat to beat despite a regular rhythm (see Fig. 21.6). *Pulsus alternans* implies severe myocardial dysfunction and is most often seen in left ventricular failure. It may also occur in association with severe aortic stenosis and severe coronary artery disease. *Pulsus alternans* is thought to be due to variability in myocardial contractility on a beat-to-beat basis because of abnormal intracellular calcium cycling [24].

Pulmonary artery catheter intravascular waveform tracings can also help differentiate various etiologies of shock. Large *v*-waves on the pulmonary capillary wedge pressure tracing suggest shock from acute, severe mitral regurgitation. Likewise, large *v*-waves may be seen on the RAP tracing with severe tricuspid regurgitation. Cannon *a*-waves suggest complete heart block. Elevated and equalized diastolic pressures with loss of y descent suggest cardiac tamponade. Markedly elevated right atrial and right ventricular diastolic pressures and a normal pulmonary capillary wedge pressure suggest CS related to right ventricular infarction. An increase in right-sided pressures with inspiration (Kussmaul's sign) may be observed in right ventricular infarction due to decreased ventricular compliance.

Data obtained from the pulmonary artery catheter may reveal complications of acute myocardial infarction that occur in association with CS. For example, an oxygen step-up upon advancing the catheter from the right atrium to the right ventricle suggests left to right shunting related to ventricular septal rupture.

Arterial hypoxia may complicate shock. Evaluation of hypoxia begins with calculation of the alveolar-arterial (A-a) oxygen gradient. A normal A-a gradient equals 4 + (age/4) or 2.5 + (0.21 × age). Alveolar oxygen is calculated using the alveolar air equation: partial pressure alveolar oxygen (P_AO_2) = oxygen concentration (F_iO_2) × (barometric pressure at sea level (760 mmHg) − partial pressure water vapor (43 mmHg)) − (partial pressure carbon dioxide (P_ACO_2)/respiratory exchange ratio (0.8)). [$P_AO_2 = (F_iO_2 \times (760 - 43)) - (P_ACO_2/0.8)$]. Arterial partial pressure of oxygen is measured using conventional blood gas analysis.

If the A-a gradient is normal and P_aCO_2 is increased, hypoventilation is the suggested cause of hypoxia. With an elevated A-a gradient, proceed to check the mixed venous oxygen saturation. A low mixed venous oxygen saturation suggests hypermetabolism, anemia, or decreased cardiac output. If mixed venous oxygen is normal, administer 100% oxygen. If hypoxia corrects, ventilation/perfusion mismatch is suggested. Ventilation/perfusion mismatch

is caused by airway (e.g., asthma and chronic obstructive pulmonary disease), alveolar (e.g., pneumonia and congestive heart failure), and vascular (e.g., pulmonary embolism) phenomenon. Shunting is suggested if hypoxia does not correct with oxygen supplementation and may be physiological or vascular. Physiological shunting occurs with alveolar collapse (e.g., atelectasis) or decreased alveolar filling (e.g., pneumonia and congestive heart failure). Vascular shunting occurs with right-to-left intracardiac shunts (e.g., atrial or ventricular septal defect) and intrapulmonary shunts (e.g., arteriovenous malformation and hepatopulmonary syndrome).

Hemodynamic data can also be utilized to risk-stratify patients with acute myocardial infarction complicated by CS. In the SHOCK trial, cardiac power (cardiac power = MAP × CO/451) was the strongest independent correlate of in-hospital mortality in patients with CS [25].

Pearls of Assessment

There can be considerable overlap in the clinical presentation of the various categories of shock. Although classically associated with vasoconstriction and cold extremities, patients with CS can present with peripheral vasodilation and warm extremities. Indeed, in the SHOCK trial, the average SVR was not elevated, and the range of values was wide, suggesting that compensatory vasoconstriction is not universal [8].

Patients with distributive shock typically have increased cardiac output. However, in sepsis, depressed myocardial function may occur due to metabolic acidosis and other factors. Acidemia is detrimental to LV contractility and may result from decreased clearance of lactate by the liver, kidneys, and skeletal muscle, further compounded by an anaerobic metabolic state. Inadequate intravascular volume may complicate distributive shock and result in decreased cardiac preload and cardiac output.

Review Questions

1. Which of the following types of shock is typically associated with a high mixed venous oxygenation saturation?
   (a) Septic
   (b) Cardiogenic
   (c) Hypovolemic
   (d) Anaphylactic
   - Answer: (a) In severe sepsis, the mitochondrial respiratory chain does not utilize oxygen effectively. As a result there is more oxygen than expected in the venous blood.
2. Which of the following hemodynamic profiles is most consistent with cardiogenic shock?
   (a) Systolic blood pressure 120 mmHg, pulmonary capillary wedge pressure 10 mmHg, cardiac index 3.5 L/min/m^2, systemic vascular resistance (SVR) 1000 dyn, and mixed venous oxygen 75%
   (b) Systolic blood pressure 80 mmHg, pulmonary capillary wedge pressure 5 mmHg, cardiac index 1.3 L/min/m^2, SVR 1800 dyn, and mixed venous oxygen 60%
   (c) Systolic blood pressure 80 mmHg, pulmonary capillary wedge pressure 10 mmHg, cardiac index 3.5 L/min/m^2, SVR 600 dyn, and mixed venous oxygen 85%
   (d) Systolic blood pressure 80 mmHg, pulmonary capillary wedge pressure 20 mmHg, cardiac index 1.3 L/min/m^2, SVR 1800 dyn, and mixed venous oxygen 60%
   - Answer: (d) Hemodynamic criteria typically associated with cardiogenic shock include systolic blood pressure less than 90 mmHg for at least 30 min or need for vasopressor or intra-aortic balloon support to maintain systolic blood pressure greater than 90 mmHg, pulmonary capillary wedge pressure greater than 15 mmHg, and cardiac index less than 2.2 L/min/kg/m^2 [7].
3. An 85-year-old male presents with hypotension, oliguria, and confusion. An electrocardiogram reveals inferior ST segment elevation. A pulmonary artery catheter is inserted, and the hemodynamic parameters are consistent with cardiogenic shock. His lung fields are clear, and the jugular venous pulse is elevated.

A transthoracic echocardiogram reveals normal left ventricular function. What is the cause of this patient's clinical presentation?
(a) Right ventricular infarct
(b) Ventricular septal rupture
(c) Acute mitral regurgitation
(d) Tamponade
- Answer: (a) The classic findings of right ventricular infarction are hypotension, jugular venous distension, and clear lung fields.

4. An 85-year-old female presents 1 week after developing severe chest pain. She has dyspnea with minimal activity. She is hypotensive and has pulmonary rales. An electrocardiogram reveals anterior *q*-waves. Troponin is elevated but CK-MB is within normal limits. Other laboratory analysis reveals renal and liver injury. Pulmonary artery catheter hemodynamic findings are consistent with cardiogenic shock. An oxygen saturation run reveals an increased oxygen gradient upon advancing from the right atria to the right ventricle. Which complication of acute myocardial infarction is the cause of this patient's shock?
(a) Ventricular free wall rupture
(b) Ventricular septal rupture
(c) Acute mitral regurgitation
(d) Tamponade
- Answer: (b) Ventricular septal rupture may complicate myocardial infarction. An oxygen step-up upon advancing from the right atria to the right ventricle is typical.

Acknowledgments We would like to thank Venu Menon for his contribution to the previous edition of this chapter.

Intracoronary Hemodynamics

22

James E. Harvey and Stephen G. Ellis

Selective coronary angiography is the gold standard for evaluating the presence and extent of epicardial coronary artery disease. Despite advances in fluoroscopic imaging and catheterization techniques, the evaluation of the intermediate coronary stenosis (luminal diameter narrowing between 40% and 70%) remains a challenge for invasive cardiologists secondary to multiple issues. Angiography provides only a two-dimensional projection of the arterial lumen along the length of the vessel. Vessel characteristics (e.g., significant angulation and tortuosity) and limitations related to image acquisition (e.g., vessel overlap, inability to obtain a true perpendicular projection of the lesion, and the visualization of a focal short stenosis) impair the accuracy of lesion severity assessment despite obtaining coronary angiograms in multiple fluoroscopic views. Studies comparing coronary angiography and postmortem histopathological analysis have demonstrated the discrepancy between angiographic and actual anatomic findings [1–3]. Significant intra- and interobserver variability is also a factor when determining the percent narrowing of a stenosis by angiography [4]. The application of quantitative coronary angiography (QCA) may minimize this discrepancy, but it does not eradicate the limitations of coronary angiography. Intravascular visualization techniques such as intravascular ultrasound (IVUS) or optical coherence tomography (OCT), augment anatomical analysis but do not necessarily provide information on the functional significance of a lesion. Thus, cardiologists have focused on physiologic assessment of a lesion to aid in management decisions. Noninvasive testing (i.e., stress testing) to determine objective evidence of ischemia is frequently conducted prior to performing coronary angiography and subsequent percutaneous coronary intervention (PCI). However, these studies are not always feasible nor are the results always reliable; therefore a physiologic method of evaluating an intermediate coronary lesion while in the catheterization suite is desirable.

Sensor-tipped 0.014″ diameter guidewires have been manufactured to accurately and safely measure flow velocities or pressure within a coronary artery. By employing this technology, three methods [coronary flow reserve (CFR), fractional flow reserve (FFR), and instantaneous wave-free ratio (iFR)] have been developed to evaluate the physiologic or functional significance of coronary lesions in the cardiac catheterization suite.

discomfort. Exercise nuclear stress test revealed reversible perfusion defects in the apical anterior and anteroseptal wall and in the mid inferior wall. Coronary angiography revealed "normal coronary arteries" and intravenous infusion of ergonovine did not precipitate coronary vasospasm. Coronary flow reserve (CFR) of the left anterior descending artery was 1.2 consistent with severe microvascular dysfunction.

Coronary Flow Reserve (CFR)

CFR is defined as the ratio of mean blood velocity at maximal hyperemia to mean blood velocity at rest for a given coronary artery [5]. Developed in the 1970s, it is based on the principle that the volume of blood flow in a healthy coronary artery will increase with hyperemia to a greater extent than that of an artery with a physiologically significant stenosis (Fig. 22.1). Since blood flow as volume per time cannot be directly measured in the cardiac catheterization suite, blood velocity is measured as a surrogate because it is proportional to blood volume flow for a constant lumen area. CFR is assessed by placing a Doppler-tipped guide wire into a coronary artery distal to the epicardial stenosis in question. One then measures the flow velocities at rest and at maximal hyperemia. Hyperemia is pharmacologically induced typically by intravenous infusion of adenosine. The Doppler-derived CFR, which is inversely proportional to lesion severity [6], has been validated with good correlation to nuclear stress testing. A CFR value of ≤2.0 indicates a physiologically significant stenosis (Fig. 22.2) [7–10].

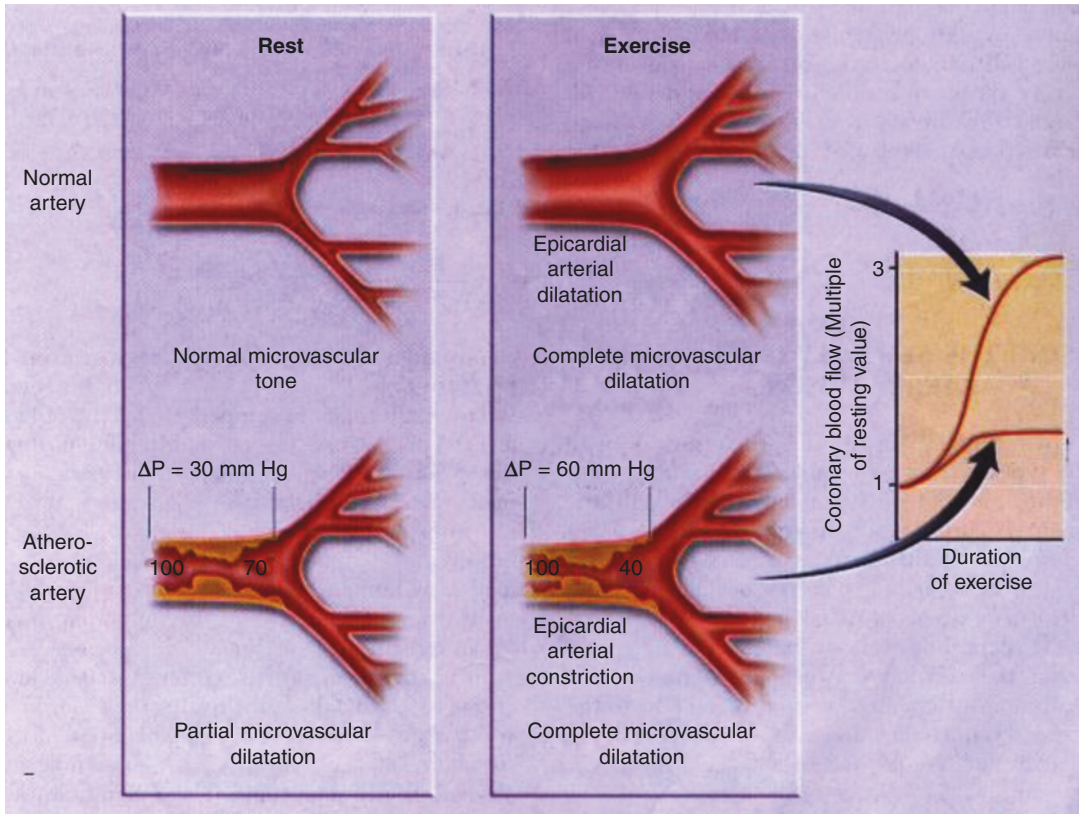

Fig. 22.1 Depiction of coronary blood flow at rest and at maximal hyperemia. A normal coronary artery will have a larger increase in blood flow than a diseased artery with a hemodynamically significant stenosis. By measuring the blood velocity or pressure proximal and distal to the stenosis, one can calculate the relative increase in blood flow or decrease in pressure caused by inducing maximal hyperemia

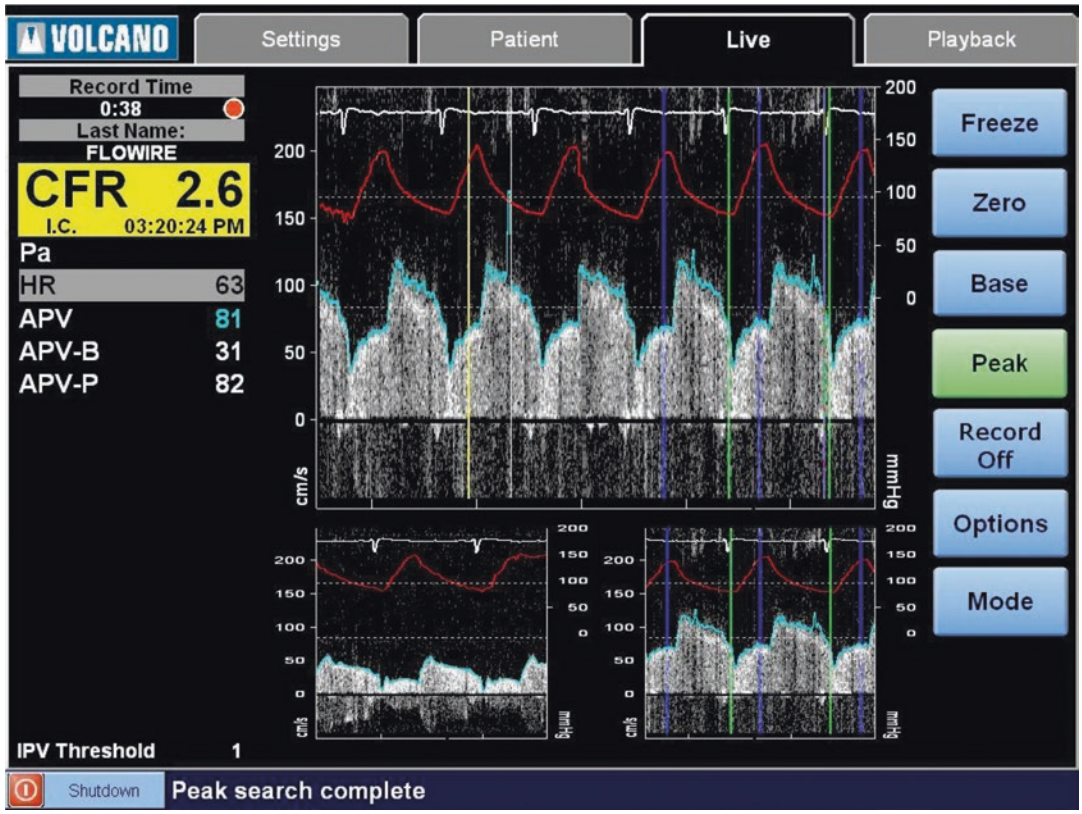

Fig. 22.2 A typical CFR display screen. Intracoronary Doppler blood flow velocity waveforms before intracoronary adenosine are shown on the small graph on the lower left portion of the display screen. Intracoronary Doppler blood flow velocity waveforms after intracoronary adenosine are shown on the small graph on the lower right portion of the display screen and on the large graph in the center of the display. CFR is the ratio of the average peak velocities before and after adenosine; here it is reported as 2.6 on the top left portion of the display. This is suggestive of normal microvascular function

Unfortunately, CFR is affected by both the severity of an epicardial stenosis and the extent of microvascular resistance. Microvascular resistance is influenced by common conditions such as diabetes mellitus, age, and ventricular hypertrophy. Each of these can significantly affect the CFR value regardless of the severity of epicardial stenosis [11–14]. In an effort to overcome this inherent limitation, the concept of relative CFR was developed. Relative CFR is determined by dividing the CFR of the diseased vessel by the CFR of another undiseased coronary vessel and accounts for the contribution of microvascular resistance to the CFR value. This improved the correlation in the detection of ischemia by stress myocardial perfusion imaging [15]. Use of this method requires increased time and risk of evaluating an additional vessel. Due to these inherent limitations of CFR and relative CFR, these modalities are now rarely used to evaluate the severity of an epicardial arterial stenosis. Instead, FFR has become the method of choice for determining the physiologic significance of an epicardial arterial stenosis.

Cardiac Syndrome X

Despite its limitations in the interrogation of epicardial stenoses, CFR is the modality of choice for evaluation of coronary artery microvascular dysfunction. Cardiac syndrome X, or angina with an abnormal cardiac stress test and angiographically normal coronary arteries, is an increasingly

recognized disorder with significant prognostic implications [16]. Diminished coronary flow velocity reserve in response to intracoronary adenosine, defined as a CFR ≤ 2.0, is suggestive of microvascular dysfunction and seen in up to 47% of patients with angina and no significant epicardial stenoses [17]. The patient described in *Clinical Vignette 1* has findings consistent with cardiac syndrome X. Patients with this condition have a rate of adverse cardiac events (myocardial infarction, congestive heart failure, stroke, and sudden cardiac death) of 2.5% per year [16].

Case Vignette 2

A 62-year-old man with past medical history of hypertension, hyperlipidemia, and cigarette smoking presents with 1 month of worsening exertional chest discomfort that radiates down his left arm. Left heart catheterization reveals a focal 70% stenosis in the proximal left circumflex artery (LCx) and a long 60% stenosis in the mid right coronary artery (RCA). A pressure sensor-tipped 0.014″ coronary wire was advanced down the LCx and FFR was performed with a value of 0.83. The pressure sensor-tipped 0.014″ coronary wire was withdrawn and then advanced down to the distal RCA. FFR was 0.72. Percutaneous coronary intervention (PCI) was performed on the mid RCA lesion. No PCI was performed on the LCx, but rather aggressive medical management was employed.

Fractional Flow Reserve (FFR)

FFR is a method to invasively assess the hemodynamic significance of an intermediate coronary stenosis while in the catheterization suite. It is defined as the ratio of the mean distal coronary artery pressure to the mean aortic pressure while at maximal hyperemia [18–20]. It is performed by advancing a 0.014″ pressure-sensor tipped coronary wire across an epicardial stenosis and simultaneously recording the pressure distal to the stenosis (via the coronary wire) and proximal to the stenosis (via the guide catheter) while at maximal hyperemia (Fig. 22.3). Adenosine is the pharmacologic agent typically used to achieve maximal hyperemia because of its safety profile and low cost; however, papaverine or dobutamine can also be used [21–23].

As opposed to CFR, FFR measurement is baseline independent of blood pressure, heart rate, prior infarction, or contribution of collateral circulation [20, 24]. A normal FFR value is 1, while a value of <0.75 is associated with provocable ischemia; this has been shown to correlate well with ischemia demonstrated on noninvasive stress testing [19, 20, 25, 26]. Mortality and adverse cardiovascular event (MACE) rates have been shown to be very low in patients with an FFR >0.75 [27, 28], and multiple studies have demonstrated that PCI can be safely deferred in such patients [19, 27, 29].

Multivessel CAD

FFR is "lesion specific" and can be used to assess intermediate lesions in patients with single-vessel or multivessel CAD. [30] This is particularly useful in clinical scenarios in which patients present with symptomatic CAD and are found to have multivessel disease with multiple intermediate stenoses. In this subset of patients, noninvasive stress testing can demonstrate "balanced ischemia," and thus interpretations of culprit lesions are often inaccurate. Because of this, it has become commonplace to perform multivessel PCI for complete revascularization in this group, although this approach is not proven to be associated with improved outcomes. It was hypothesized that utilization of FFR could aid in the better identification of culprit lesions and thus more appropriate management. To assess the utility of FFR in this group of patients, 1005 patients with multivessel coronary artery disease were randomized to PCI with drug-eluting stents of all stenoses ≥50% versus FFR-guided PCI of stenoses with a value ≤0.80. At 1 year, the rate of death, non-fatal myocardial infarction, and repeat revascularization was significantly lower in the FFR-guided group than in the angiography-guided group (13.2% versus 18.3%), and the FFR group received a significantly fewer number of stents [31]. Eighty percent of patients in both groups

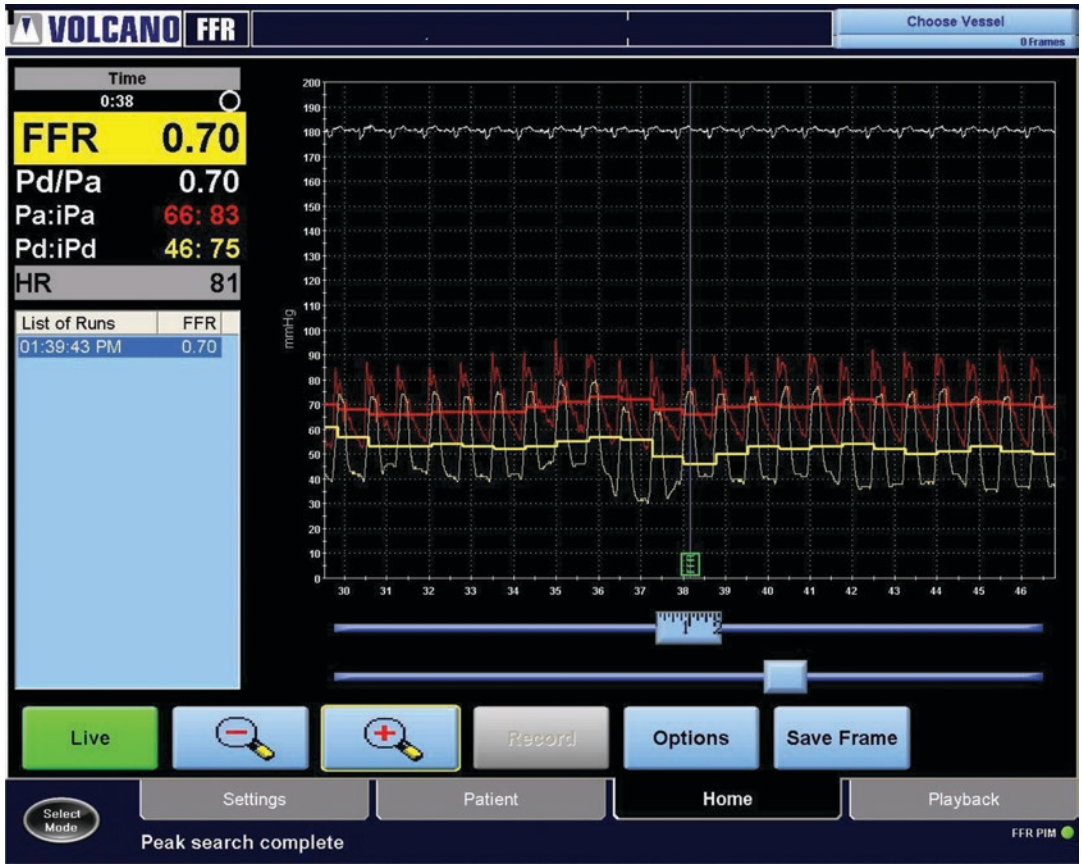

Fig. 22.3 A typical FFR measurement display screen. The aortic pressure is measured through the guiding catheter (red line). The pressure distal to the coronary lesion is measured by the 0.014″ pressure sensor-tipped wire (yellow line). In this example, the ratio of the distal coronary pressure to proximal coronary pressure is 0.70 and consistent with a hemodynamically significant stenosis

were angina-free at 1 year; however, the FFR-guided strategy was significantly less expensive than the angiography-guided group ($14,315 versus $16,700) [31].

Diffuse CAD or Long Coronary Lesions

Another subset of patients in which FFR can be helpful to guide the decision for PCI is in patients with diffuse disease or long coronary lesions. Similar to the assessment of multiple lesions in a single vessel, the pressure-sensor tipped wire can be slowly withdrawn from a vessel during maximal hyperemia and concomitant fluoroscopy can be used to precisely indicate where hemodynamically significant lesions exist. A gradual loss of pressure is consistent with diffuse disease and may suggest that PCI is technically less favorable and that possibly coronary artery bypass grafting (CABG) or medical management should be considered. However, an abrupt decrease in pressure is consistent with a focal hemodynamically significant stenosis and suggests that PCI may be more favorable [32, 33].

Left Main Coronary Disease and Bifurcation Lesions

Angiographic assessment of a left main coronary artery stenosis poses a great challenge for operators. As previously mentioned, factors such

as vessel overlap and unfavorable vessel orientation in relation to achievable camera angles often result in a suboptimal angiographic assessment of the vessel and significant intra-observer variability [34]. In this subset of patients, the use of FFR to further assess the vessel has been shown to be beneficial. One study demonstrated that patients with an intermediate left main stenosis and an FFR >0.75 had superb 3-year outcomes suggesting that PCI can safely be deferred in this subgroup [35].

Similar to left main coronary artery lesions, the evaluation of bifurcation lesions poses a significant challenge to the angiographer. By performing a separate FFR of each branch of the bifurcation, the hemodynamic significance of the lesions can be reliably determined and can assist the operator in deciding the most appropriate course of action for the patient [36].

Coronary Bypass Grafts

There is a paucity of data regarding the utility of FFR in assessing the physiologic significance of intermediate stenoses in a saphenous vein graft (SVG). A small study observed 10 veterans who had a stress myocardial perfusion imaging (MPI) study and were referred for PCI of an SVG stenosis. The sensitivity, specificity, and accuracy of FFR <0.75 for the detection of ischemia on stress MPI were 50%, 75%, and 70%, respectively. The authors concluded that the use of FFR to assess the physiologic significance of SVG lesions was feasible and provided acceptable sensitivity and specificity in comparison to stress MPI.

Acute Myocardial Infarction and Post Myocardial Infarction

While FFR does provide valuable information regarding intermediate coronary lesions in patients with stable and unstable angina, it should not be used in the acute phase of a myocardial infarction (MI). Animal studies have shown that even after reperfusion of an epicardial coronary occlusion, significant perivascular edema and capillary leukocyte plugging occur causing microvascular dysfunction and incomplete restoration of myocardial perfusion [37]. This has been shown to result in up to a 5% overestimation of FFR in humans [38]. Six days after an MI, however, FFR has been shown to be accurate and can be used to identify hemodynamically significant coronary lesions that supply areas with significant remaining ischemic but viable myocardium [39]. Myocardial perfusion SPECT imaging and FFR were performed in 57 patients who had sustained a myocardial infarction at least 6 days prior. Patients with demonstrable ischemia on SPECT imaging had a significantly lower FFR value than those who had evidence of scar without ischemia. When using a cutoff FFR value of 0.75, this demonstrated a sensitivity and specificity of 82% and 87%, respectively. However, when only truly positive and truly negative stress tests were considered, the sensitivity and specificity rose to 87% and 100%, respectively. When sensitivity and specificity were plotted against FFR, the value of FFR for which sensitivity and specificity were equal (88%) was 0.78; however, this value did not show a statistically significant difference in accuracy when compared to a cutoff value of 0.75.

FFR Post PCI

FFR has been shown to have significant prognostic value after PCI has been performed [40–42]. An FFR $\geq$ 0.90 is considered a successful result for balloon angioplasty, and an FFR $\geq$0.94 is successful post stent deployment. FFR values lower than these predict adverse outcomes.

Another area where FFR can be helpful is in the evaluation of jailed side branches after stenting. One study observing the feasibility of FFR for the assessment of jailed side branches showed that only 20% of lesions with QCA >75% had an FFR <0.75 and no lesion with QCA <75% had an FFR <0.75 [43]. These data suggest that most jailed side branches do not have hemodynamically significant stenoses and that PCI of

the daughter vessel can likely be safely deferred. This information is particularly useful given the higher rate of restenosis and stent thrombosis associated with dual stenting of bifurcation lesions [44].

Limitations of FFR

While several randomized controlled trials have demonstrated the clinical benefit of FFR-guided coronary revascularization, certain limitations do exist. FFR is not always accurate in AMI and will often show a falsely elevated value due to microvascular dysfunction. Also, animal studies have suggested that up to 16% of subjects undergoing FFR with adenosine or papaverine do not achieve maximal hyperemia [45]. This suggests that the physiologic significance of some lesions may be underestimated when using standard current vasodilator doses and that higher doses may be needed in order to achieve maximal hyperemia.

Instantaneous Wave-Free Ratio (iFR)

Recently, a new method of invasively assessing the severity of intermediate coronary stenoses has been introduced called the Instantaneous Wave-Free Ratio (iFR). Unlike FFR, coronary lesion assessment with iFR is performed during the resting, or non-hyperemic state, such that the administration of adenosine or other vasodilating agents is not necessary.

iFR is based on the finding that there are multiple distinct pressure waves that occur throughout the cardiac cycle that affect the instantaneous flow and pressure in a coronary artery. The relationship between intracoronary pressure and flow varies throughout the cardiac cycle and is different in the region proximal to a coronary stenosis than it is in the region distal to a coronary stenosis [46]. However, there is a period of time in diastole called the wave-free period (WFP) where there is an absence of new intracoronary pressure waves. During this period, the intracoronary pressure and the intracoronary flow decline in a parallel linear fashion and the microvascular resistance is significantly lower and more stable than that over the remainder of the cardiac cycle [47]. As such, this provides an ideal set of circumstances to allow for the assessment of the hemodynamic significance of a coronary stenosis in a non-hyperemic state.

Similar to FFR, iFR is performed by advancing a 0.014″ pressure-sensor tipped coronary wire across an epicardial stenosis and simultaneously recording the pressure distal to the stenosis (via the coronary wire) and proximal to the stenosis (via the guide catheter) (Fig. 22.3). However, unlike FFR, the iFR measurement is recorded during the instantaneous wave-free period of diastole. As such, this is done with the patient in the resting state without inducing hyperemia.

iFR and the Hybrid Approach

Initially, it was proposed that the use of iFR would complement that of FFR via a "hybrid approach" for the assessment of intermediate intracoronary lesions. With this strategy, iFR would be performed with the patient in the resting state. An iFR value of more than 0.93 would be considered not significant and revascularization would be deferred, while an iFR value of less than 0.86 would be considered ischemic and revascularization would be pursued. However, the values ranging between 0.86 and 0.93 would be considered in the "gray zone." In these patients, adenosine would be administered to calculate the FFR to determine whether or not the lesion should be revascularized. Utilization of this strategy was able to reduce the unnecessary use of adenosine in 60 to 70% of patients [48]. While this strategy provided a practical way to integrate the use of iFR into current clinical practice, two large randomized clinical trials have recently demonstrated the non-inferiority of iFR when compared to FFR such that utilization of the hybrid approach is no longer necessary.

iFR Versus FFR in Clinical Trials

Two large randomized clinical trials have demonstrated that the use of iFR with a single cut-off value of ≤0.89 to guide revascularization is a safe and feasible alternative to FFR. With a primary endpoint of MACE at 1 year, the Functional Lesion Assessment of Intermediate Stenosis to Guide Revascularization (DEFINE-FLAIR) trial was a double-blinded, controlled trial that randomized 2492 patients to iFR vs. FFR for guidance of coronary revascularization for intermediate lesions [49]. The primary endpoint occurred in 78 of 1148 patients (6.8%) in the iFR group and in 83 of 1182 patients (7.0%) in the FFR group ($p < 0.001$ for non-inferiority). In addition, the number of patients with adverse procedural symptoms or clinical signs was significantly lower in the iFR vs. FFR group (3.1% vs. 30.8%, respectively; $p < 0.001$) as was the median procedural time (40.5 min vs. 45.0 min; $p = 0.001$). Similarly, the Instantaneous Wave-free Ratio versus Fractional Flow Reserve in Patients with Stable Angina Pectoris or Acute Coronary Syndrome (iFR SWEDEHEART) trial was an open-label randomized trial comparing iFR to FFR guided revascularization in patients presenting with stable angina or an acute coronary syndrome. Among the 2037 patients enrolled, the primary endpoint of MACE at 1 year occurred in 68 of the 1012 patients (6.7%) in the iFR group and in 61 of the 1007 patients (6.1%) in the FFR group ($p = 0.007$ for non-inferiority) [50]. The secondary endpoint of adverse procedural symptoms was again significantly higher in the FFR group with chest pain occurring in 68.3% of these patients compared to only 3.0% in the iFR group ($p < 0.001$).

Despite the demonstration of non-inferiority of iFR to FFR, the DEFINE-FLAIR and iFR SWEDEHEART trials demonstrated that the deferral of revascularization occurred more frequently in patients undergoing iFR as compared to those undergoing FFR [51]. In a pooled analysis of the two trials, revascularization was deferred in 1119 of the 2240 patients (50.0%) in the combined iFR groups and in 1015 of the 2246 patients (45.0%) in the combined FFR groups. Most importantly, the primary outcome between the groups was similarly low despite the higher rate of deferral in the pooled iFR group. As a result, the resultant healthcare costs for the iFR group were significantly lower than that of the FFR group.

In addition to the benefits of decreased adverse procedural symptoms, procedural time, and procedural cost of iFR vs. FFR, another potential benefit exists. In the hyperemic state such as that during FFR, coronary flow distal to a stenosis begins to decrease once the stenosis is 40–50% narrowed. As such, when multiple sequential intermediate lesions are present, the hyperemic flow through the proximal stenosis is affected by that of the distal stenosis and vice versa. Thus, it is not possible to determine the severity of an individual stenosis in the hyperemic state [52]. Conversely, coronary flow in the resting state is preserved distal to a coronary lesion until a critical stenosis develops [46]. As a result, there is minimal interaction between sequential intermediate stenoses. This allows for accurate assessment of individual lesion severity in the presence of tandem stenoses with slow pullback of the 0.014″ pressure-sensor tipped coronary wire.

Conclusions

CFR and relative CFR can be used to invasively measure flow velocity in a coronary artery and thus evaluate the hemodynamic significance of epicardial stenoses or microvascular dysfunction. Due to the limitations of CFR and increased time requirements and risk of relative CFR, these methods are now rarely used to assess epicardial lesions. However, CFR is still the test of choice to evaluate for microvascular dysfunction.

FFR is the current method of choice to evaluate the physiologic significance of an intermediate epicardial stenosis. Designated as "lesion specific," it compares the ratio of distal to proximal pressure across an epicardial stenosis. This technique adds important functional information that augments the anatomic information provided by angiography and intravascular imaging modalities (i.e., IVUS and OCT). It has been validated

to improve clinical outcomes when used to guide PCI in patients with single and multivessel CAD and also has been shown to provide useful information when examining a variety of coronary lesions. Furthermore, the use of FFR to guide PCI has been shown to significantly reduce the cost of treatment when compared to PCI guided by angiography alone.

iFR is the newest method of invasively assessing the severity of intermediate coronary stenoses. There are several advantages of iFR over FFR including decreased procedural time and cost and reduced adverse procedural symptoms. With the completion of two large randomized trials, the use of iFR is supported by more than twice the outcome data of that of FFR. Although slowly being adopted by practitioners worldwide, it is believed that iFR will become the method of choice for the evaluation of intermediate coronary stenoses in the years to come.

Review Questions

Questions 1–2

A 62-year-old patient undergoing left heart catheterization for chest pain has a 65% stenosis in a large first diagonal branch. While performing an FFR measurement, the aortic pressure is 102/77 mmHg and the distal diagonal branch mean pressure is 60 mmHg.

1. What is the FFR of the diagonal branch?
   A. 0.779
   B. 0.588
   C. 0.703
   D. Cannot be determined with the information provided.
2. Is PCI of the diagonal branch indicated?
   A. Yes. The FFR was >0.75
   B. No. The FFR was <0.75
   C. Yes. The FFR was <0.75
   D. It depends on the severity of the stenosis in the artery.

Questions 3–4

A 63-year-old hypertensive patient presents with 12 months of intermittent exertional chest pain. An exercise nuclear stress test performed at an outside hospital reported a reversible perfusion defect involving the anteroseptal and lateral walls; however, left heart catheterization revealed angiographically normal coronary arteries. You perform CFR of the LAD which gives a result of 1.6.

3. What is the diagnosis does this patient have?
   A. Non-cardiac chest pain.
   B. Cardiac chest pain due to missed coronary stenosis.
   C. False-positive nuclear stress test.
   D. Cardiac syndrome X.
4. What is the risk of this patient having an adverse cardiovascular event in the next year?
   A. 2.5%
   B. 1%
   C. 10%
   D. 15%
5. You perform a left heart catheterization on a 59-year-old man with worsening exertional angina. Coronary angiography of the RCA reveals a mid 60% stenosis followed by a distal 60% stenosis; the left main trunk, LAD, and LCx have mild disease. You perform iFR of the RCA with slow pullback of the pressure sensor-tipped 0.014″ coronary wire. You obtain the following results:

   - iFR of the right posterior descending artery: 0.76
   - iFR of the RCA between the mid and distal lesions: 0.81
   - iFR of the proximal RCA: 1.00

   What is the most appropriate management decision at this time?

   A. Perform PCI on both the mid and distal RCA lesions.
   B. Perform PCI on the mid RCA lesion.
   C. Perform PCI on the distal RCA lesion.
   D. None of the above.

Answers

1. The Answer is **C**. In order to calculate the FFR you first need to calculate the mean pressure (MP) in the aorta. This can be calculated by the following equation: MP = Diastolic

pressure + (Systolic pressure − diastolic pressure)/3. Plugging the numbers into the equation, the MP = 85.3 mmHg. FFR = MP_{distal}/MP_{aorta} = 60/85.3 = 0.703.

2. The Answer is **C**. PCI is indicated based on the DEFER (FFR <0.75) and FAME (FFR <0.80) studies.
3. The Answer is **D**. Cardiac syndrome X, or angina with an abnormal cardiac stress test and angiographically normal coronary arteries. A CFR ≤2 is suggestive of microvascular disease, the underlying pathophysiology of this syndrome.
4. The Answer is **A**. This patient has a 2.5% chance of having a myocardial infarction, stroke, sudden cardiac death, or developing congestive heart failure over the next year.
5. The Answer is **B**. Performing a slow pullback across multiple serial stenoses in a single vessel during iFR allows the operator to determine the hemodynamic significance of each individual stenosis. In this example, the hemodynamic contribution of the distal RCA stenosis was 0.95 ((1 − (0.81 – 0.76) = (1 – 0.05) = 0.95). The hemodynamic significance of the mid RCA stenosis was 0.81. Thus, the most appropriate management decision is to perform PCI on the mid RCA lesion only.

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

ELSEVIER Book Aid International Working together to grow libraries in developing countries

www.elsevier.com • www.bookaid.org

Keenly aware of the time and energy diverted from our families that was required to perform these procedures and assemble the recordings into a form accessible by readers, we dedicate this volume to our beloved wives (Jeanne, Rekha, and Joan), who have allowed us the privilege of putting this work together. We also dedicate this work to the readers, who we hope will benefit from the lessons we have tried to convey, and finally to their patients, who we hope will in turn benefit from their learning.

Foreword

The practice of clinical cardiac electrophysiology is one of clinical exploration that starts with integration of the patient's symptoms and cardiac evaluation with electrocardiographic interpretation. One of the most gratifying experiences for patient and physician is when this process culminates in the electrophysiology laboratory with confirmation of the diagnosis and implementation of effective therapy for the arrhythmia with catheter ablation. Mastery of each component is needed, and the knowledge that is gained from each step can be applied to the previous step to refine one's diagnostic acumen. We became much better electrocardiographers by applying the knowledge gained from the pioneering work that defined cardiac activation patterns and arrhythmia mechanisms using cardiac mapping and programmed electrical stimulation. Expertise in the last step, interventional electrophysiology, is the most challenging to acquire. It requires assimilation of complex patterns of cardiac activation, interpretation of spontaneous changes in patterns, and application of maneuvers to confirm a diagnosis, and this confirmation is critical for guiding catheter ablation.

Drs. Miller, Das, and Zipes have assembled a wonderful book that captures the spirit of clinical exploration leading to effective therapy. They use cases to describe pathophysiologic concepts that start with fundamentals and proceed to complex concepts. From the electrophysiology laboratory they incorporate findings ranging from those that are classic to those that are only recently described and that require a nuanced interpretation and understanding, but that are critical to arriving at the correct diagnosis. Examples include the newest technologies that are now being applied for delineation of arrhythmia mechanisms and substrate.

The authors are renowned teachers who apply their wealth of experience in communicating complex scenarios and concepts to make the cases accessible for the complete range of students of clinical electrophysiology, from the trainee to the advanced practitioner. The cases clarify concepts and provide fundamentals for the new student, but also provide insights that will expand the knowledge of experienced clinicians. Dr Miller's hand is evident throughout in the superb graphics, for which he is widely known among teachers of cardiology.

One of the amazing aspects of biology, medicine, and certainly extending to cardiac electrophysiology, is the variability that one encounters from patient to patient. After years in the field, one still encounters new arrhythmia problems. A solid basis in understanding mapping and diagnostic maneuvers is required for solving new puzzles in the electrophysiology laboratory, and this learning is acquired from the study of cases. You can never analyze too many cases. I congratulate the authors of *Case Studies in Clinical Cardiac Electrophysiology* on a wonderful book.

William G. Stevenson, MD
Director, Cardiac Arrhythmia Program
Cardiovascular Division
Brigham and Women's Hospital
Professor of Medicine, Harvard Medical School
Boston, Massachusetts

Preface

The understanding and care of patients with heart rhythm disturbances (clinical cardiac electrophysiology [EP]) has evolved in the last three decades from simple diagnostic studies of the conduction system using a few electrodes, to complex diagnostic and therapeutic procedures involving recording and stimulation from a large number of electrodes, for the purpose of finding and ablating arrhythmogenic tissue. With this dramatic change in the character of EP studies has come the critical need for careful analysis and thorough understanding of the meaning of recordings that are made and results of stimulation in order to achieve optimal results from ablation. At the same time, EP training programs have come under increasing pressure to perform more procedures in a shorter amount of time, resulting in compromising time for careful and methodical study of and learning from these procedures that are rich with teaching material. Although many excellent texts in our field explain the principles of recording and stimulation in treatment of arrhythmias, for example, *Clinical Arrhythmology and Electrophysiology*, few are structured to show their practical application in a case-study format. In light of this, the purpose of this volume is to take the reader through a representative series of EP procedures from start to finish, evaluating results of diagnostic pacing maneuvers, sampling and comparing characteristics of electrograms, and selection of appropriate sites for ablation. It is our hope that readers will benefit from this mode of presentation, highlighting some of the limitations of techniques that are used on a daily basis, with the aim of improving the efficacy and safety of procedures they perform on their patients.

Acknowledgments

We gratefully acknowledge the role played by our nursing and technical staff with whom we performed the procedures reviewed in this work, as well as electrophysiology fellows, whose patience in keeping catheters in place during long procedures contributed greatly to the quality of the figures. We also acknowledge our patients, who provide a constant source for learning.

1 Sinus Node and Atrioventricular Conduction Disease

Case Presentation

A 56-year-old man experienced syncope while walking at work. Coworkers called emergency medical services (EMS). Upon the arrival of EMS, he was awake and feeling normal but was convinced to go to the emergency room (ER). The patient had a history of anterior wall myocardial infarction (MI), percutaneous coronary intervention (PCI), to left anterior descending coronary artery (LAD) several years before, and a negative stress test within the last 6 months. Examination results were normal except for obesity. ECG showed sinus rhythm, long PR, right bundle branch block (RBBB), left anterior fascicular block (LAFB), and anterior scar. Echocardiogram revealed ejection fraction (EF) 40% and anterior hypokinesis. The patient was referred for electrophysiology (EP) study.

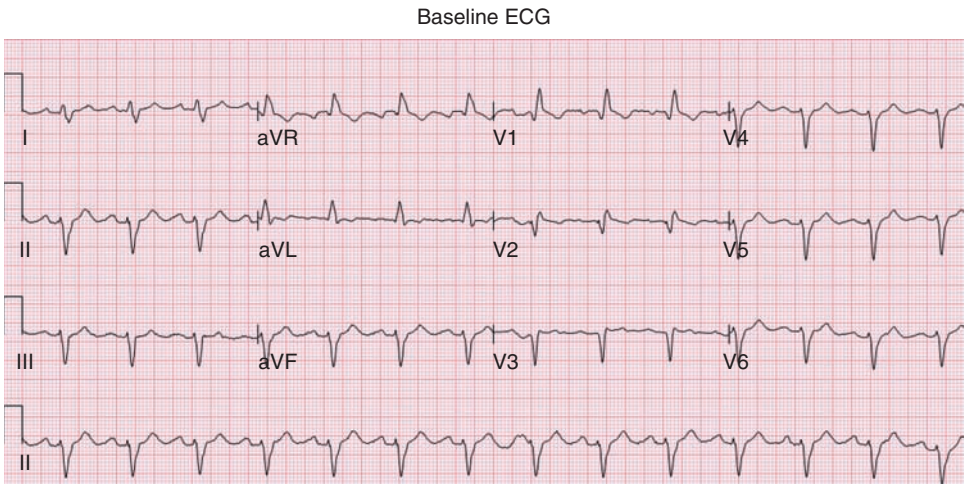

Figure 1-1

The ECG in Fig. 1-1 shows sinus rhythm with a prolonged P wave (left atrial abnormality), slightly prolonged PR interval, RBBB and left anterior fascicular block, and an extensive anterior infarction. On the basis of this, there are many possible causes of syncope—atrial arrhythmias (atrial flutter and fibrillation, other reentrant atrial tachycardias), heart block (either in AV node or His-Purkinje system), or ventricular arrhythmia (ventricular tachycardia or fibrillation). There is nothing in the ECG to favor one cause of syncope over another, and because treatment strategies are very different depending on the cause (medications or ablation for atrial arrhythmias; pacemaker for heart block; implantable defibrillator for ventricular arrhythmias), further investigation is needed.

Evaluation

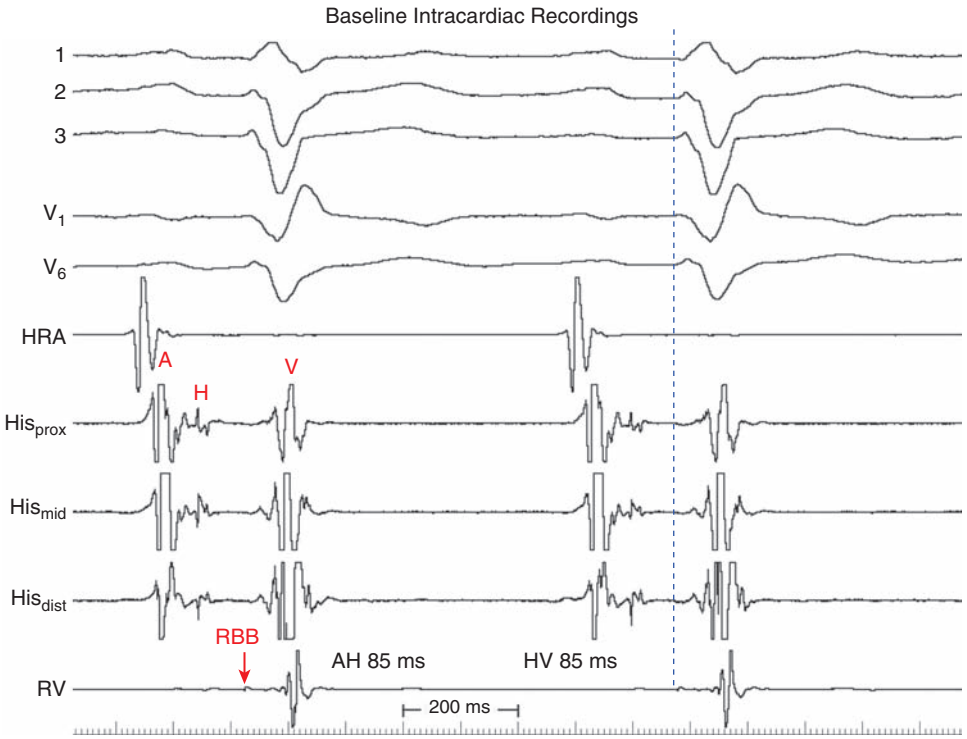

Figure 1-2

Intracardiac recordings during sinus rhythm (Fig. 1-2) show atrial (A), His (H), and ventricular (V) recordings as noted. This confirms the presence of His-Purkinje disease, with an HV interval of 85 ms—prolonged (normal, 40 to 55 ms), but not enough to implicate His-Purkinje dysfunction as a cause of heart block. Surprisingly, though the PR interval is somewhat prolonged, the AH interval is normal (85 ms [normal, 60 to 125 ms]). Usually, prolongation of the PR interval is caused by the AV nodal (AH) component, because to prolong the PR even 60 ms from His-Purkinje disease would require a lengthening of the HV to a degree (that is, from 40 ms to 100 ms) that 1:1 conduction would be unlikely. Note also that there is a delay between the distal His recording and right bundle branch (RBB)—there is usually <10 ms between these—and that the RBBB is further caused by delay or block between the RBB and RV apical electrogram, with a QRS onset *(dashed blue line)* to RV electrogram of 75 ms (normal, 10 to 35 ms).

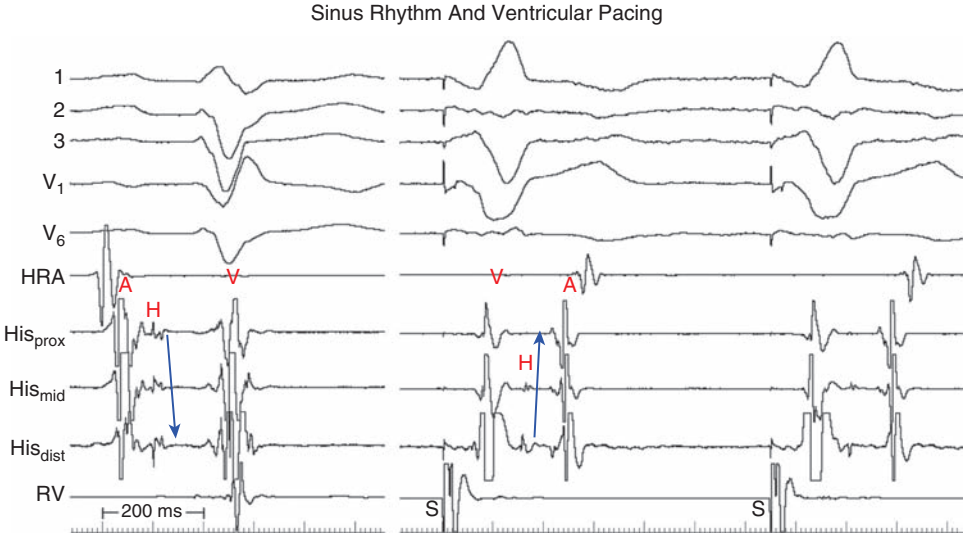

Figure 1-3

The left side of Fig. 1-3 shows a sinus rhythm complex as in the previous figure for reference, whereas the 2 complexes on the right are during pacing from the right ventricular apical region. Note that there is retrograde conduction to the atria, with the His bundle activated from distal to proximal as expected. Usually, the timing of the His potential is before the local ventricular electrogram in the His recoding, because conduction proceeds more rapidly up the RBB to the His than does muscle-to-muscle propagation from apex to base. Because there is RBBB in this case, the impulse cannot ascend the RBB as it normally would and instead must traverse the interventricular septum, enter the left bundle branch, and then activate the His retrogradely. These findings just confirm the His-Purkinje disease but give no further insight as to the cause of syncope.

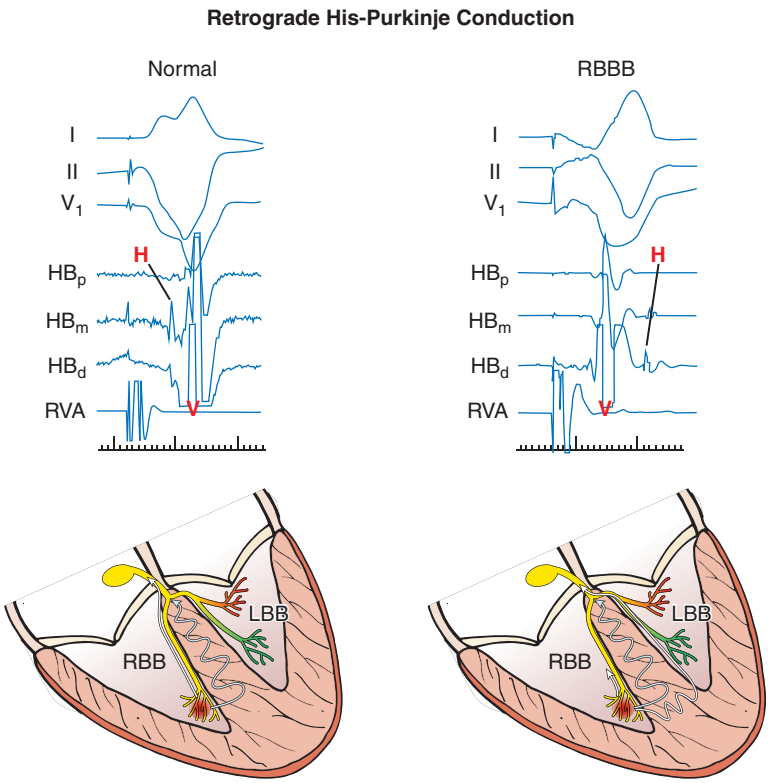

Figure 1-4

As illustrated in Fig. 1-4, in patients with normal His-Purkinje function (at *left*), pacing from the right ventricular apex *(red circle)* results in retrograde conduction over the RBB *(white line)* that is more rapid than muscle-to-muscle conduction (*wavy line* in septum), resulting in a His potential (H) inscribed before the larger local ventricular recording (V). At right, in the presence of anterograde RBBB, the paced wavefront cannot ascend the blocked right bundle and instead crosses the interventricular septum *(wavy horizontal line)* to engage the left bundle, and then proceeds rapidly to the His that now appears after the local ventricular recording (that is again generated after muscle-to-muscle spread).

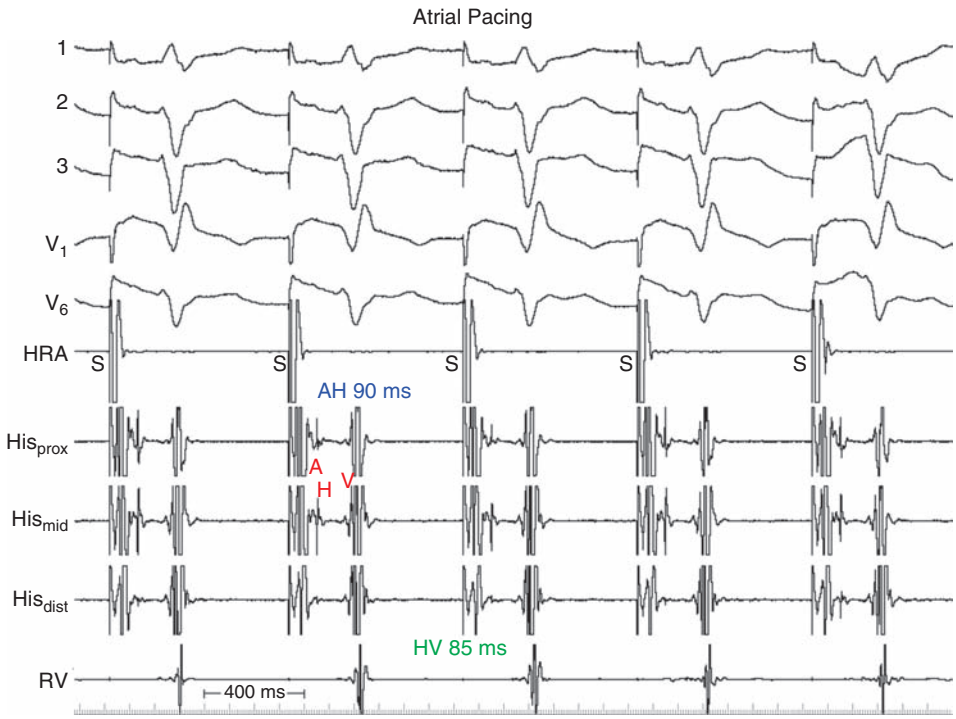

Figure 1-5

Rapid pacing can often reveal abnormalities of AV conduction that were not very evident at rest. In Fig. 1-5, pacing the atrium (S) slightly faster than the sinus rate shows minimal change in either AH (90 ms) or HV (85 ms) intervals. It is useful to display multiple electrode pairs of His recordings because the signal amplitude may vary enough between complexes that the His potential may be poorly visible or even absent in one electrode pair (His_{dist} in this case), whereas it is readily visible in other electrode pairs.

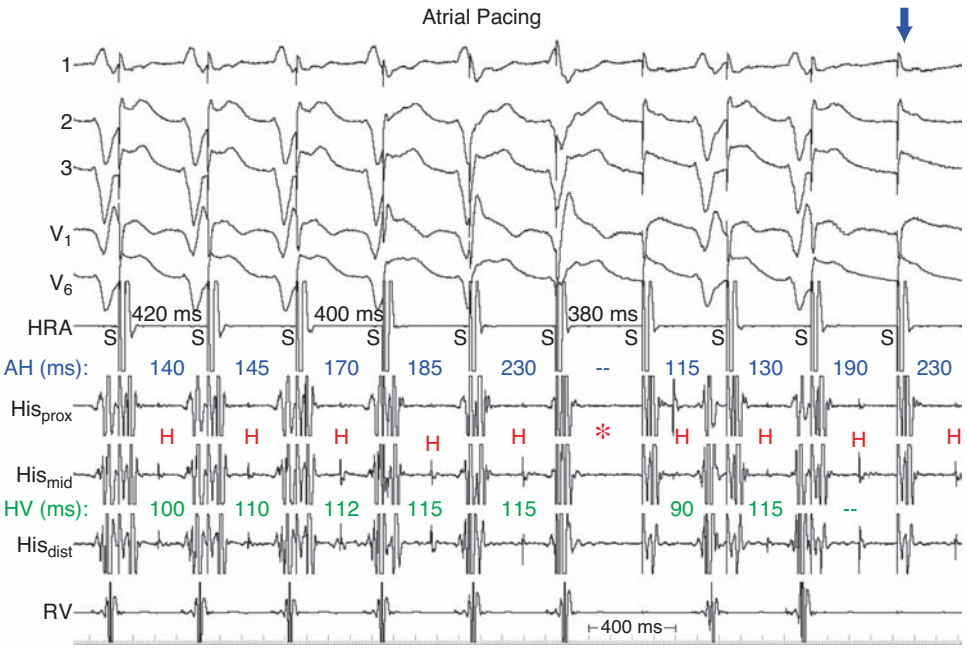

Figure 1-6

More rapid pacing starts to reveal some abnormalities. As the pacing rate increases (cycle length decreases), the AH is expected to prolong but the HV interval usually remains constant. In Fig. 1-6, the AH (in *blue*) does prolong, but so does the HV interval (in *green*). The *asterisk* denotes where AV nodal block occurs (no subsequent His potential), but three cycles after this, there is a His potential not followed by a QRS (infra-His block; *green dash*)

and the HV intervals on the prior two cycles had prolonged (thus, infra-His Wenckebach). This is distinctly abnormal and likely warrants pacemaker implantation. However, this may not be the reason that syncope had occurred (there may be other abnormalities that have not yet been uncovered during the study).

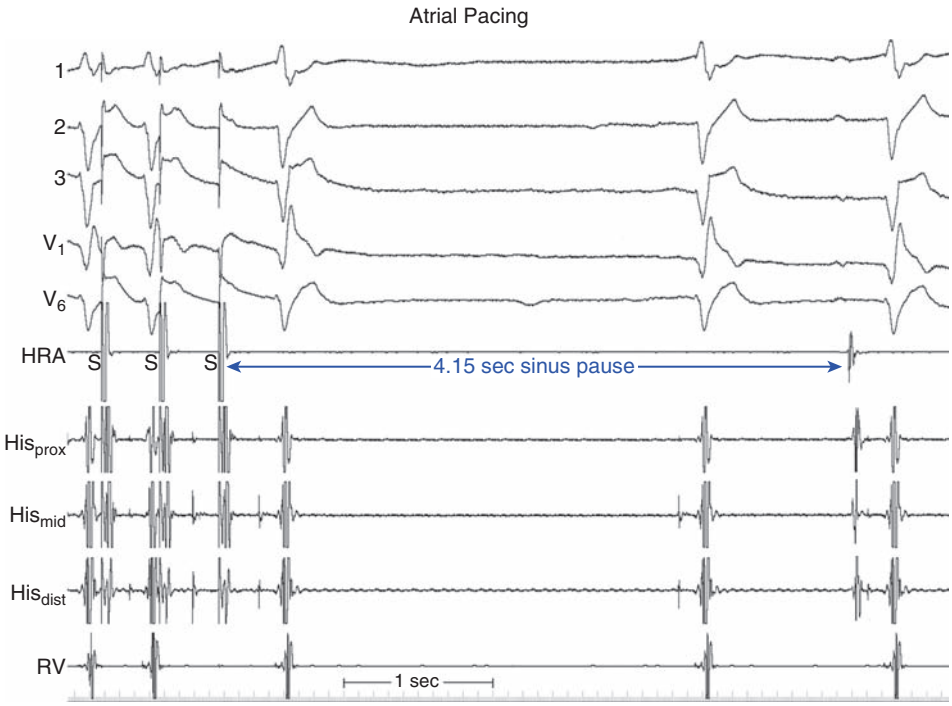

Figure 1-7

In Fig. 1-7, pacing is repeated for 1 min at the same cycle length as shown in the prior figure to stress the sinus node. Upon cessation of pacing, a prolonged sinus pause (4.15 seconds) is observed; a junctional escape complex occurs after 3 seconds. This is another potential cause of syncope (sinus node dysfunction).

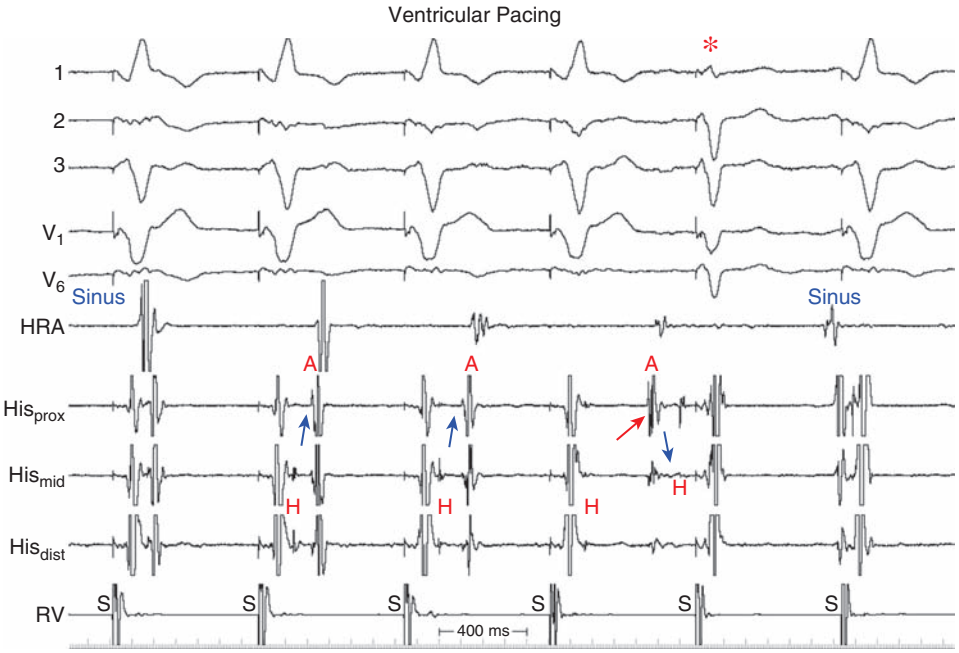

Figure 1-8

Turning to the ventricles (Fig. 1-8), slow ventricular pacing again shows that there is retrograde conduction; the first and last atrial complexes are sinus in origin (HRA before His atrial recordings) but the middle three complexes are retrogradely conducted. The first two of these *(blue arrows)* are over the fast pathway, but after the fourth ventricular stimulus, the ventriculoatrial interval suddenly increases, signifying a switch to a slow pathway *(red arrow)*. Immediately after this, there is a QRS complex that is not fully paced *(asterisk)*; this is because of fusion between the paced wavefront and one over the normal conduction system (see His potential). This is the result of an atypical AV nodal echo (retrograde slow pathway, anterograde fast—*blue arrow*). This is a common finding and, unless accompanied by sustained atypical AV nodal reentrant SVT, has no relevance for the diagnosis of syncope.

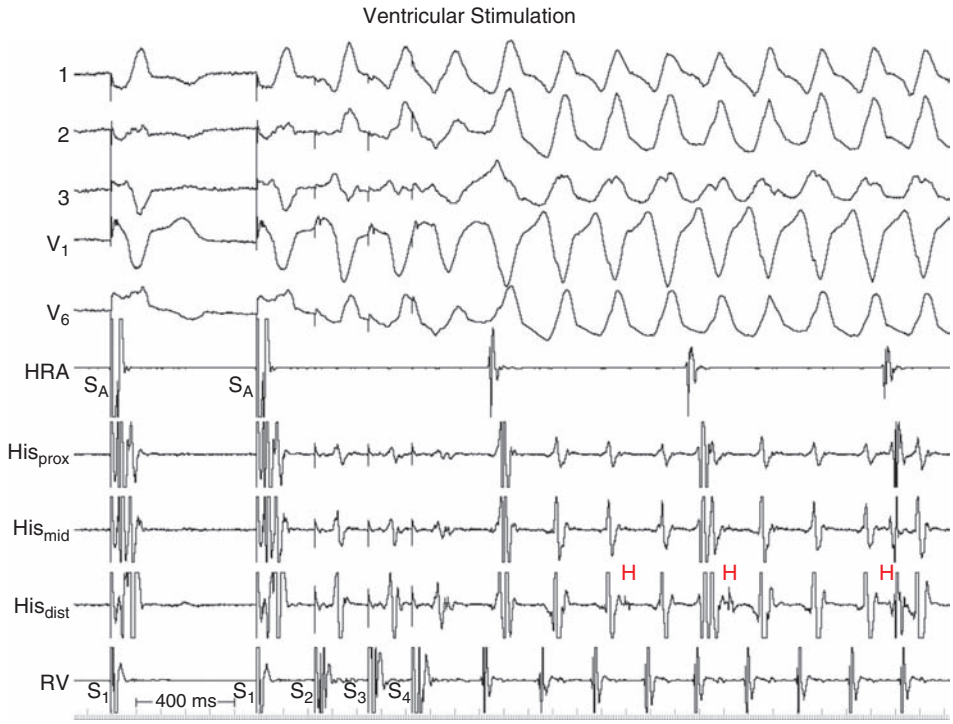

Figure 1-9

The last part of the syncope evaluation consists of programmed ventricular stimulation. As shown in Fig. 1-9, standard stimulation (here, with triple extrastimuli, S2 to S4) initiates a rapid, hemodynamically unstable ventricular tachycardia (CL 250 ms) that stopped spontaneously after 15 seconds. Given the presence of a prior MI and "serious" syncope, this arrhythmia was deemed a reasonable candidate for the cause of his syncope. He received a dual-chamber ICD later that day. Note that a His potential is seen on occasion but not with every complex—excluding bundle branch reentry as a possible cause of the tachycardia (S_A = atrial stimulus).

Summary

- This man had syncope in the presence of structural heart disease—which always needs further evaluation.
- Multiple potential causes of syncope may be present in the same patient; in this case,
  - Sinus node dysfunction
  - His-Purkinje dysfunction
  - Ventricular tachycardia
- Judgment must be used to determine which possible cause(s) of syncope should be treated and how.

Typical ("Slow-Fast") Atrioventricular Nodal Reentry

2

Case Presentation

A 48-year-old woman had a history of palpitations for ~5 years. Her episodes started and stopped suddenly, lasted 1 to 2 minutes, and were associated with lightheadedness. She came to a local emergency room with a prolonged episode: ECG showed a narrow QRS tachycardia (by report; no ECG available) that was terminated with adenosine. She was treated with oral diltiazem and metoprolol but continued to have supraventricular tachycardia (SVT) episodes. She had a normal physical exam; non-invasive evaluation showed no structural heart disease. She was referred for catheter ablation of her SVT.

Baseline ECGs and Intracardiac Recordings

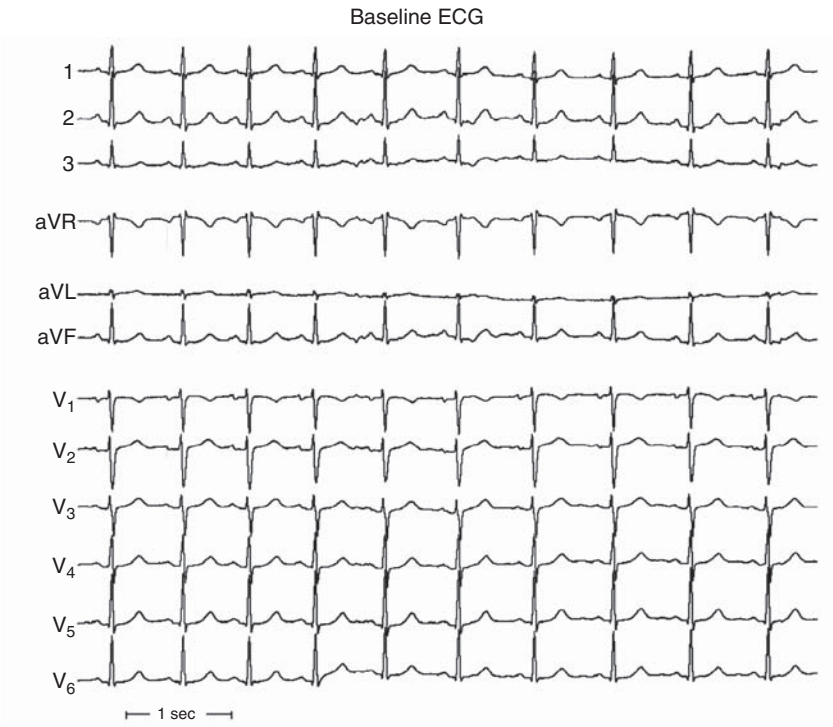

Figure 2-1

Fig. 2-1 demonstrates normal sinus rhythm without delta waves, fractionation, or prolongation of the P wave or QRS and normal QT. ECG is normal.

Figure 2-2

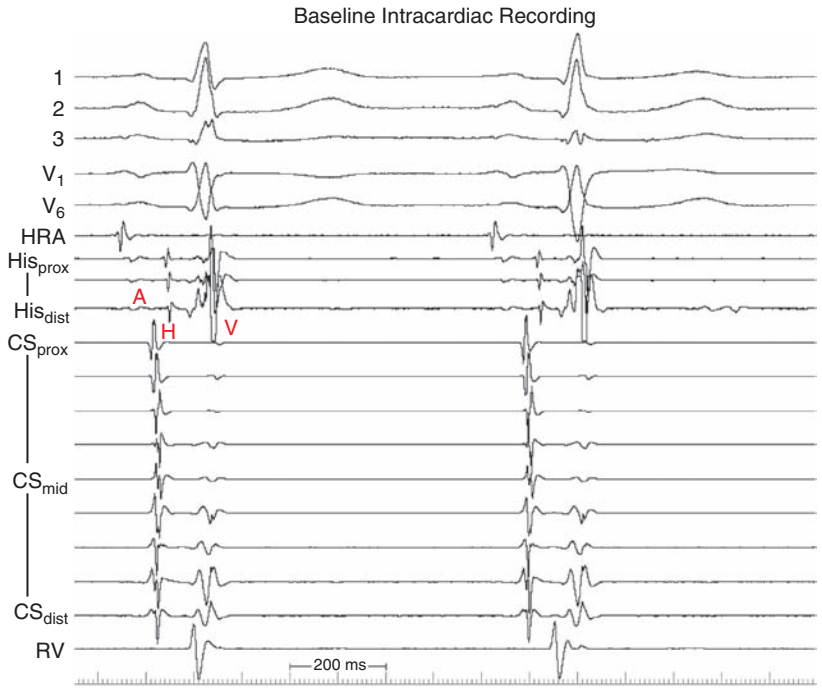

Fig. 2-2 shows normal intracardiac intervals (AH, HV); there is no evidence of preexcitation on intracardiac recordings. Normal progression of atrial activation is seen from right atrium to His to coronary sinus proximal to distal.

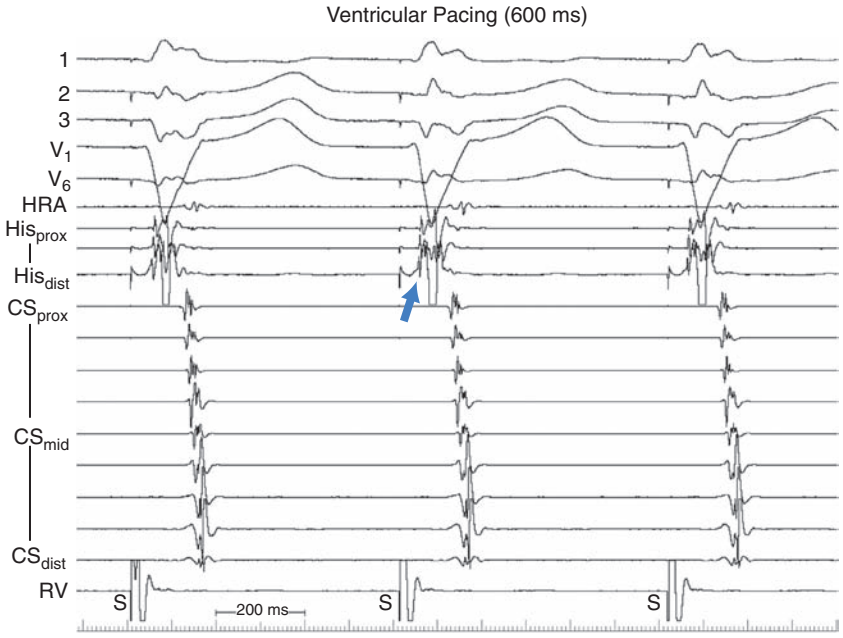
Ventricular Pacing

Figure 2-3



In Fig. 2-3, with ventricular pacing at 600 ms, retrograde conduction is present with a concentric activation pattern; a retrograde His potential *(arrow)* is seen between stimulus artifact and local ventricular electrogram.

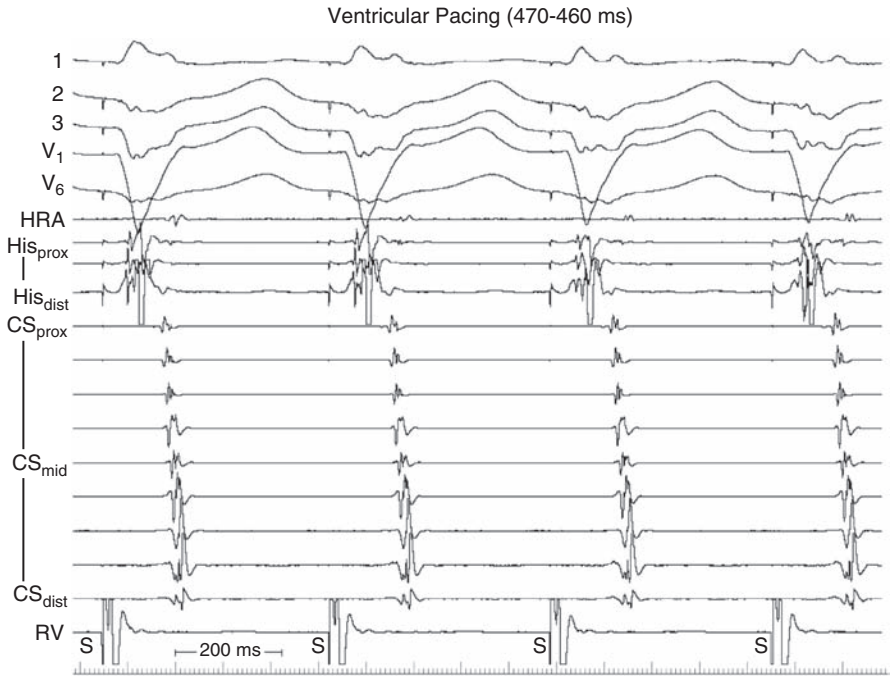


Figure 2-4

With more rapid ventricular pacing (470–460 ms) the same activation sequence is seen in Fig. 2-4, with a longer VA interval—most consistent with AV nodal conduction.

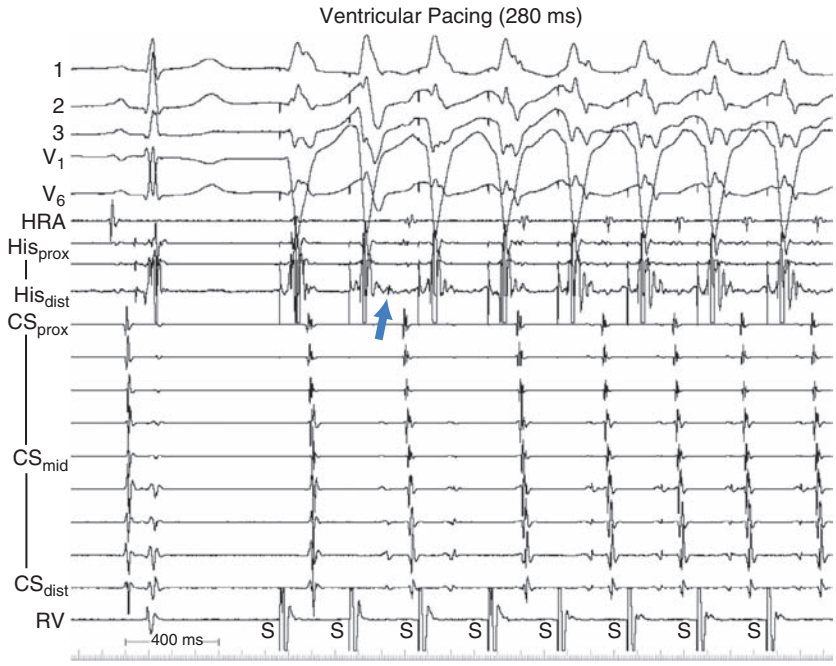

Figure 2-5

In Fig. 2-5, with the sudden onset of ventricular pacing (280 ms), a His "out the back" *(arrow)* is seen after second stimulus, with atrial activation dependent on His (ie, no bypass tract). Retrograde block occurs after the third stimulus likely because of block in the His-Purkinje system, which recovers by the fourth stimulus (after which 1:1 retrograde conduction resumes).

ECGs Compared

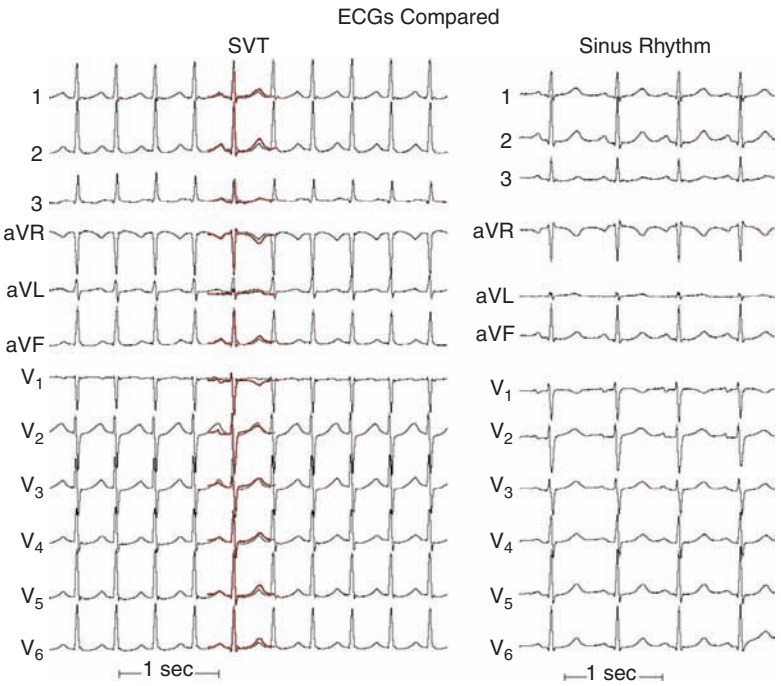

Figure 2-6

SVT was induced ((*left)*; sinus rhythm is shown at right in Fig. 2-6. A superimposed sinus complex *(red)* overlaid on SVT shows no clear difference, implying that the P wave must be hidden within the QRS complex.

Ventricular Pacing in SVT

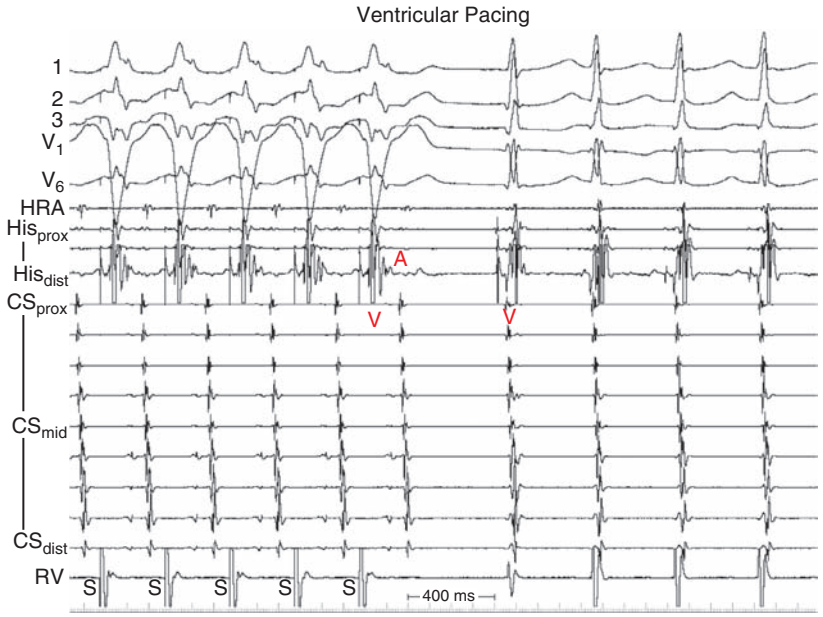

Figure 2-7

In Fig. 2-7, ventricular pacing during SVT conducts retrogradely to atrium with the same activation pattern as during SVT. During SVT that resumes on cessation of pacing, atrial activation appears concentric and within (even before) the QRS complex, excluding orthodromic SVT. The long pause after pacing suggests conduction down an AV nodal slow pathway. The "VAV" response is consistent with typical atrioventricular nodal reentry (AVNRT), not atrial tachycardia (AT).

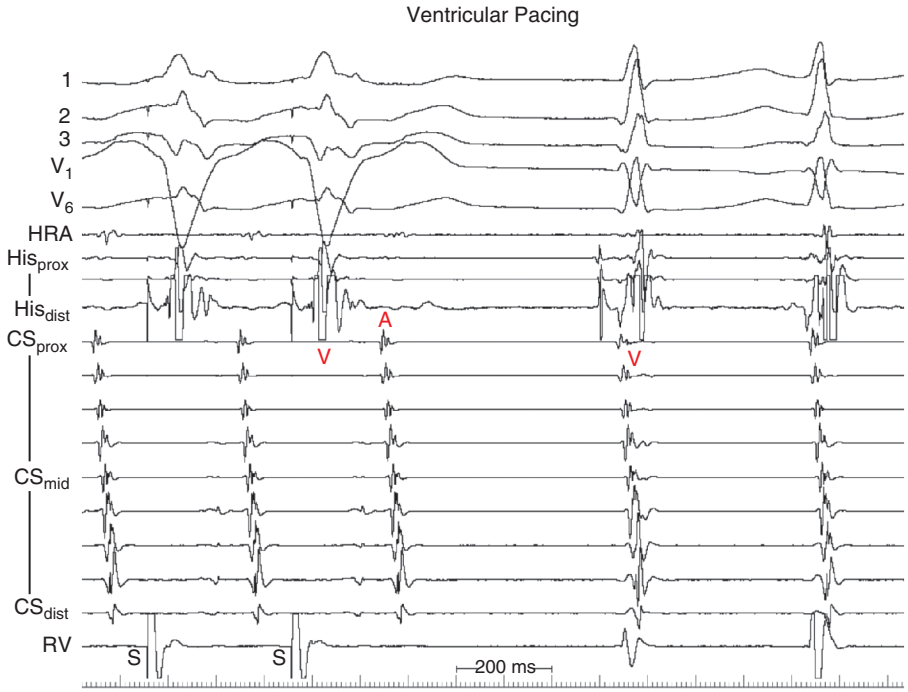

Figure 2-8

Fig. 2-8 is a faster sweep speed of Fig. 2-7, showing the same findings.

Para-Hisian Pacing

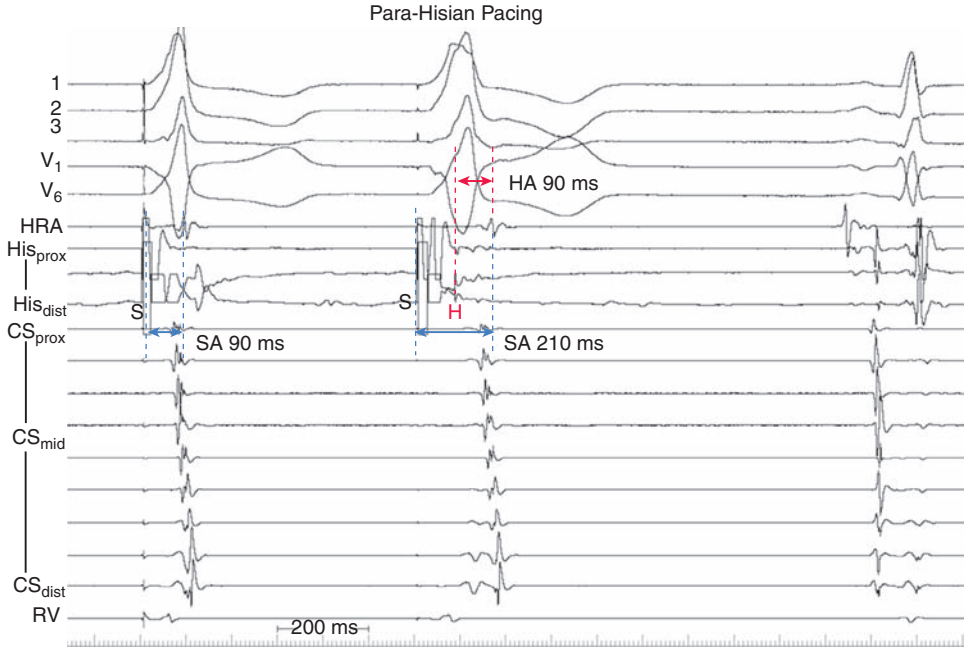

Figure 2-9

The complex at right of Fig. 2-9 shows a normal sinus complex. The complex in middle has a wide QRS suggesting pure ventricular capture. Retrograde conduction is evident. The complex at left is relatively narrow, indicating some element of His capture, though not pure His capture (His + V capture); retrograde conduction is evident with the same pattern as during the wider complex and S-A interval is 90 ms; in the wide complex (V capture only), the S-A interval is 210 ms, indicating conduction only over AV node. The retrograde His is visible (H), with HA still 90 ms.

Ventricular Extrastimuli in Sinus Rhythm

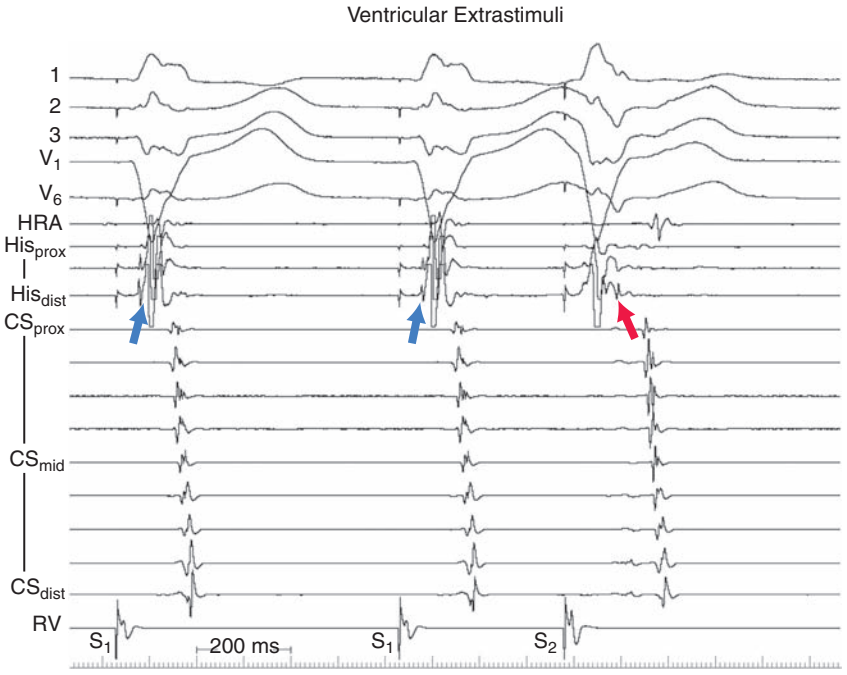

Figure 2-10

A single ventricular extrastimulus at a drive of 600 ms is shown in Fig. 2-10. A retrograde His *(blue arrow)* is seen before the local ventricular electrogram on drive complexes, whereas the His is "out the back" *(red arrow)* after the extrastimulus complex, as a result of block in the right bundle branch with transseptal conduction to and then up the left bundle to the His. If this relationship (atrial activation dependent on prior His activation) remains constant over a range of coupling intervals, a bypass tract is excluded.

Ventricular Extrastimuli in SVT

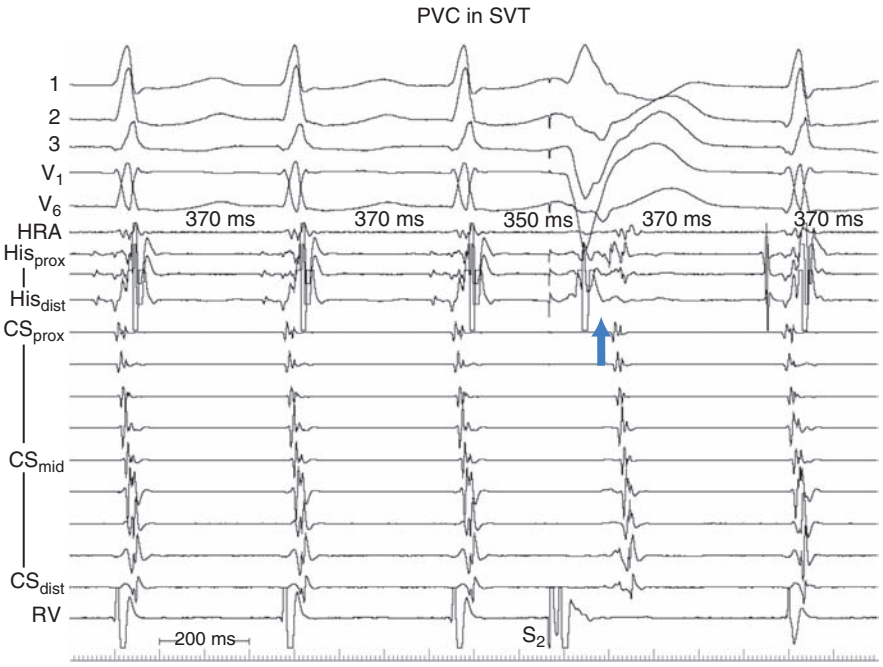

Figure 2-11

In Fig. 2-11, a ventricular extrastimulus is given during SVT. The A-A interval surrounding the extrastimulus is shorter than the rest of the A-A intervals, but the His was not refractory (*blue arrow*

shows where it would be expected if not for the extrastimulus). Advancement of the timing of atrial activation surrounding a *His-refractory* ventricular extrastimulus demonstrates the existence of a path of conduction extrinsic to the normal conduction system (bypass tract). If the extrastimulus occurs at a time when the His is not refractory (as here), it is feasible that conduction could occur through the His to the AV node and atrium, and would not implicate a bypass tract.

Atrial and Ventricular Pacing and Extrastimuli During SVT

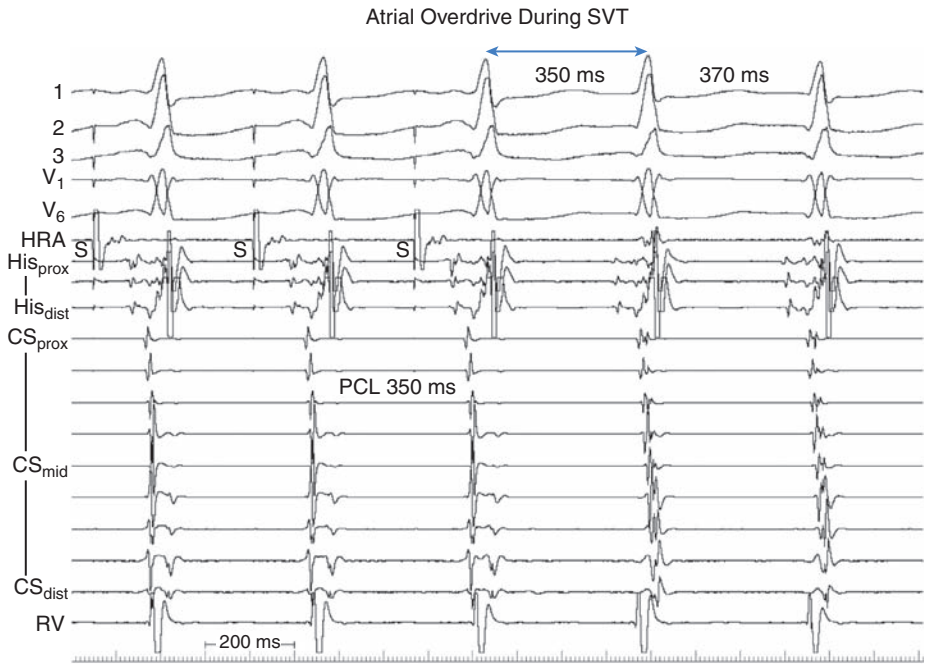

Figure 2-12

Overdrive atrial pacing during SVT is shown in Fig. 2-12. At first glance, the third QRS complex appears to result from the third stimulus. On closer inspection, it is clear that the third stimulus causes the fourth QRS complex because the V-V interval there is the same as the paced cycle length (350 ms). This indicates the presence of slow AV nodal conduction (no surprise, because this type of AV nodal reentry uses an anterograde slowly conducting pathway).

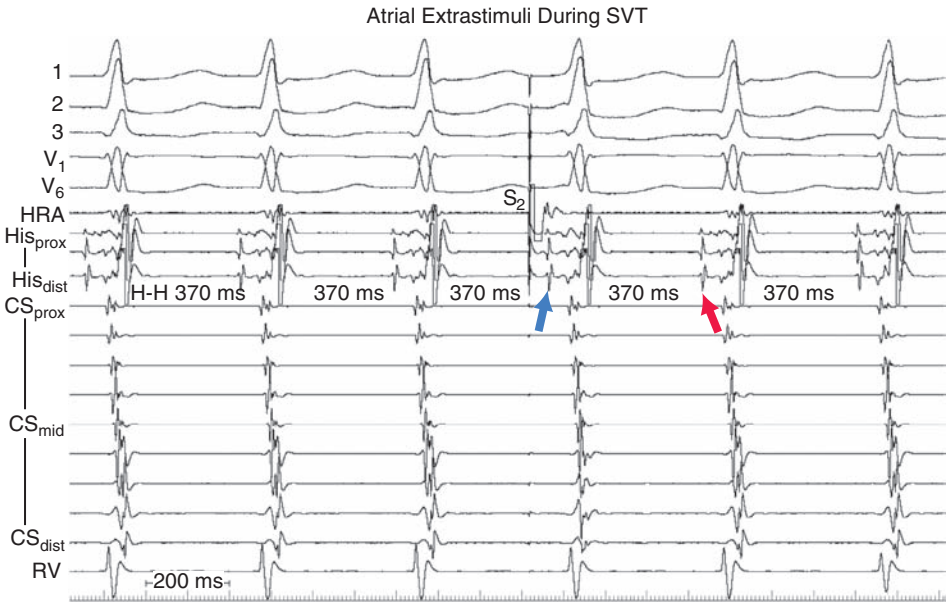

Figure 2-13

In Fig. 2-13, a single atrial extrastimulus is given during SVT. His-His intervals are as indicated; the His immediately after the extrastimulus *(blue arrow)* is on time and unaffected by the stimulus. Thus, if this were a focal junctional tachycardia, it would have already "fired" for that complex and its next occurrence should be right on time. Although this is exactly what happens—the next His *(red arrow)* occurs on time—this finding is also consistent with AV nodal reentry or even AT conducting over a slow AV nodal pathway (the impulse is already on its way down the slow pathway and is unaffected by the atrial extrastimulus). Thus this finding by itself is not diagnostic of focal junctional tachycardia.

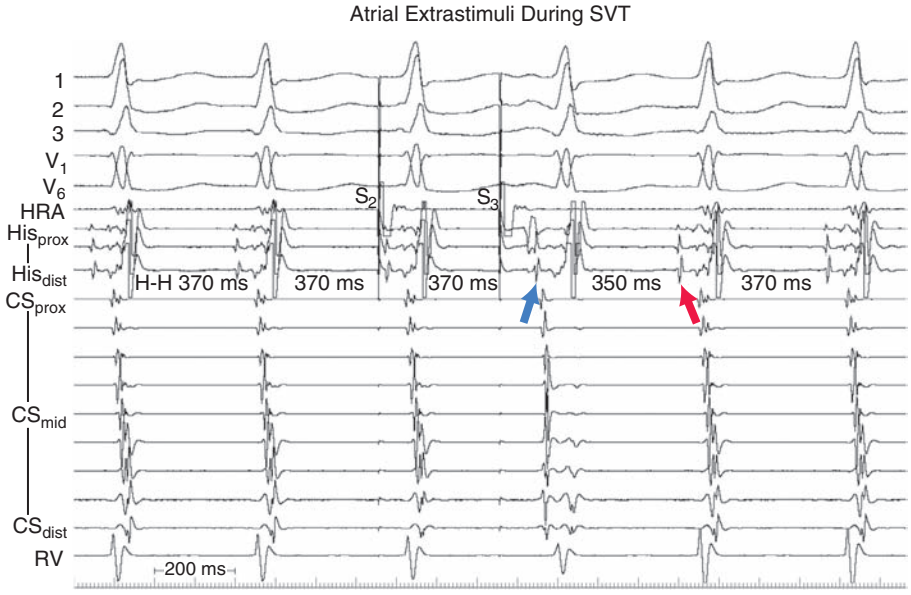

Figure 2-14

Double atrial extrastimuli are now given during SVT (Fig. 2-14). The His potential after second extrastimulus *(blue arrow)* is on time (370 ms), unaffected by the first atrial stimulus (S_2). However, the next His *(red arrow)*, driven by the second atrial stimulus (S_3) is advanced by 20 ms. This shows that focal junctional tachycardia cannot be the diagnosis, because a focal discharge from the His at the red arrow cannot be advanced by an atrial stimulus that did not affect the prior His.

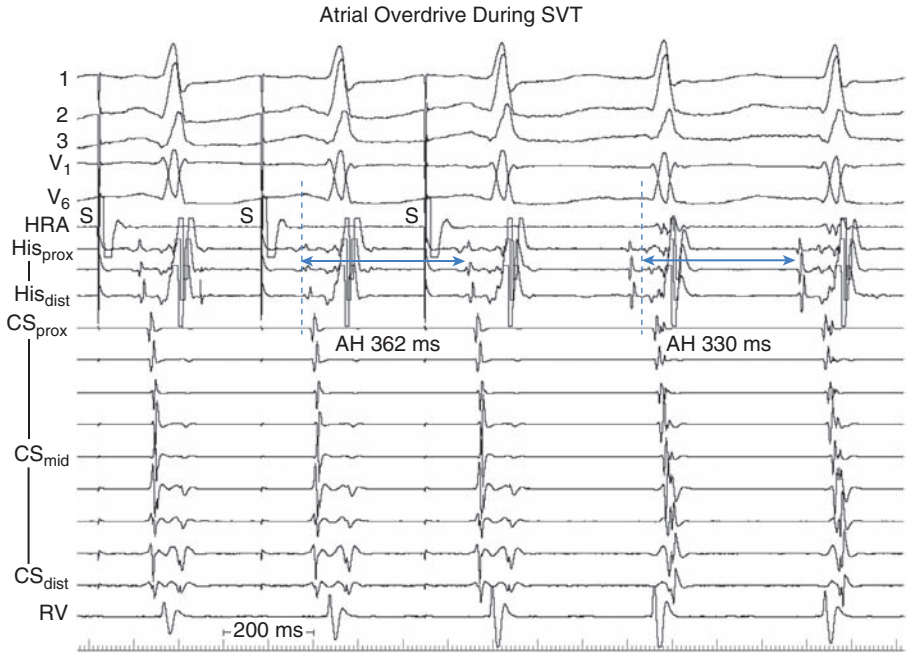

Figure 2-15

Atrial overdrive pacing during SVT is performed again, as shown in Fig. 2-15; the AH interval with pacing (362 ms) exceeds the AH in SVT (330 ms); this is consistent with AV nodal reentry and inconsistent with right AT (in which case the AH intervals should be similar between pacing and SVT).

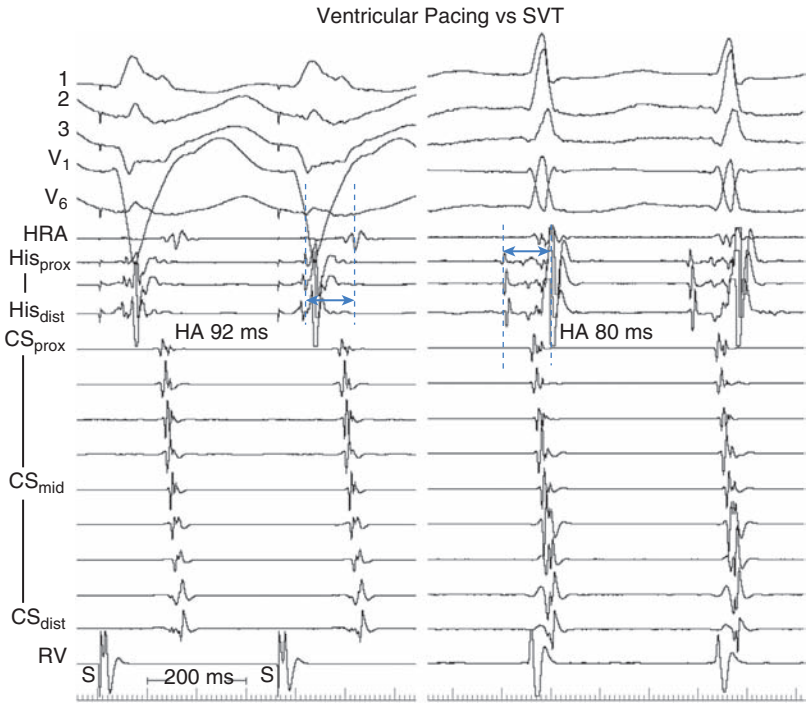

Figure 2-16

The HA interval with ventricular pacing at the SVT cycle length (92 ms) is always the same as or longer than HA in SVT (80 ms), when measured as shown in Fig. 2-16 (end of His to A during pacing, onset of His to A during SVT, with standard 5-mm interelectrode recording catheters). This is not found with very closely spaced, very proximal His recordings, however, where the difference between HA intervals with pacing and SVT narrows as the point of turnaround between anterograde slow and retrograde fast pathways occurs.

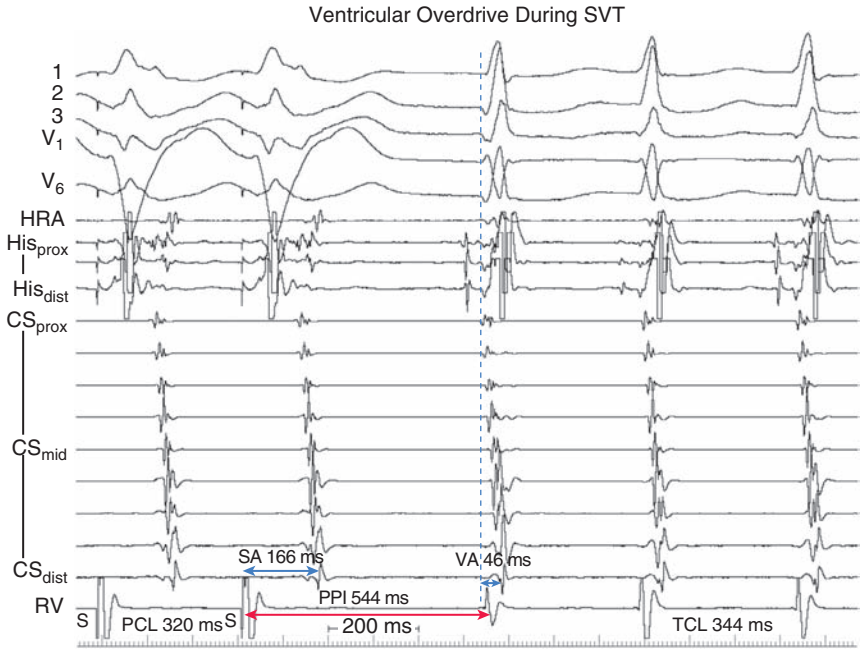

Figure 2-17

Ventricular overdrive pacing during SVT is shown in Fig. 2-17, with intervals as indicated; the SA-VA difference (120 ms) exceeds 85 ms, and the postpacing interval (PPI)–tachycardia cycle length (TCL) difference (200 ms) exceeds 115 ms; both indices indicate AV nodal reentry rather than orthodromic SVT.

Cartoons and Ladder Diagrams of Pacing

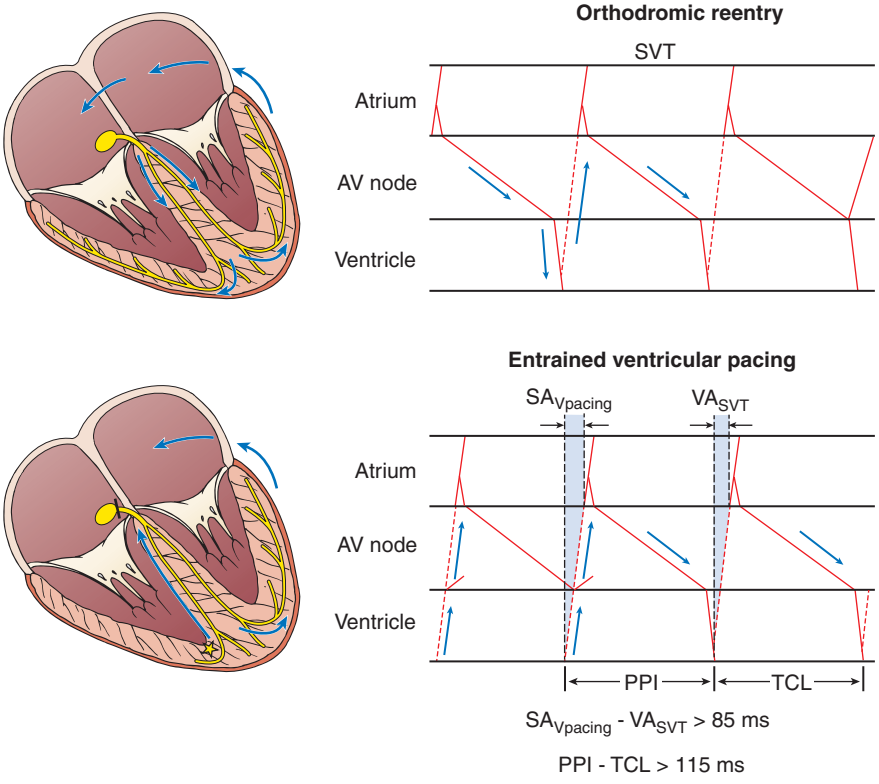

Figure 2-18

Fig. 2-18 displays entrained ventricular pacing during orthodromic SVT; the bypass tract shown here (connecting left atrium and left ventricle) is indicated in the ladder diagrams as a *dotted line*.

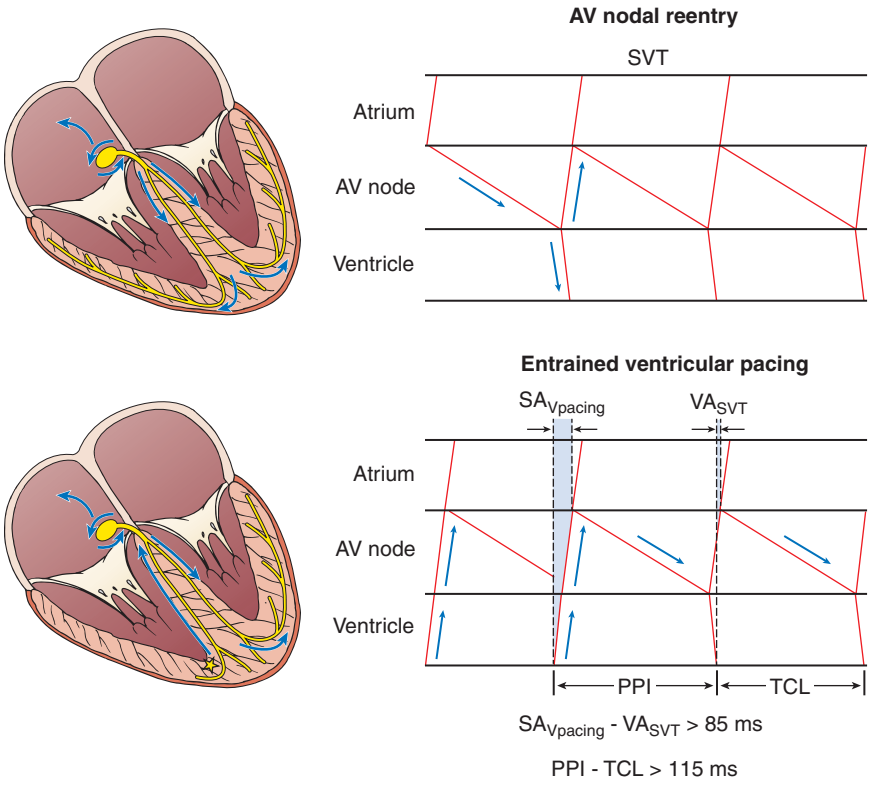

Figure 2-19

Fig. 2-19 shows entrained ventricular pacing during AV nodal reentry.

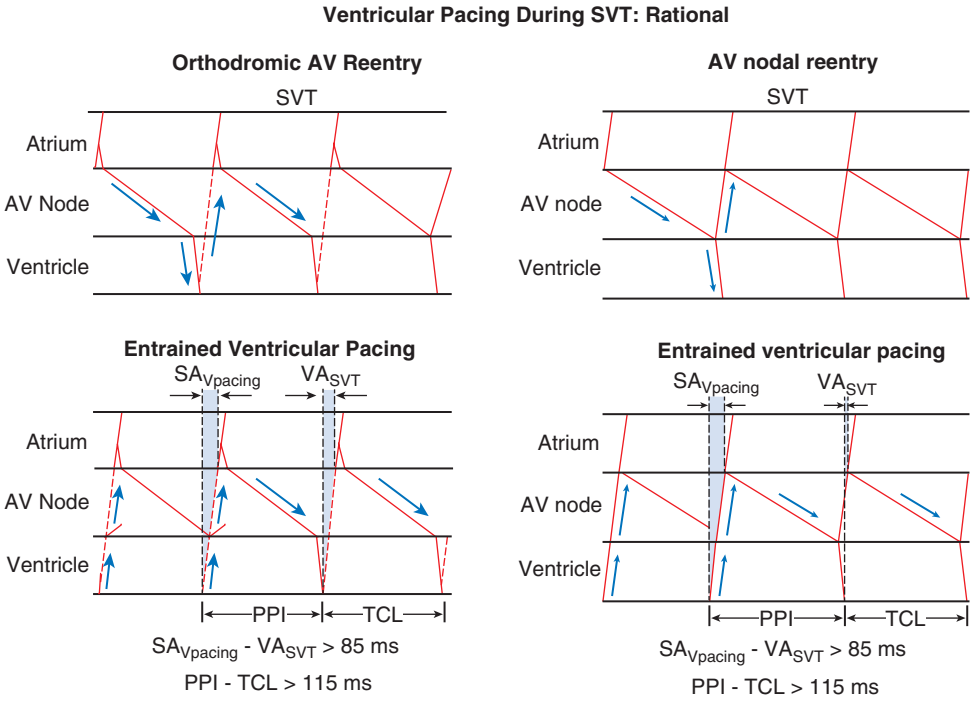

Figure 2-20

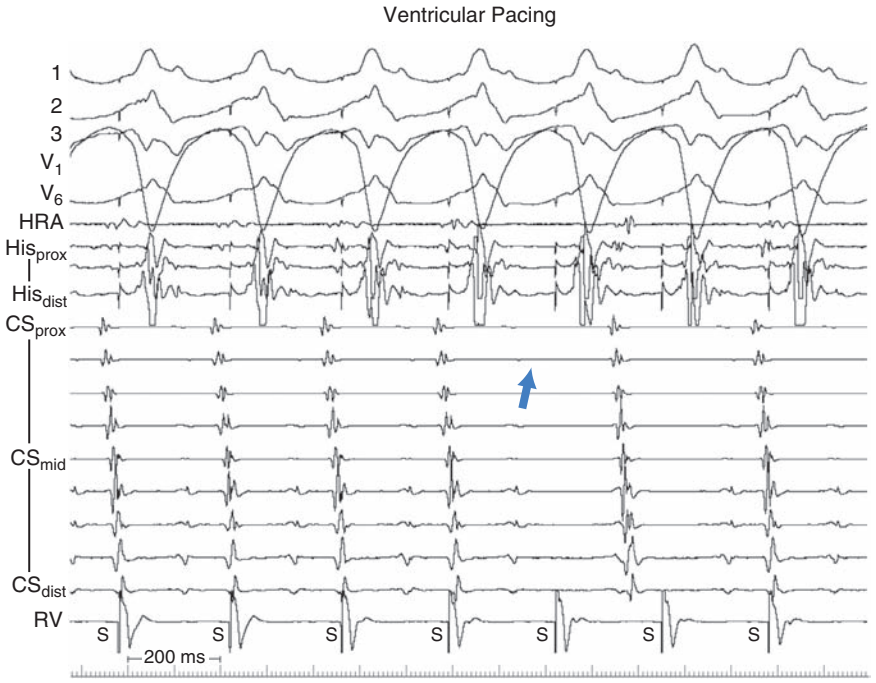
(From Michaud et al. Differentiation of atypical atrioventricular node reentrant tachycardia from orthodromic reciprocating tachycardia using a septal accessory pathway by the response to ventricular pacing. *JACC* 2001;38:1163-7.)

Fig. 2-20 is a comparison of SVT and responses to overdrive ventricular pacing in orthodromic reentry with a bypass tract versus AV nodal reentry. In each case, the paced wavefront must travel from the pacing site to the circuit (stimulus-atrial interval, SA) and back to the pacing site (PPI). Fundamentally, because a right ventricular pacing site is relatively near an orthodromic tachycardia circuit, the SA-VA and PPI-TCL differences are shorter than similar indices in cases of AV nodal reentry, in which the ventricular pacing site is remote from the circuit.

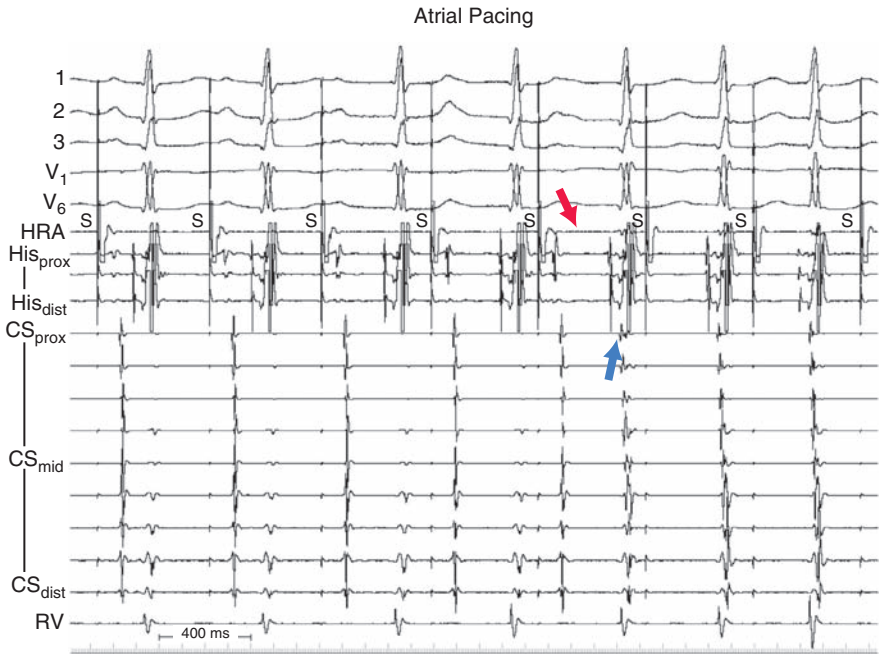
Ventricular and Atrial Pacing in Sinus Rhythm

Figure 2-21



Ventricular pacing to retrograde block in a pattern of Wenckebach is shown in Fig. 2-21 *(blue arrow)*.

Figure 2-22



In Fig. 2-22, burst atrial pacing shifts from fast to slow pathway *(red arrow)* and initiates SVT *(blue arrow)*. Subsequent stimuli do not capture because SVT has superseded them.

Atrial Extrastimulus Testing

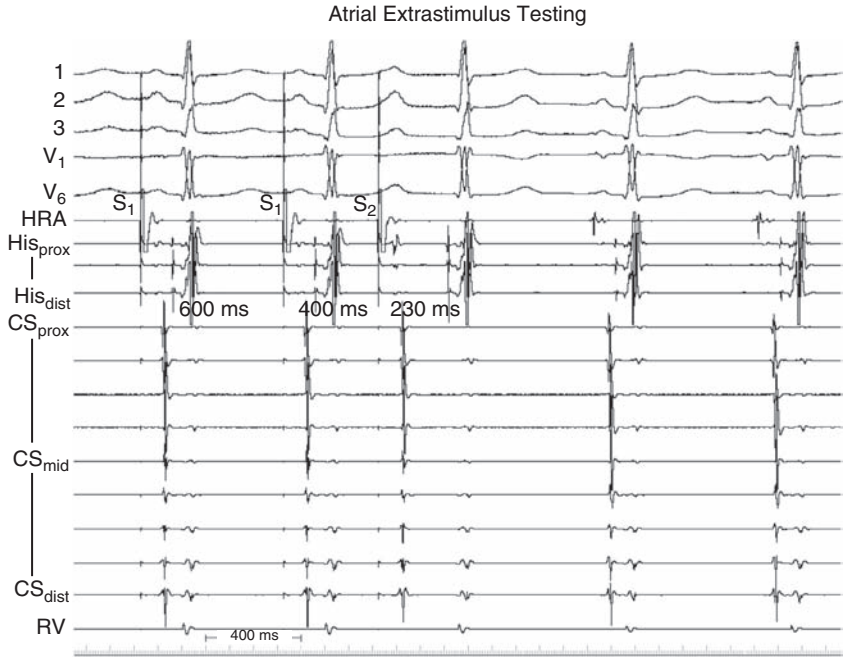


Figure 2-23

Atrial extrastimulus testing 600/400 ms (Fig. 2-23) yields an AH of 230 ms.

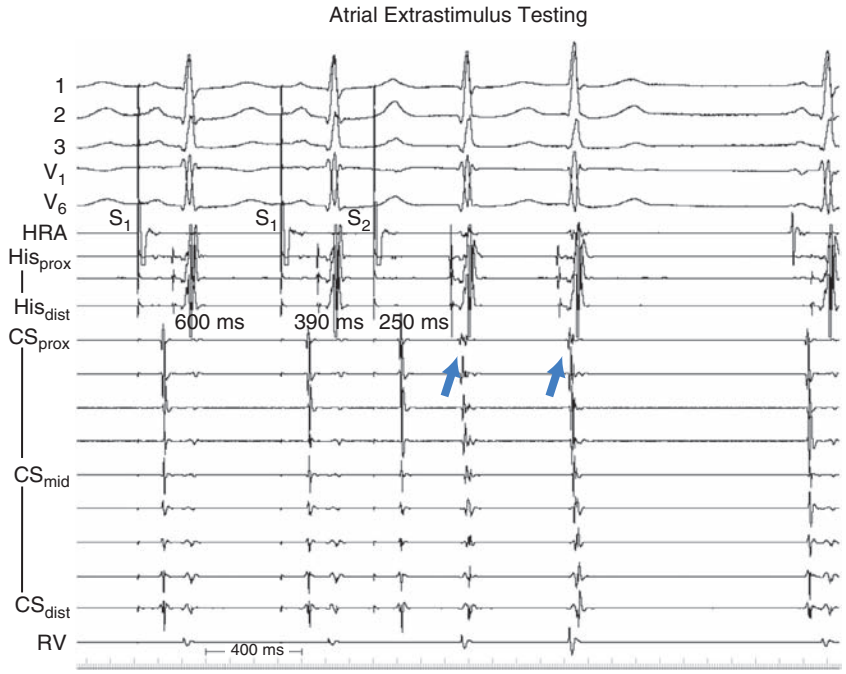

Figure 2-24

Atrial extrastimulus testing 600/390 ms (Fig. 2-24) yields an AH of 250 ms; though not a classic AH "jump" (because the difference in AH intervals resulting from extrastimuli 10 ms apart is <50 ms), the extrastimulus is followed by two echoes *(arrows)*.

Ablation Sites and Assessments

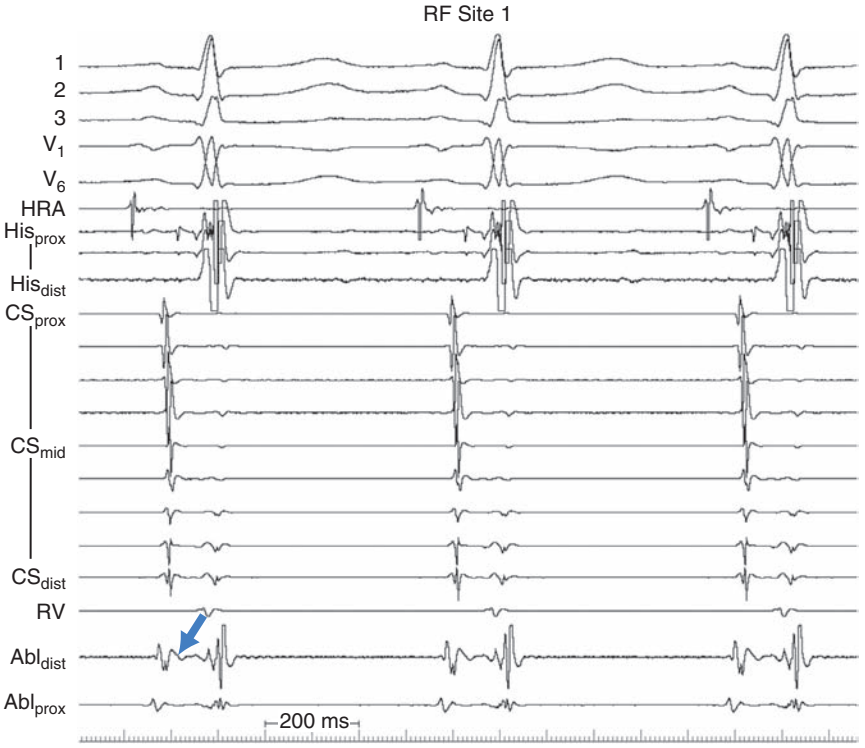

Figure 2-25

Having established AVNRT as the diagnosis, slow pathway ablation commences, as shown in Fig. 2-25. A typical slow pathway potential *(arrow)* is evident.

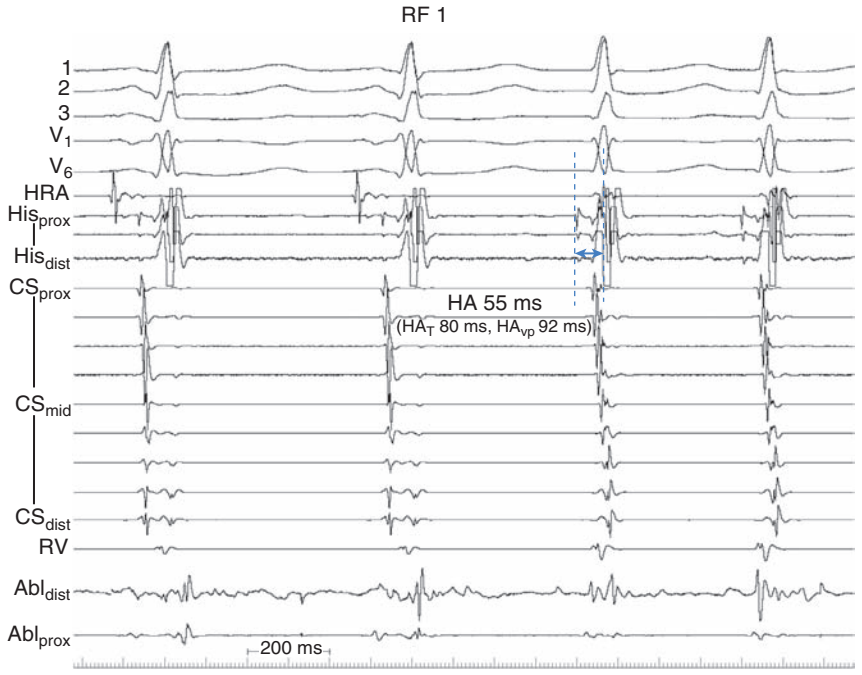

Figure 2-26

During radiofrequency (RF) energy delivery, accelerated junctional rhythm is seen on the last two complexes at right of Fig. 2-26; the HA interval during junctional rhythm is almost always less than the HA in SVT. This is one way to determine whether a rapid 1:1 VA rhythm during RF energy delivery is caused by accelerated junctional rhythm (successful ablation site) versus initiation and continuation of SVT (unsuccessful ablation site).

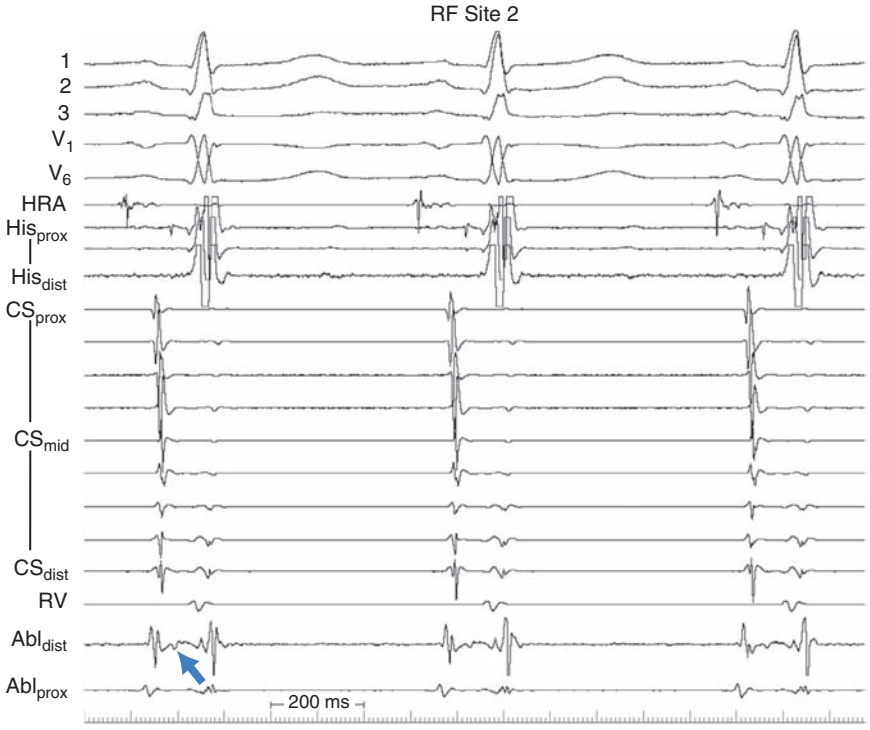

Figure 2-27

After RF 1 (Fig. 2-27), evidence of dual pathways persisted; another site was chosen as shown with another signal compatible with slow pathway activation *(arrow)*.

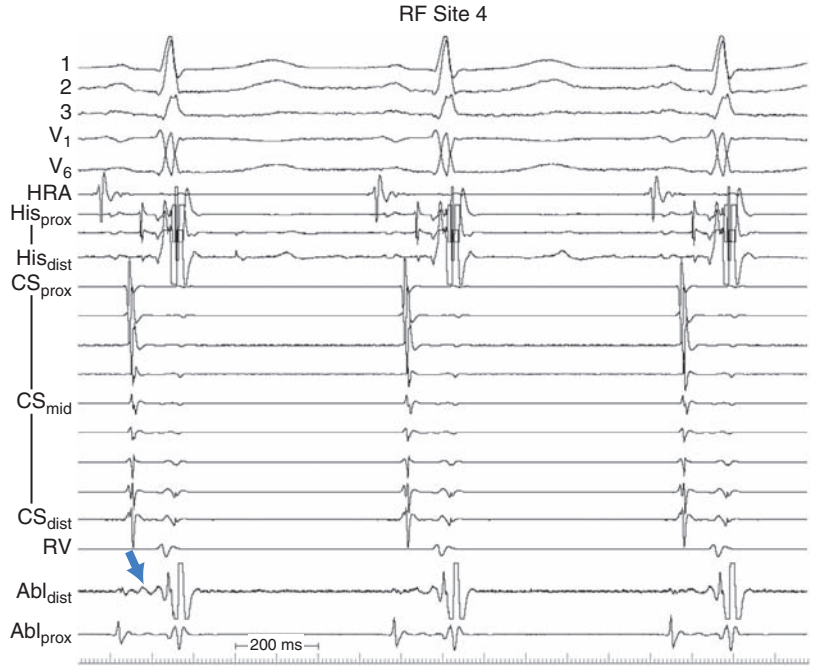

Figure 2-28

As shown in Fig. 2-28, because of persistence of dual pathway physiology, another site of ablation was chosen, with a different type of slow pathway potential *(arrow)*.

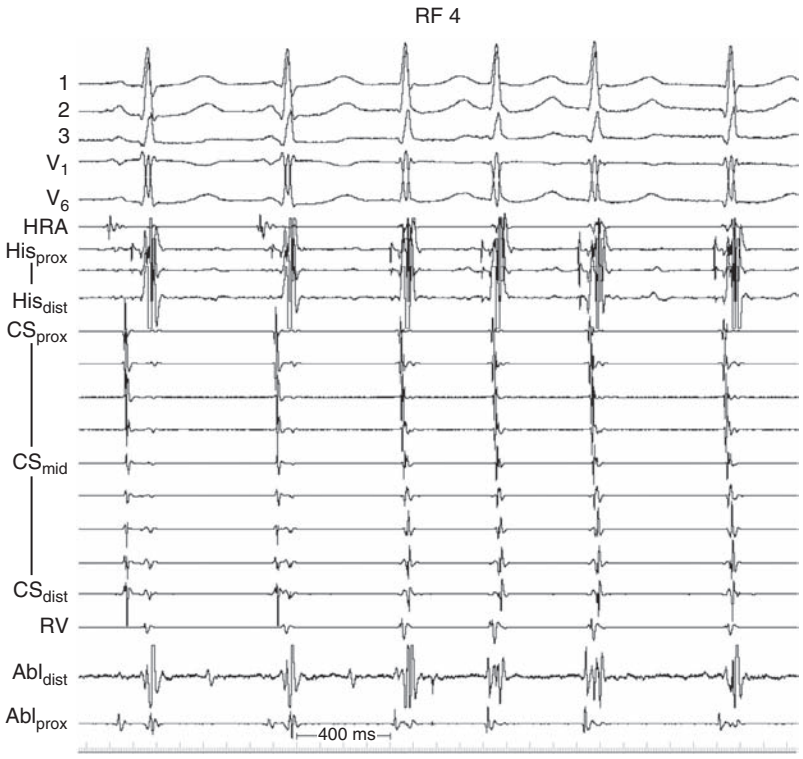

Figure 2-29

At this site in Fig. 2-29, junctional rhythm during RF ablation occurs rather early in the energy application.

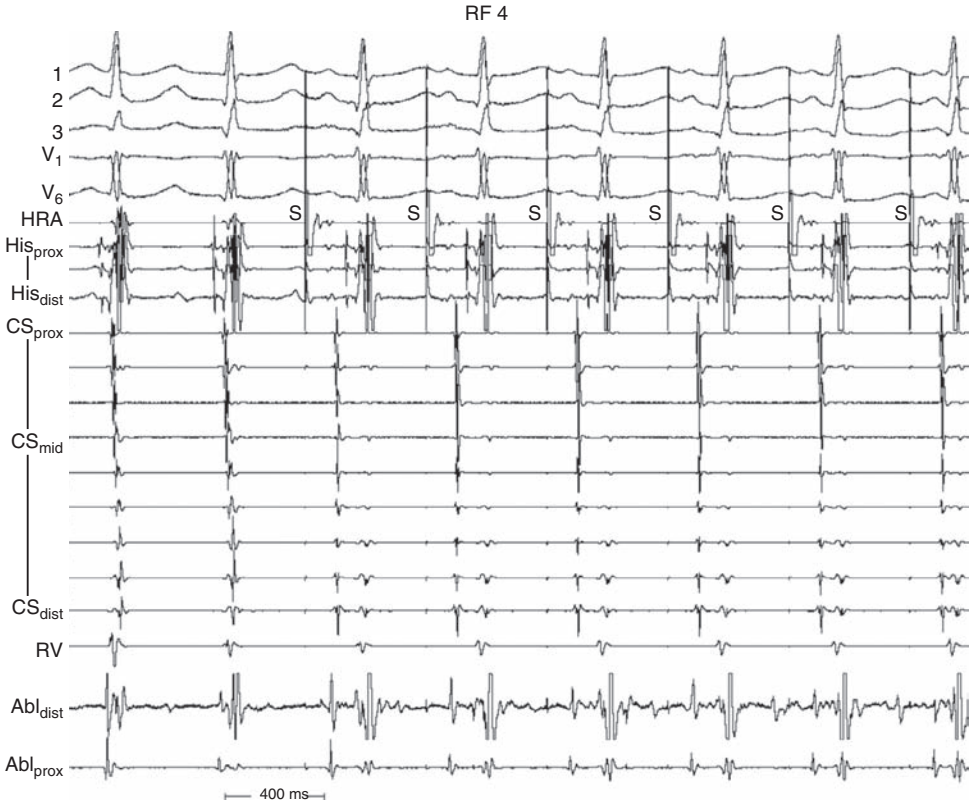

Figure 2-30

Once stable accelerated junctional rhythm is seen, it can be followed by overdrive atrial pacing to ensure the integrity of AV conduction during a more rapid infranodal rhythm (Fig. 2-30). If the PR interval prolongs or AV block occurs, RF delivery can be immediately stopped and almost always conduction returns to what it was before that RF delivery.

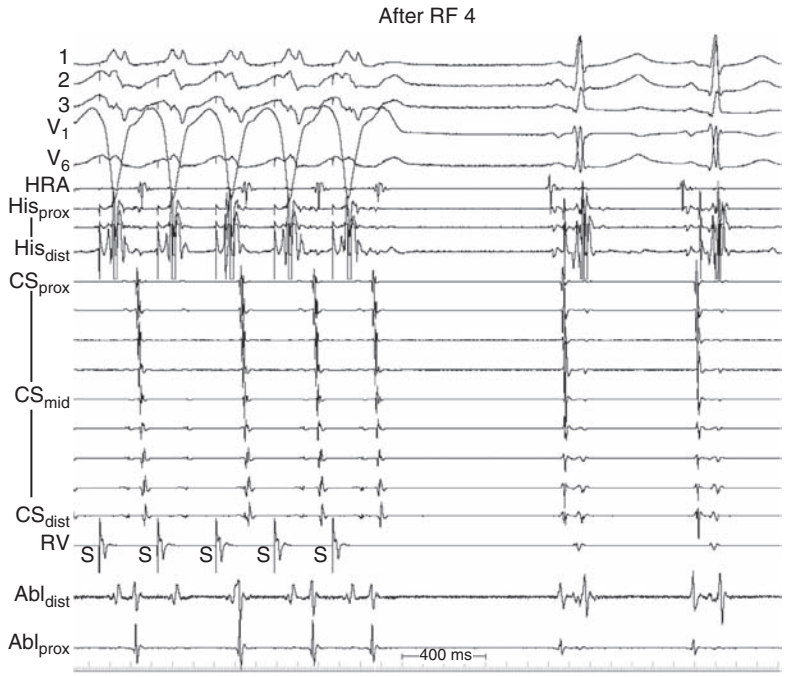

Figure 2-31

Retrograde conduction after RF No. 4 is still good, as is anterograde conduction during sinus rhythm (at right of Fig. 2-31).

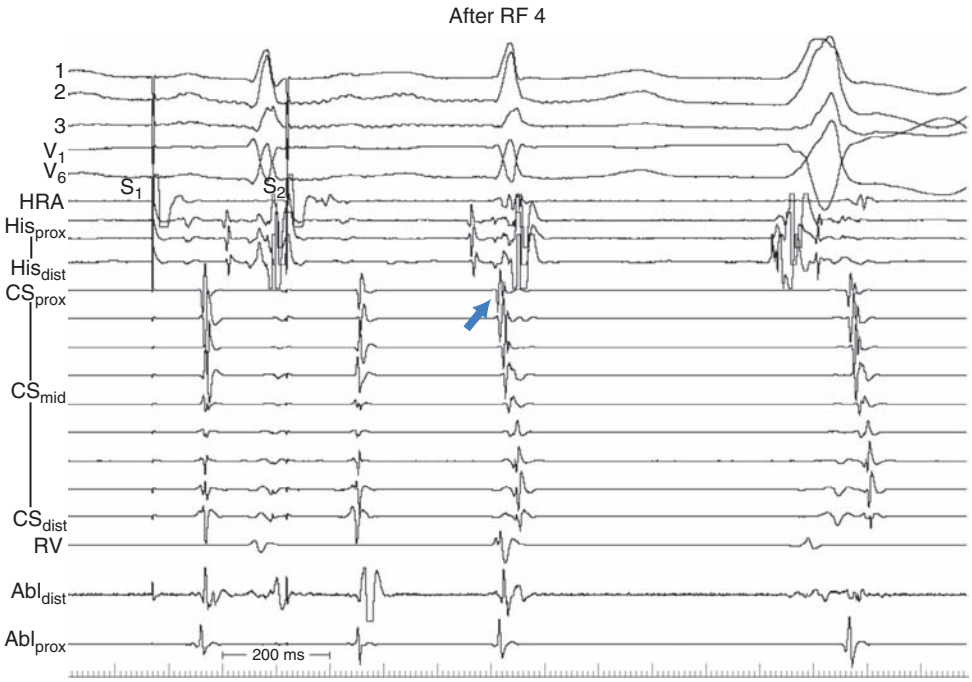

Figure 2-32

Atrial extrastimulus testing after RF 4 still shows an AV nodal echo (only one, *arrow*). A premature ventricular complex (PVC) at the right of Fig. 2-32 shows retrograde His and atrial activation.

SVT Repeatedly Initiated with Atrial Stimulation After Four Attempts at Slow Pathway Ablation,

- No inducible SVT
- Anterograde dual AV nodal pathways and single echoes still
- Preserved AV conduction

What Should You Do Now?

- Try to eliminate dual pathways and echoes?
- End the procedure, risk of AV block is too high?

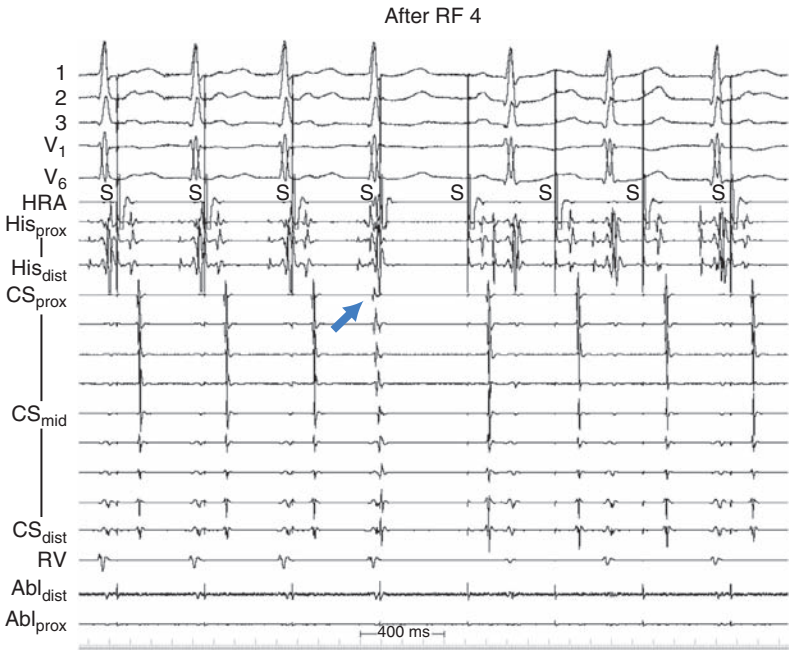

Figure 2-33

In Fig. 2-33, single echoes *(arrow)* remain on atrial drive train; what should be done now? As review, in the baseline state, sustained SVT was easily and repeatedly initiated with atrial pacing, but the slow pathway is still present (although only single echoes are inducible) after four RF applications to the AV nodal slow pathway region. Normal AV conduction is preserved. Is this a good endpoint of the procedure? It would be reasonable to stop here, anticipating a good clinical outcome without risking heart block with additional ablation. We elected to try a little more to eliminate the slow pathway and echoes, however.

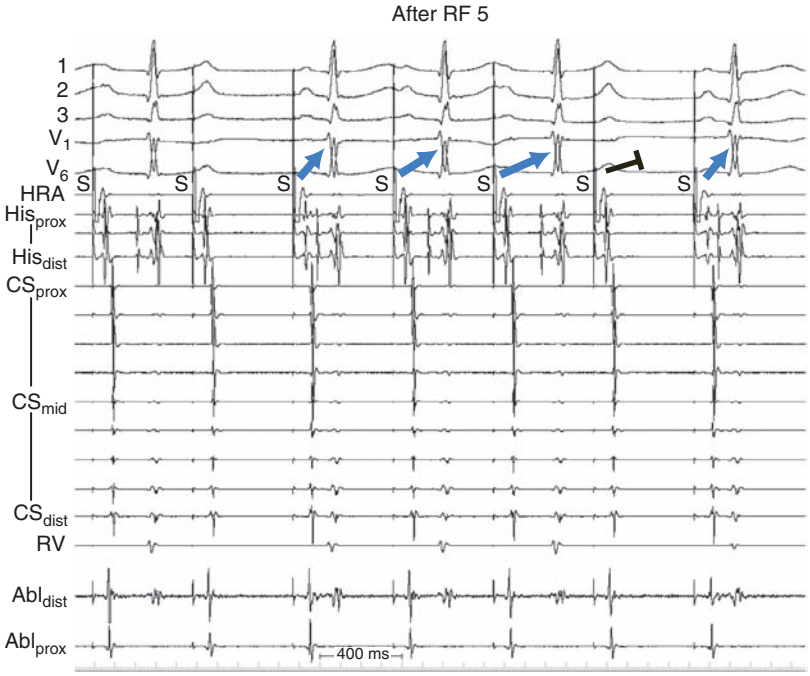

Figure 2-34

In Fig. 2-34, another RF application was given in a similar area, resulting in complete elimination of anterograde slow pathway conduction. (Of note, electroanatomic mapping was not used in this procedure.)

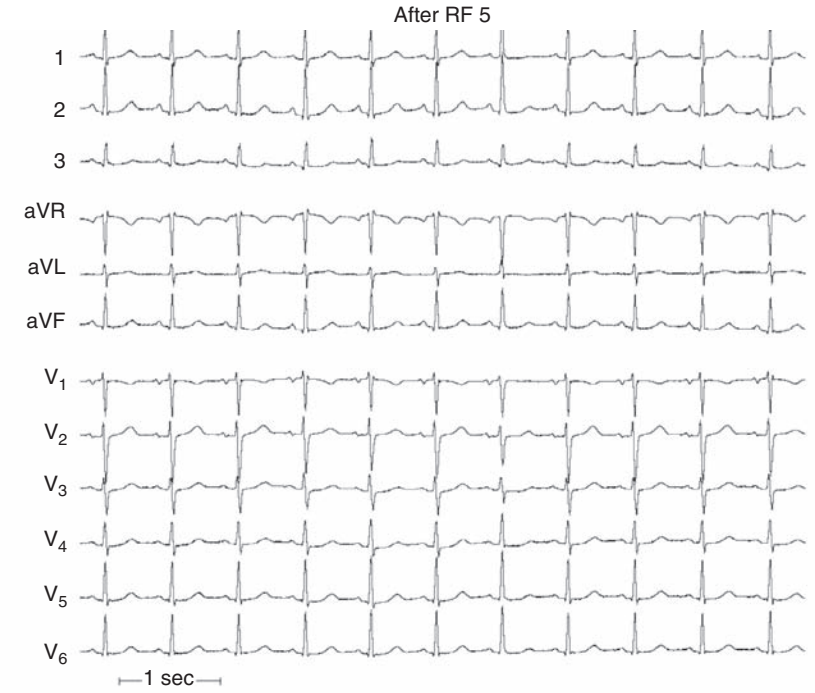

Figure 2-35

Fig. 2-35 demonstrates sinus rhythm after all ablations remains, with normal intervals.

Summary

- AV nodal reentry should be readily distinguished from other SVTs in order to select the appropriate RF targets.
- The vigor of slow pathway ablation should be (Table 2-1)
  - Proportional to the amount of clinical impact SVT has
  - Inversely proportional to the ease of SVT initiation
  - Inversely proportional to the risk of heart block

TABLE 2-1 How Aggressive to be with Slow Pathway Ablation?

Finding	Vigor of Slow Pathway Ablation
Clinical Importance of SVT	
Very bothersome	Relatively safe to be aggressive
Occasional mild nuisance	Be very careful!!!
Ease of SVT Initiation	
Easily reproducible sustained SVT	Eliminate sustained SVT (dual pathways, echoes OK)
Dual pathways + reproducible echoes	Eliminate slow pathway if possible
Dual pathways only	Eliminate slow pathway
Distance from CS os to His Bundle	
Long (≥10 mm)	Relatively safe to be aggressive
Short (<10 mm)	Be very careful!!!

3 Atypical ("Fast-Slow") Atrioventricular Nodal Reentry

Case Presentation

- A 44-year-old man had palpitations for about 2 years. Episodes often occurred during exercise, lasting a few minutes to hours. With one prolonged episode, he went to the emergency room (ER). There, an ECG showed a regular, narrow QRS tachycardia at 180/min, with a long RP interval, which was terminated with intravenous adenosine. Subsequently, metoprolol in tolerated doses was ineffective at preventing recurrent episodes. Findings of physical examination and the resting ECG were normal. Echocardiogram revealed mild global left ventricular hypokinesis. He was referred for EP study and possible ablation.

Baseline ECG and Intracardiac Recordings

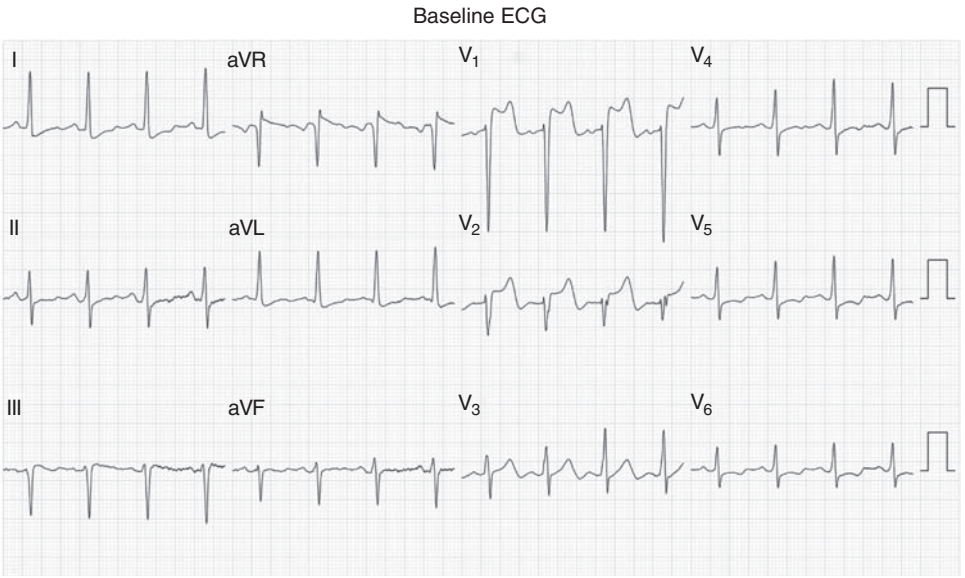

Figure 3-1

There are no clues from the sinus rhythm ECG (Fig. 3-1) as to what the patient's supraventricular tachycardia (SVT) is. ST elevation in V1-V2 is an artifact of the recording system.

Any Clues as to SVT Diagnosis? [Fig. 3-2]

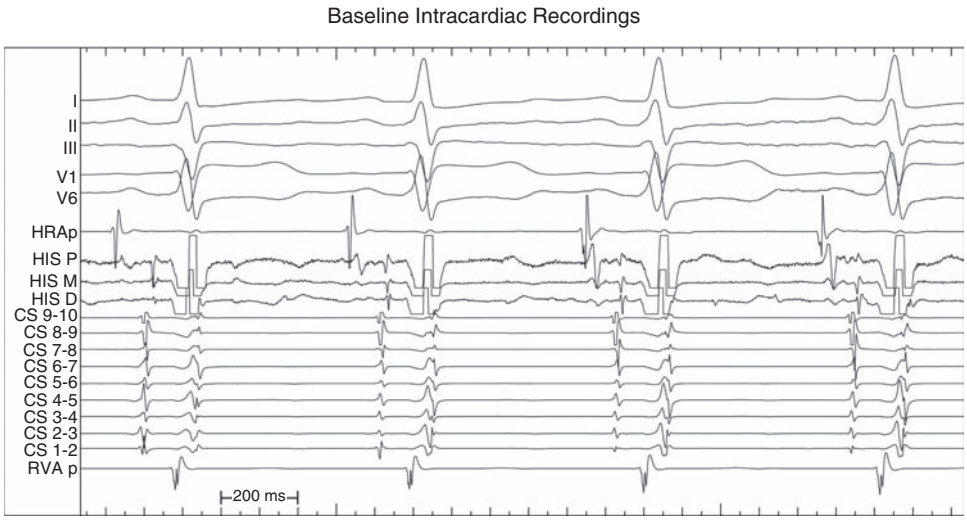

Figure 3-2

There are likewise no clues from the intracardiac recordings (Fig. 3-2), such as subtle preexcitation, as to the cause of the patient's SVT.

Baseline Ventricular Pacing

Does This Include/ Exclude Any Diagnoses? [Fig. 3-3]

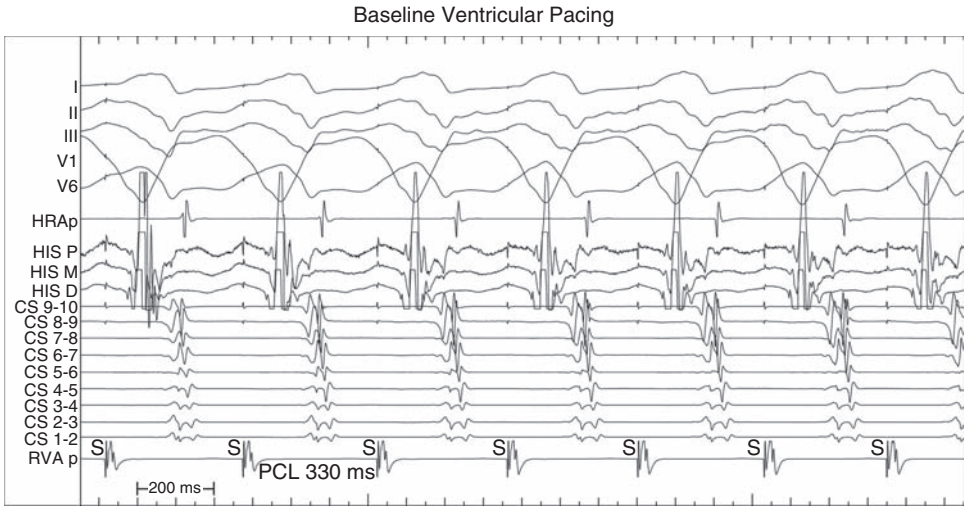

Figure 3-3

A good way to start investigating for causes of SVT is with ventricular pacing. In Fig. 3-3, it appears that retrograde conduction is rather good and midline (suggesting either a fast atrioventricular [AV] nodal pathway or a septal bypass tract). However, none of the potential causes of SVT is excluded by these findings.

Baseline Coronary Sinus Pacing

Does This Include/ Exclude Any Diagnoses? [Fig. 3-4]

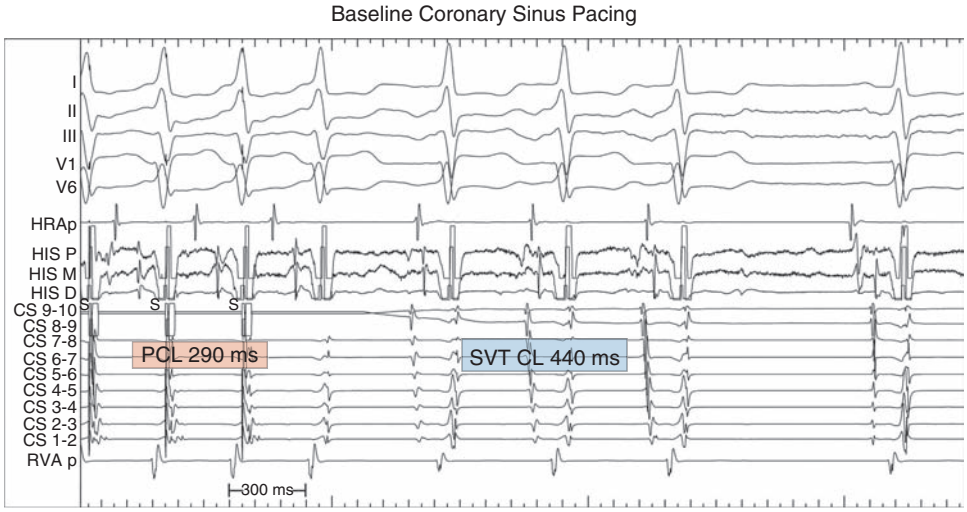

Figure 3-4

Three cycles of a "long-RP" tachycardia are initiated with atrial pacing (Fig. 3-4). The differential diagnosis for this is atrial tachycardia (AT), orthodromic AV reentry using a slowly/decrementally conducting bypass tract as the retrograde limb, or atypical AV nodal reentry (slow pathway retrograde, fast pathway anterograde). Of these diagnoses, a focal AT seems the least good fit because of the prolonged pause between the last stimulated complex and the first tachycardia complex (here, about 550 ms). Nothing in this figure differentiates between the other two possible causes.

SVT Initiation with Ventricular Pacing

What Kinds of SVT Are Initiated With Ventricular Pacing? [Fig. 3-5]

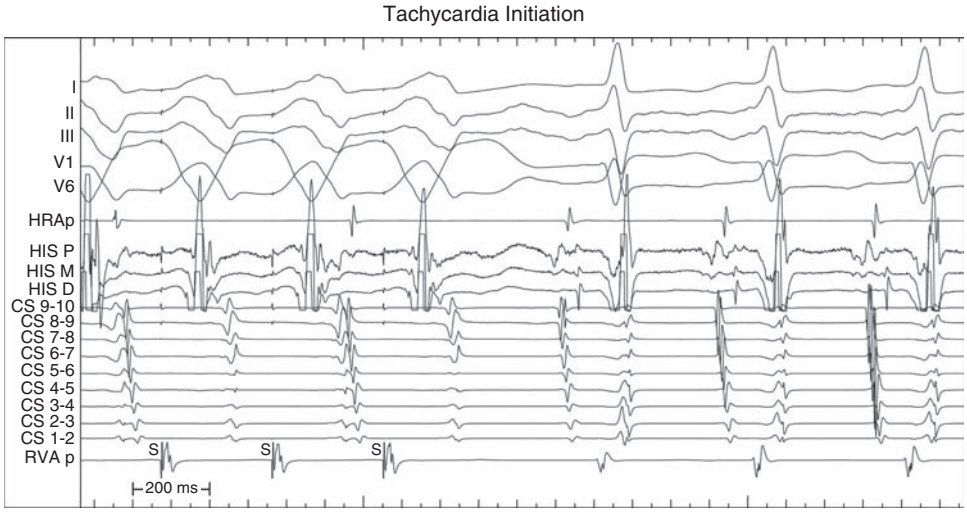

Figure 3-5

In Fig. 3-5, ventricular pacing induces SVT. Several types of SVT can be initiated with ventricular pacing, including orthodromic SVT, atypical AV nodal reentry (AVNRT), and typical AVNRT; even focal ATs (rarely) can be initiated. What information is shown in Fig. 3-5 that could help differentiate among these?

AT initiation with ventricular pacing is rare and likely related to autonomic alterations; it can even occur in the absence of retrograde conduction. The atrial activation sequence is very similar if not the same during ventricular pacing and tachycardia, which would be unusual for AT (not only septal origin—uncommon for AT—but also highly coincidental). Three unlikely events, ventricular pacing induction of AT, tachycardia having the same activation sequence as retrograde conduction, and a septal location, all occurring at once challenge credulity. Thus AT is unlikely. However, there is little here to differentiate

between atypical AVNRT and orthodromic SVT using a slowly conducting bypass tract. The longer VA interval after the last ventricular stimulus, compared with the ongoing rhythm, can be seen with either.

SVT ECG and Intracardiac Recordings

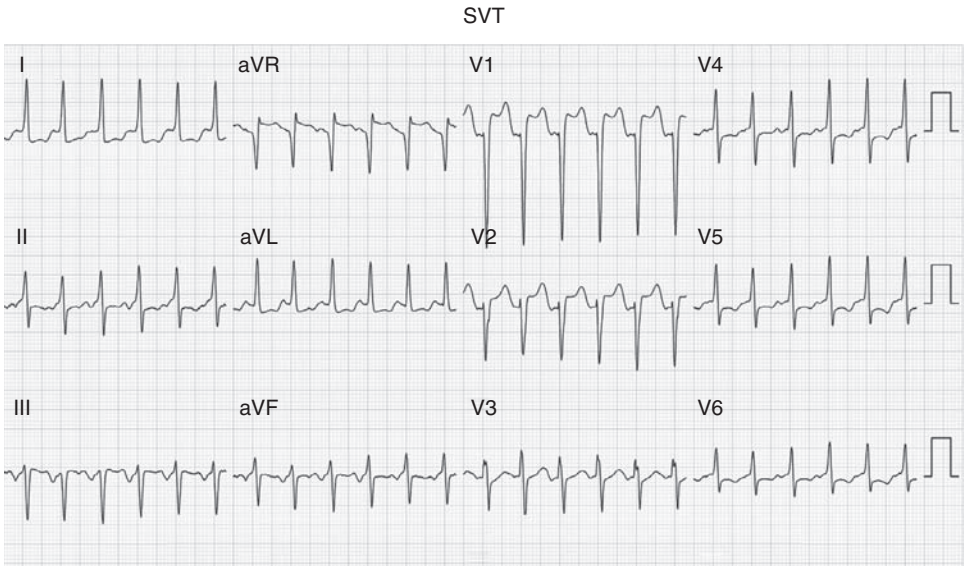

Figure 3-6

Fig. 3-6 shows a 12-lead ECG of SVT, a "long-RP" tachycardia. P-wave morphology suggests a low atrial source of earliest activation.

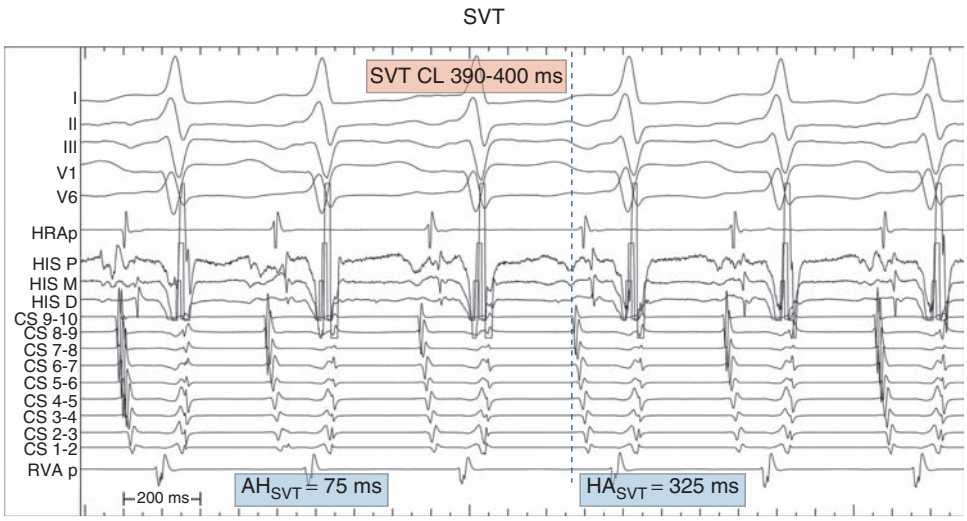

Figure 3-7

Intracardiac recordings during sustained SVT (Fig. 3-7) show an atrial activation pattern with earliest recorded activation near the AV nodal region; measured intervals are as shown for future reference.

Ventricular Extrastimuli and Overdrive Pacing During SVT

Does This Include/ Exclude Any Diagnoses? [Fig. 3-8]

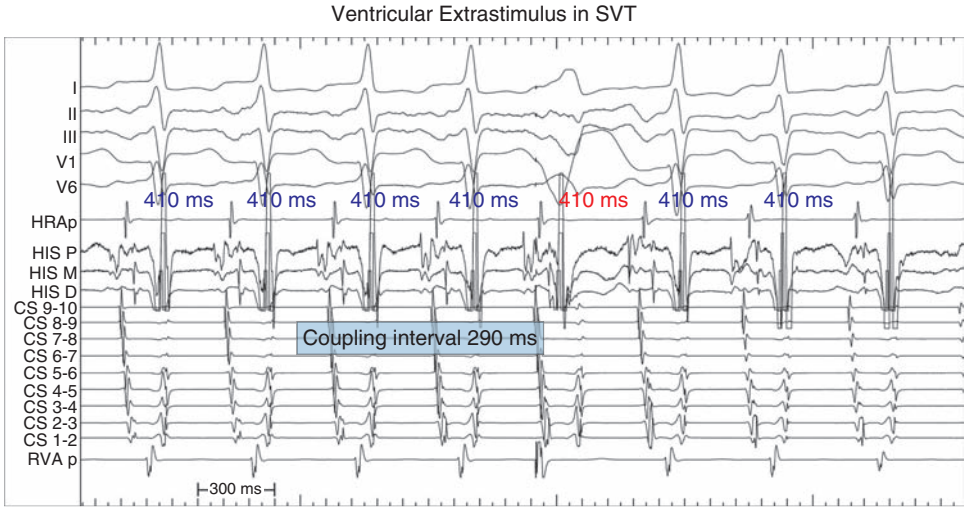

Figure 3-8

A His-refractory has no effect on the timing of subsequent atrial activation; no inference can be made from Fig. 3-8. Closer coupling intervals are needed.

Does This Include/ Exclude Any Diagnoses? [Fig. 3-9]

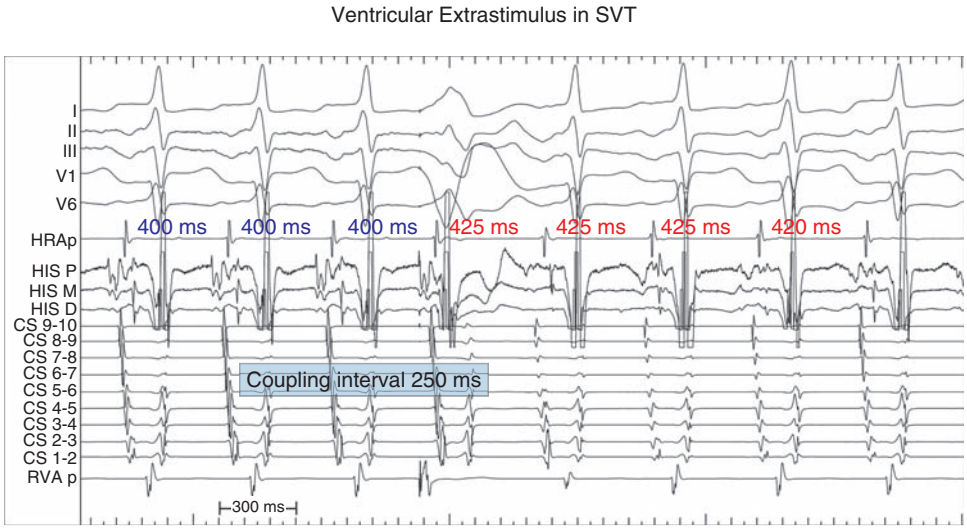

Figure 3-9

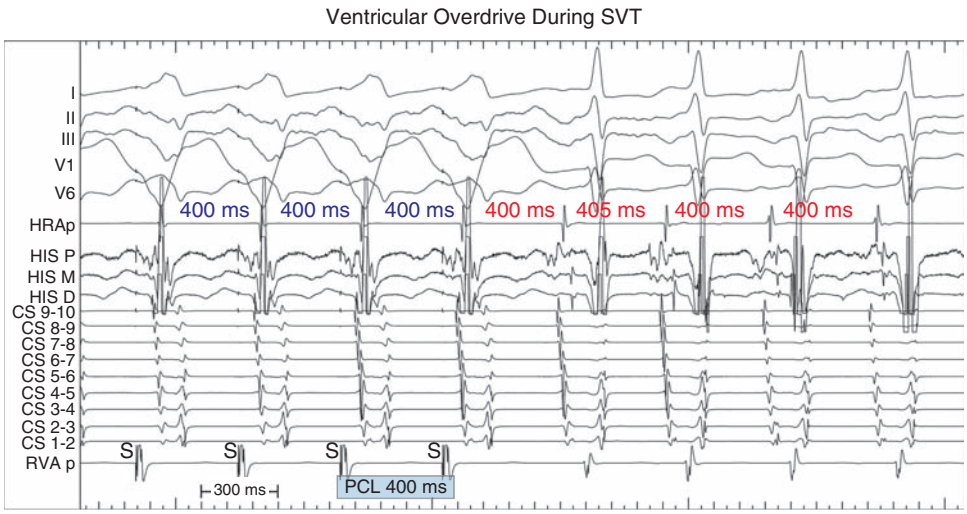
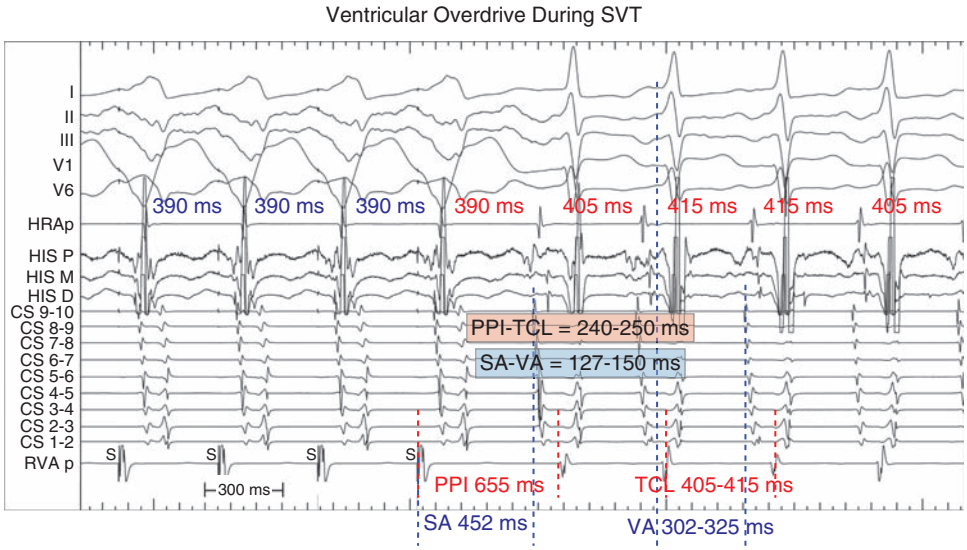
In Fig. 3-9, the A-A interval surrounding the more premature (and still His-refractory) ventricular extrastimulus is longer than baseline; however, tachycardia cycle length (TCL) after this stays at the longer A-A interval. Thus the PVC probably did not actually prolong the VA (hence, A-A) interval but happened to occur at a time when TCL was increasing independently. TCL varied during the procedure from 390 to 440 ms. Because the A-A surrounding the PVC did not differ from others during SVT, no inference can be made from it as to the nature of the tachycardia.



Does This Include/ Exclude Any Diagnoses? [Fig. 3-10]

Figure 3-10

Ventricular overdrive pacing during SVT can often yield important information regarding its diagnosis. The chosen ventricular paced cycle length (400 ms) in Fig. 3-10 is about the same as TCL at this time (400–405 ms); thus no inference should be made as to events after cessation of pacing.



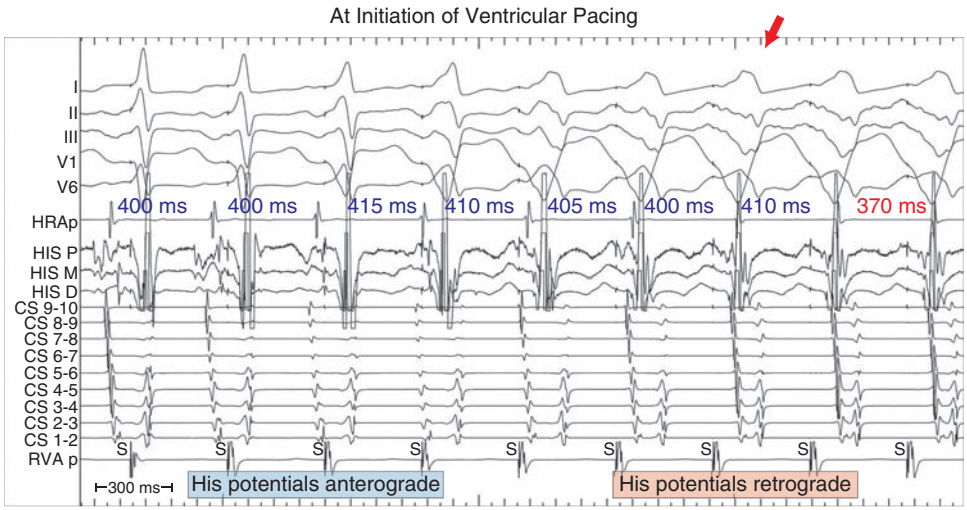
Does This Include/ Exclude Any Diagnoses? [Fig. 3-11]

Figure 3-11

The chosen ventricular paced cycle length in Fig. 3-11 is reasonably faster than TCL; now, conclusions can be made as to events after cessation of pacing. The PPI-TCL (>125 ms) and SA-VA (>85 ms) differences are in a range that suggests AV nodal reentry rather than septal bypass tract-based orthodromic reentry.

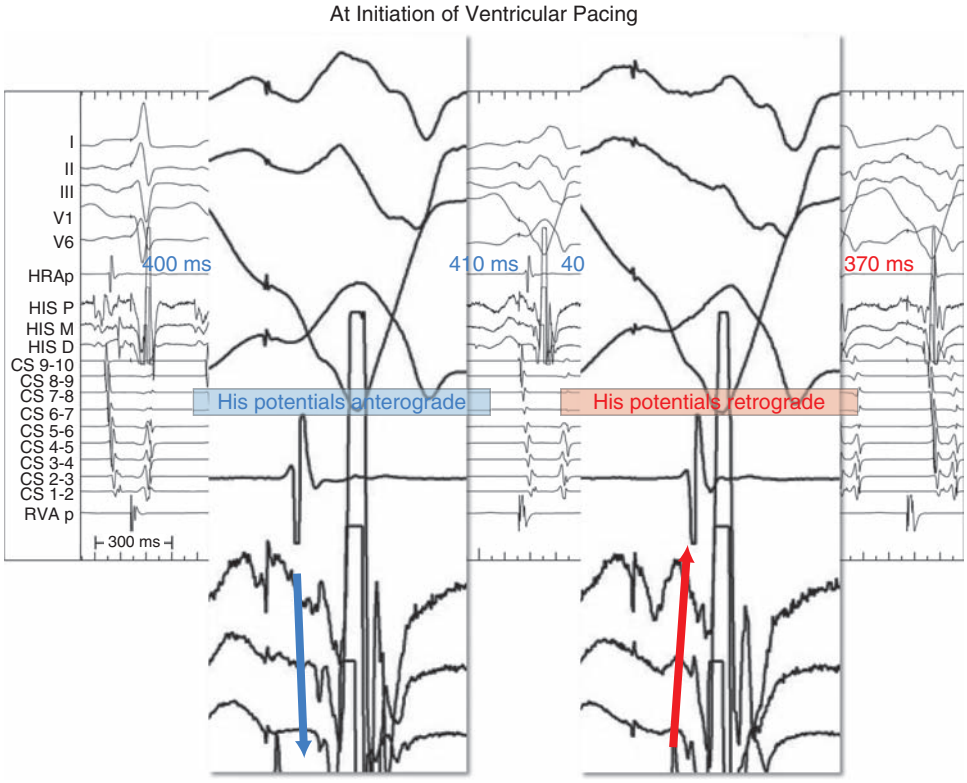
At Initiation of Ventricular Pacing [Fig. 3-12]

Figure 3-12



Fully paced complexes are present for the last 3 cycles in Fig. 3-12 (*arrow*); the A-A interval becomes the same as the ventricular paced CL only on the last cycle.

Figure 3-13



In Fig. 3-13, an enlarged single complex showing anterograde and retrograde His propagation is superimposed on Fig. 3-12.

Initiation of Atrial Fibrillation with Ventricular Pacing

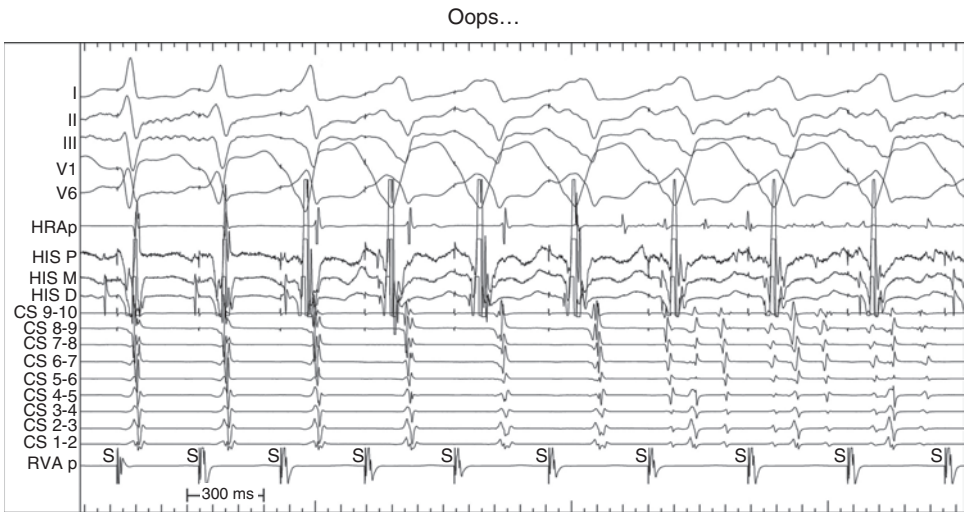


Figure 3-14

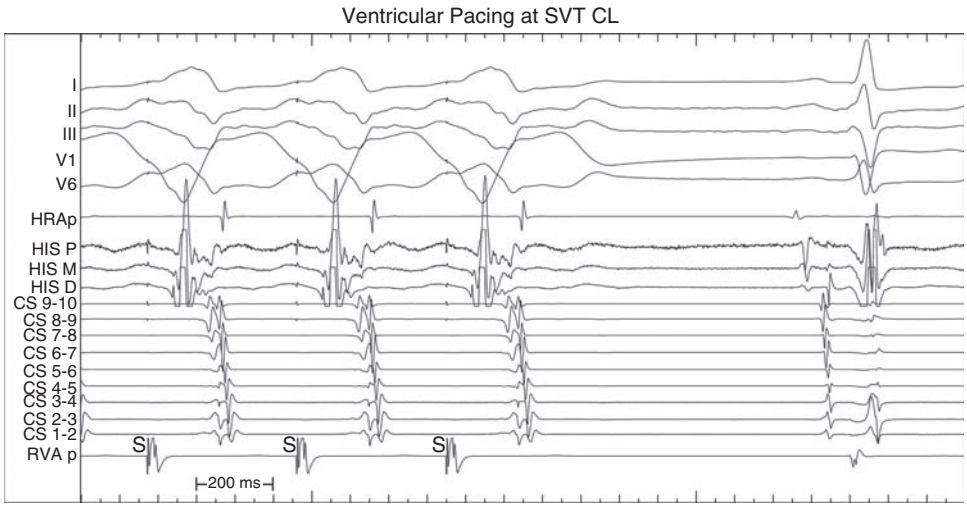
As demonstrated in Fig. 3-14, unfortunately, atrial fibrillation (AF) occasionally occurs during ventricular pacing or SVT. This may stop spontaneously or require cardioversion, because it interferes with being able to continue the study. Generally, AF is an artifact of stimulation of the procedure and does not need independent treatment.

Ventricular and Atrial Pacing at TCL During Sinus Rhythm



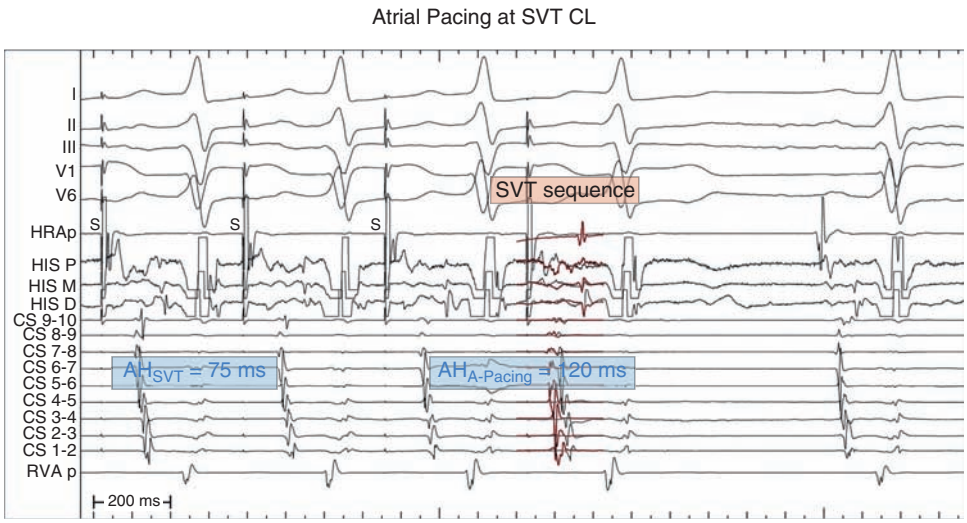
Does This Help In Any Way? [Fig. 3-15]

Figure 3-15

Fig. 3-15 shows HA interval during ventricular pacing at TCL 130 ms; however, this is traveling retrogradely up the fast pathway, not the same pathway as is used during SVT. Thus no comparison of HA intervals (pacing vs SVT) can be made.

Does This Include/ Exclude Any Diagnoses?

Figure 3-16



The AH with atrial pacing at TCL is 120 ms, and during SVT (as measured earlier), 75 ms. Fig. 3-16 is the strongest evidence so far that AV nodal reentry is the diagnosis (AH pacing–SVT difference <20 ms for AT, 20–40 ms for slowly conducting bypass tract, >40 ms for atypical AVNRT). A single complex of SVT is superimposed (*red*) to show that this is not pacing during SVT (different activation sequence with pacing than with SVT).

Parahisian Pacing

Figure 3-17

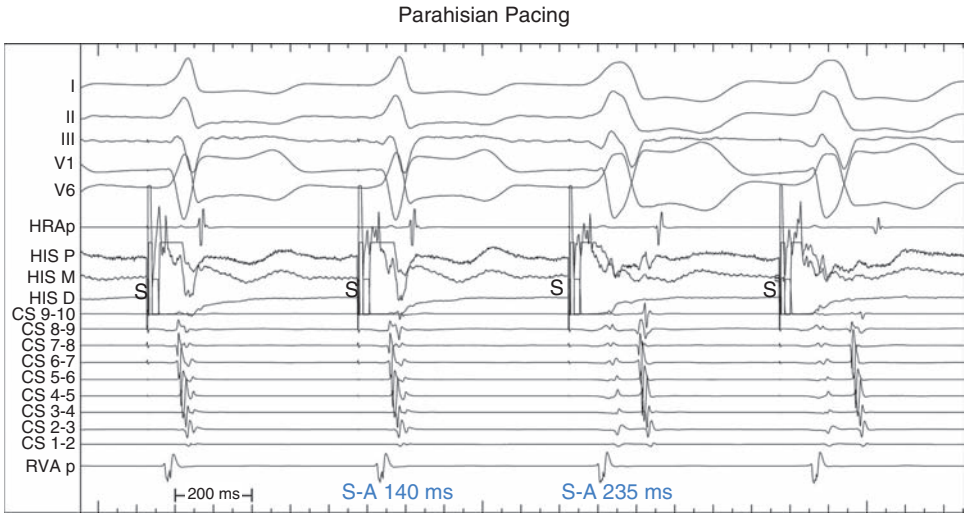


Fig. 3-17 is a nodal pattern (SA in two complexes on the left with a component of His capture shorter than SA with only ventricular capture in two complexes at right) and unfortunately sheds no light for us because any retrograde pathway operative during SVT has a long (rather than short) conduction time and is not evident here, because the retrograde AV nodal fast pathway conducts quite well.

Atrial Extrastimuli in SVT

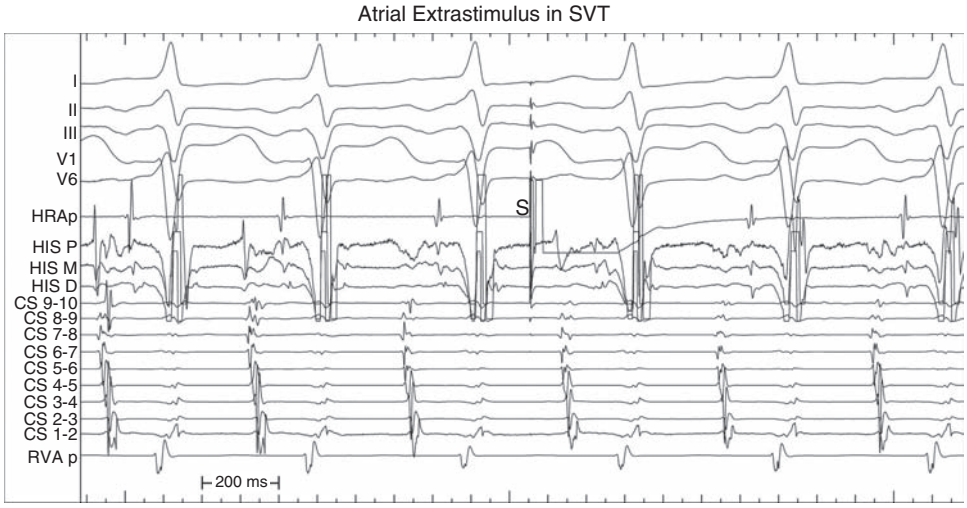

Figure 3-18

Fig. 3-18 is the most premature coupling interval obtainable during SVT (earlier ones met atrial refractoriness). The atrial recording in the His catheter as well as high right atrium are advanced but there is no effect on tachycardia. An AT would not be expected to behave thus.

Ablation Site

Figure 3-19

Having accumulated a substantial amount of data pointing to atypical AV nodal reentry as the tachycardia diagnosis, mapping for an ablation site is begun around the low atrial septum and coronary sinus os. The electrogram at the site shown in Fig. 3-19 begins slightly before all other atrial activations as well as the surface P wave (difficult to discern because of T wave).

Status

At this time, the patient has been diagnosed with atypical (anterograde fast-retrograde slow) AV nodal reentry. An ablation target site below coronary sinus (CS) ostium has been selected, but SVT is now incessant (despite pacing termination, it immediately resumes) and thus ablation cannot be performed during sinus rhythm. How best to proceed? We need to eliminate SVT and not endanger normal AV conduction. Table 3-1 illustrates the advantages and disadvantages of several possible strategies.

TABLE 3-1 Strategies for Ablation During Tachycardia

Ablation Strategy	Advantages	Disadvantages
During tachycardia	Can tell when ablation is successful	Sudden change in heart rate when SVT stops may displace catheter
During sinus rhythm	Can monitor AV conduction	Can't tell when ablation is successful
During ventricular pacing	None	Can't tell when ablation is successful Can't monitor AV conduction
During SVT/ventricular pacing	Can tell when ablation is successful	Can't monitor AV conduction
During SVT/atrial pacing	Can tell when ablation is successful Can monitor AV conduction	Hard to do

Atrial Entrainment During SVT

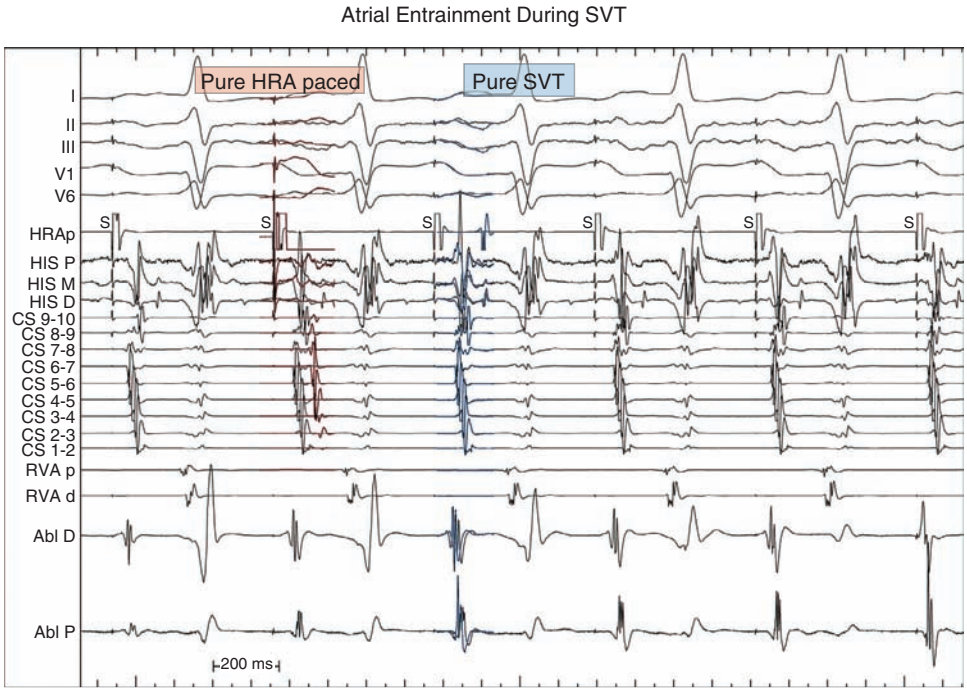

Figure 3-20

The patient had incessant SVT by this time (Fig. 3-20) in the procedure, and so ablation during sinus rhythm was not an option and ablation during SVT was required. If ablation is successful, SVT will terminate and with a sudden heart rate change, the ablation catheter may be displaced from the ablation site, leading to inadequate power delivery at the target. To prevent this, pacing the atrium at the SVT cycle length can help by maintaining the heart rate during successful ablation; the activation sequence will suddenly change when SVT is terminated but there is no sudden change in heart rate that could result in catheter

movement. Pacing has to be performed very carefully to prevent SVT termination by pacing itself. As shown in the figure, the complexes during SVT entrained by right atrial pacing are neither the same as pure atrial pacing (superimposed in *red*) nor SVT (superimposed in *blue*).

Ablation Begins

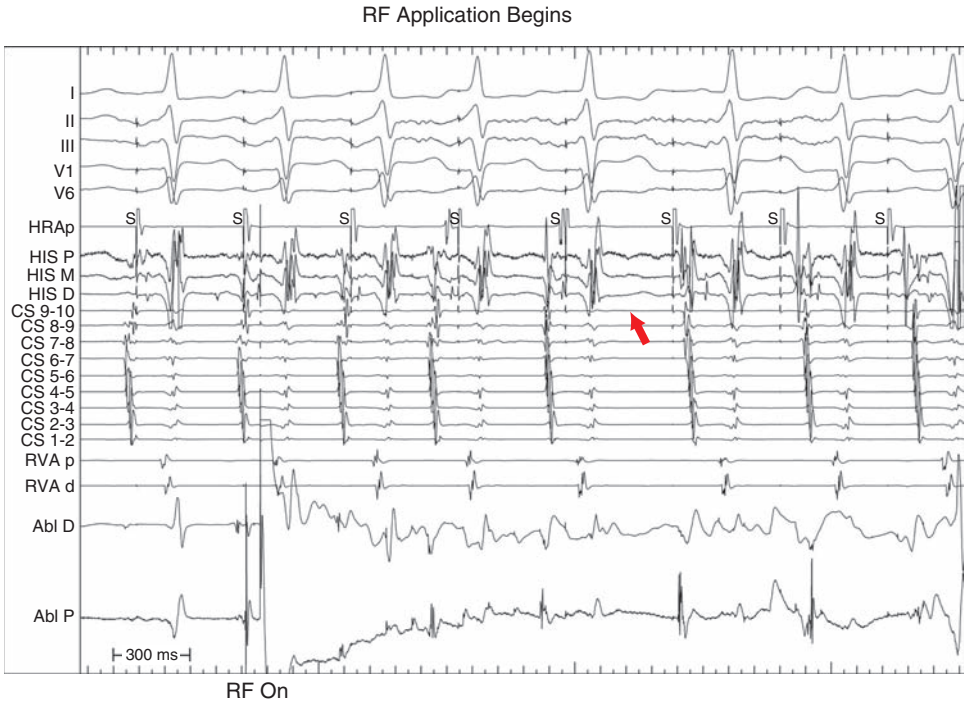

Figure 3-21

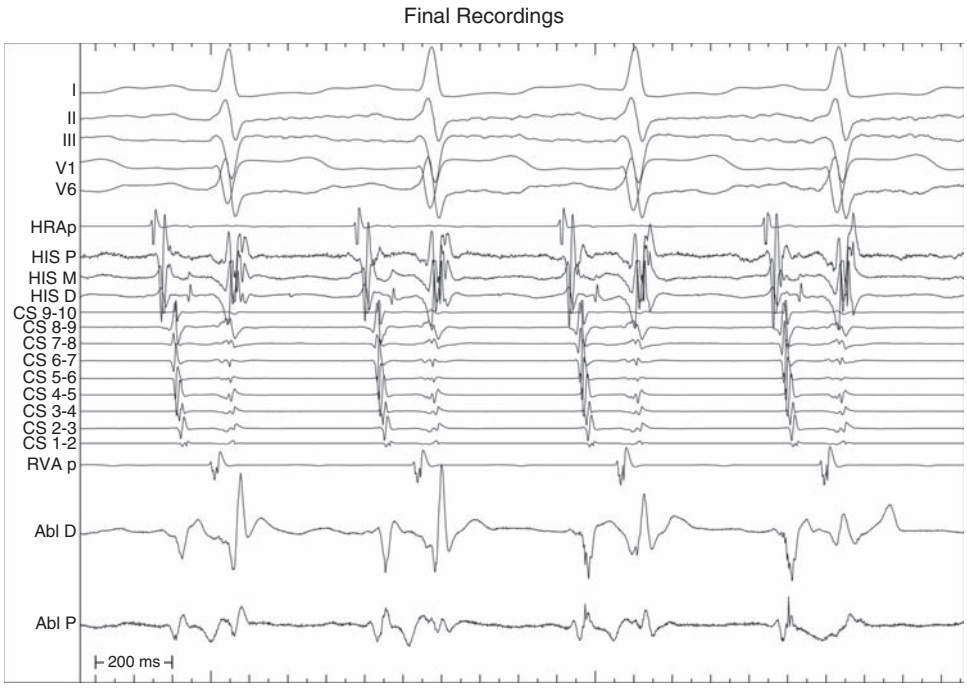
SVT terminates (Fig. 3-21, *arrow*) just over 1 second after onset of RF delivery, but the heart rate changes minimally; the ablation catheter position remains stable throughout the time of RF delivery.

Final Recordings

Figure 3-22



As shown in Fig. 3-22, SVT is no longer inducible, and AV conduction is unchanged (normal).

Summary

- Long R-P tachycardias can be challenging to diagnose, but using standard methods the right answer is usually clear:
  - Atrial tachycardia
  - Atypical (fast-slow) AV nodal reentry
  - Orthodromic AV reentry (slowly conducting bypass tract)
  - Rarely, junctional tachycardia with retrograde conduction
- Atypical (fast-slow) AV nodal reentry can occur at any age
- Ablation during incessant tachycardia has several options:
  - *Ablate during tachycardia:* can tell when successful but sudden change in HR with termination may displace ablation catheter
  - *Ablate during SR:* can't tell success but can monitor conduction
  - *Ablate during ventricular pacing:* can't see success during ablation or monitor AV conduction
  - *Ablate during SVT/ventricular pacing:* can tell when successful but AV conduction may suffer
  - *Ablate during SVT/atrial pacing:* can tell when successful as well as monitor AV conduction

Accelerated Junctional Rhythm

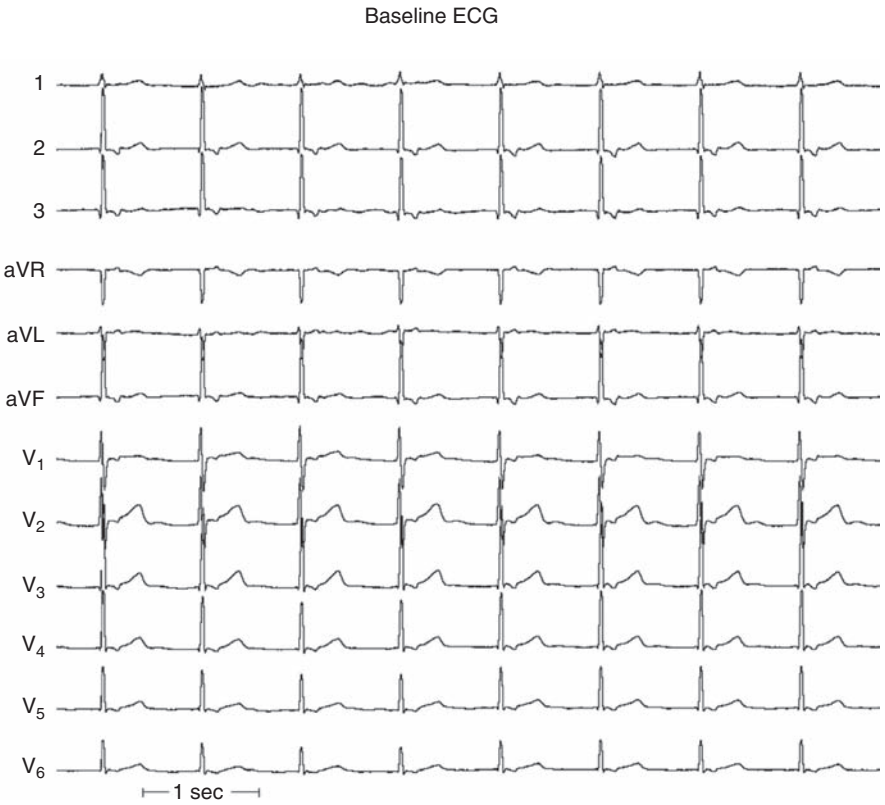
4

Case Presentation

A 29-year-old woman has a history of palpitations and dizziness since age 13. ECGs during episodes showed narrow QRS tachycardia at 190/min. She eventually underwent electrophysiology (EP) study 4 months ago, at which time typical atrioventricular (AV) nodal reentry was initiated and successful slow pathway ablation performed. She had recurrent symptoms within days that became nearly constant. Exam showed heart rate 75/min; large A waves in the jugular veins; soft S1; and was otherwise normal. ECG showed junctional rhythm at 75/min with retrograde P waves. An ambulatory monitor showed junctional rhythm 75 to 90/min most of the time; occasionally, with exertion, sinus tachycardia at 130/min overrode the otherwise constant junctional rhythm. Echocardiogram was otherwise normal. Her symptoms were refractory to beta blockade, propafenone, and flecainide and she was referred for repeat EP study and possible ablation.

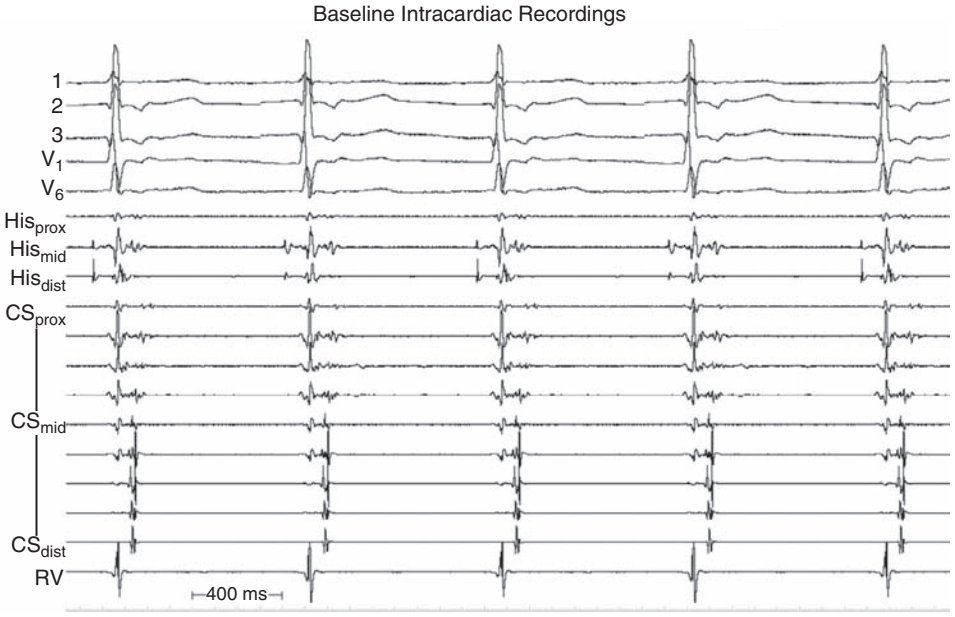
Baseline ECG and Intracardiac Recordings

Figure 4-1



Baseline ECG (Fig. 4-1) appears to show narrow complex junctional rhythm at 75/min with retrograde P waves. This was present nearly constantly and caused a functional pacemaker syndrome (nearly simultaneous atrial and ventricular contraction).

Figure 4-2



Intracardiac recordings during the baseline rhythm (Fig. 4-2) show a His potential before each QRS complex with a normal HV interval (43 ms). Atrial activation is midline and compatible with use of an AV nodal fast pathway. The differential diagnosis for this is automatic accelerated junctional rhythm, AV nodal reentry with a very slow anterograde pathway, or (least likely) atrial rhythm with very slow anterograde AV nodal conduction.

Atrial Extrastimuli in Rhythm

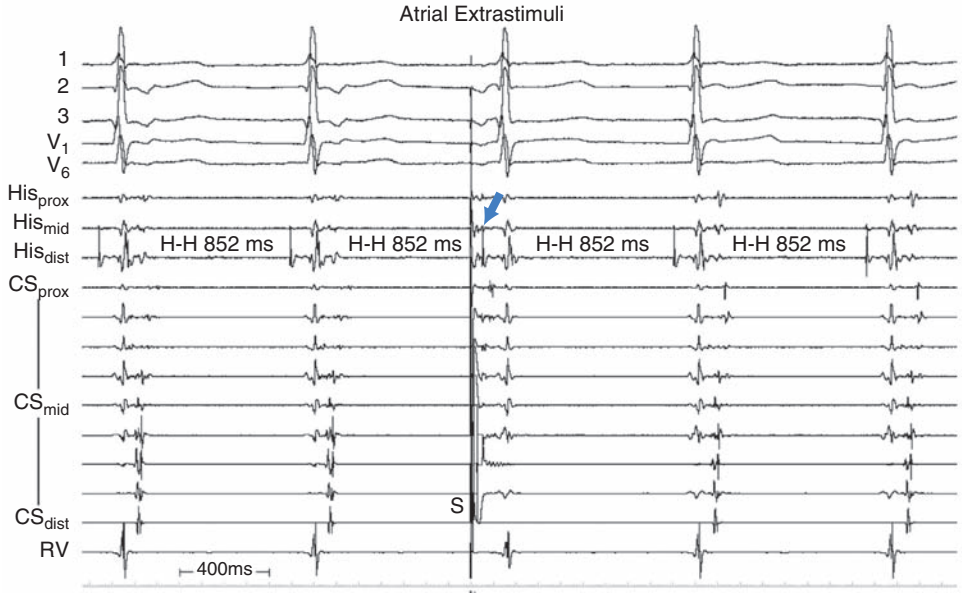


Figure 4-3

To investigate the nature of the rhythm, single atrial extrastimuli are delivered from the coronary sinus. Fig. 4-3 shows that a late-coupled extrastimulus (S), delivered when the His potential has already occurred on time *(arrow)*, captures and advances the timing of atrial activation but does not alter the timing of the next His potential (occurs on schedule at 852 ms). If the rhythm were AV nodal reentry or an atrial rhythm, the timing of the next His potential would have either been advanced or delayed (because in either case its inscription would be dependent on AV nodal conduction). Thus the rhythm is neither AV nodal reentry or atrial in origin.

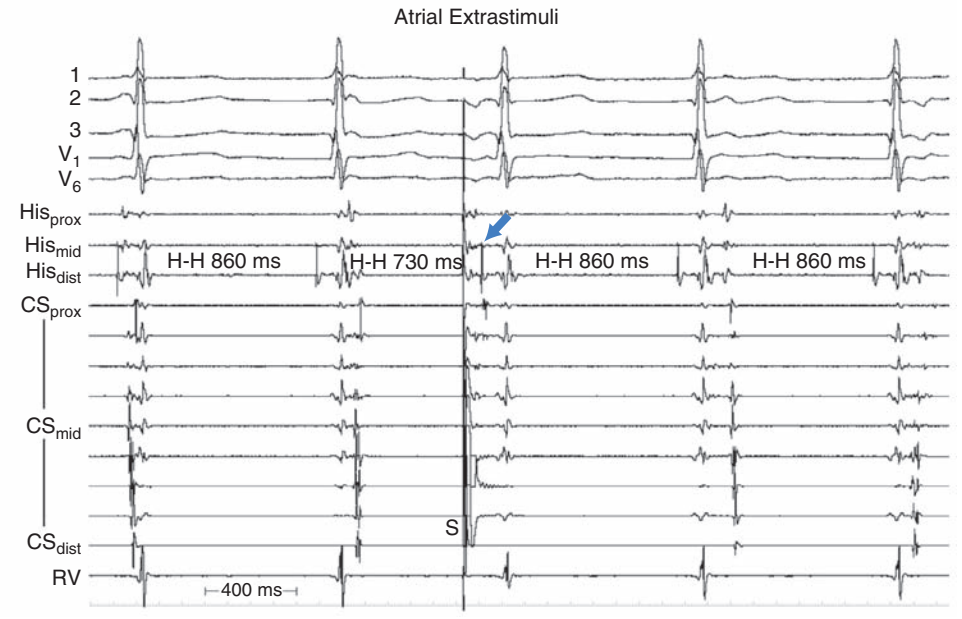

Figure 4-4

In Fig. 4-4, a more premature extrastimulus (S) not only captures and advances the timing of atrial activation, but also conducts over the fast AV nodal pathway to activate the His bundle *(arrow)*. This resets the timing of the rhythm and the next His potential occurs at the same discharge interval (860 ms now) and the rhythm continues on thereafter.

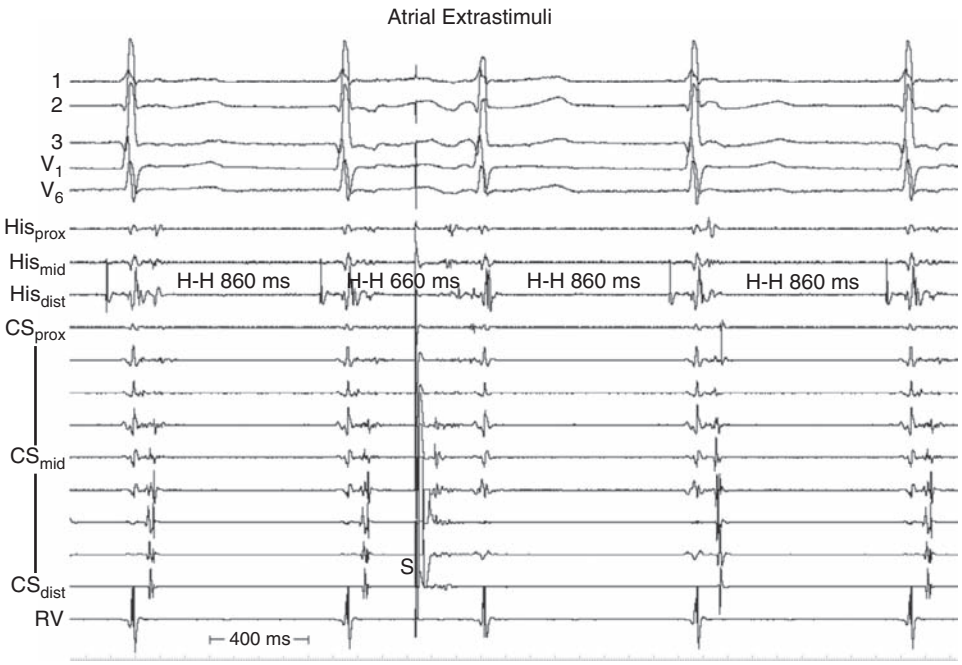

Figure 4-5

A still more premature extrastimulus (S, Fig. 4-5), the earliest one that captured, advances atrial and His activation even more than previously. The next His potential on resumption of the rhythm is at the same discharge interval (860 ms). This is all consistent with accelerated junctional rhythm.

Ventricular Extrastimuli in Rhythm

Where Is the Exact Source of the Abnormal Rhythm? [Fig. 4-6]

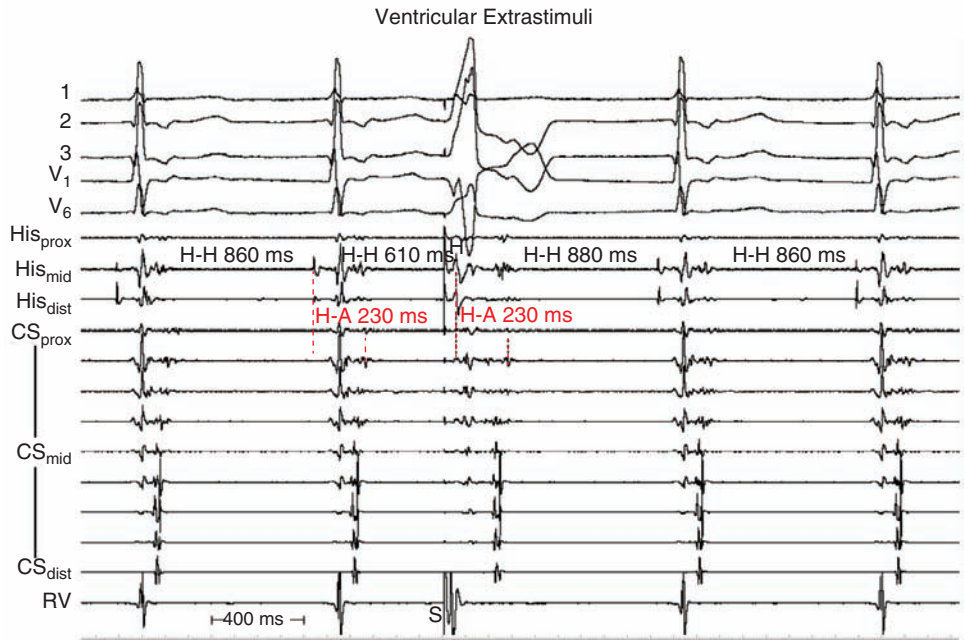

Figure 4-6

From where is the junctional rhythm arising? His propagation is anterograde, indicating somewhere proximal to the His recording site, but where? To investigate this, HA intervals can be analyzed (Fig. 4-6). Here, a ventricular extrastimulus during the baseline rhythm conducts retrogradely to the His (H); the resulting HA interval as shown is the same as during the baseline rhythm, indicating that the site of impulse formation is not far from the

His recording site: if the rhythm originated from a site significantly more proximal in the AV conduction axis, some time would be required to travel from the focus to the His recording site during the rhythm, and thus the "HA" measured would be shorter than the actual time from focus to atrium. Likewise, after ventricular stimulation, the "HA" would be longer than the actual time from the focus to the atrium. A site not far from the proximal His recording can now be sought with the mapping catheter. In this example also, the focus has been prematurely excited to the extent that it shows some overdrive suppression (HH interval after the extrastimulus 880 ms, slightly longer than the baseline interval).

Ablation Site

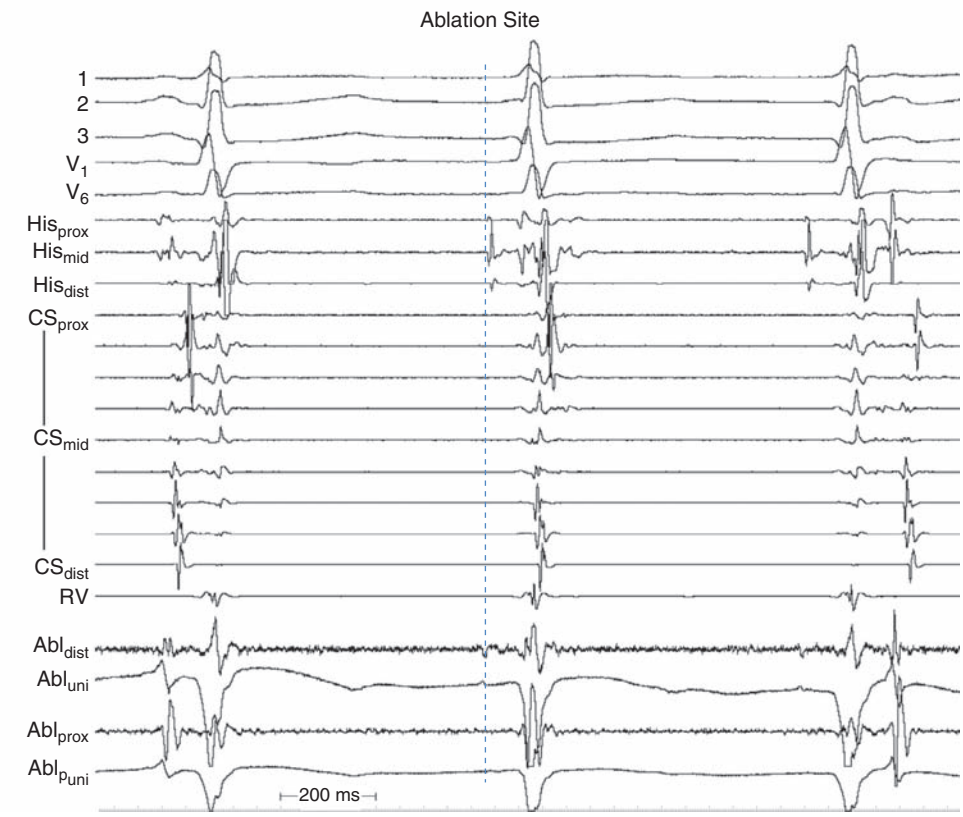

Figure 4-7

The desired ablation target should be the earliest possible His recording, often in the region of the compact AV node. In Fig. 4-7, a potential on the ablation catheter occurs about 10 ms before the earliest activation on the His catheter. At this time in the procedure, the sinus rate had accelerated somewhat accounting for the positive P waves in inferior leads.

RF Ablation Begins

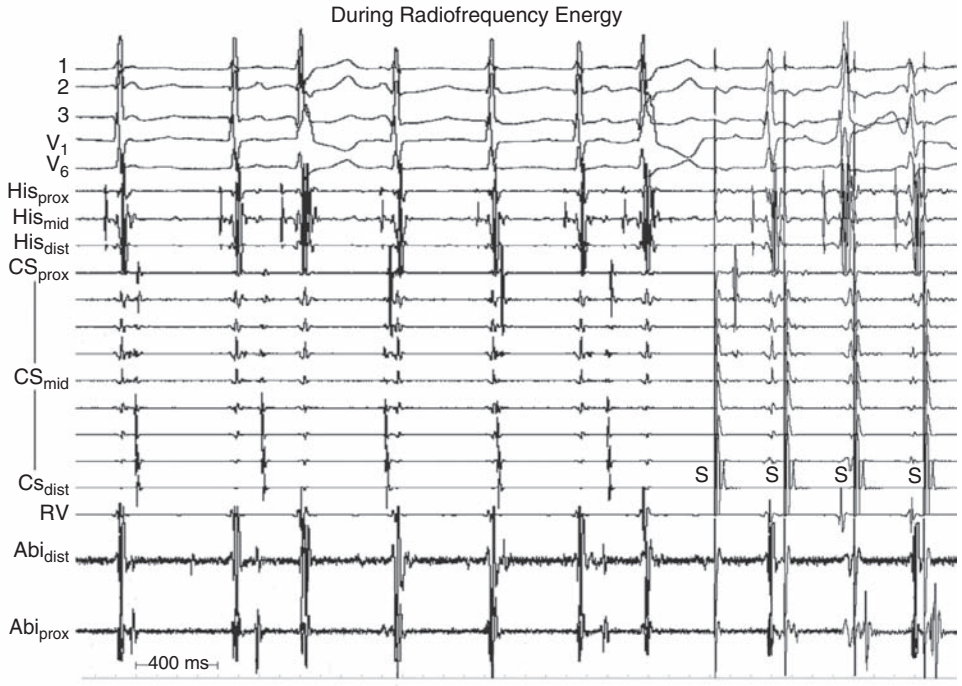

Figure 4-8

RF ablation at this site resulted in acceleration of the junctional discharge rate as well as retrograde conduction block (Fig. 4-8). As is often done during accelerated junctional rhythm with AV nodal reentry slow pathway ablation, atrial pacing (S, on *right* side of figure) is begun to ensure that anterograde AV conduction remains intact during the accelerated junctional rhythm. If the PR lengthens or conduction fails for even one cycle, RF energy delivery can immediately be stopped. Conduction remained intact with a mildly prolonged but stable PR interval throughout a 1 min RF application.

Final Recordings

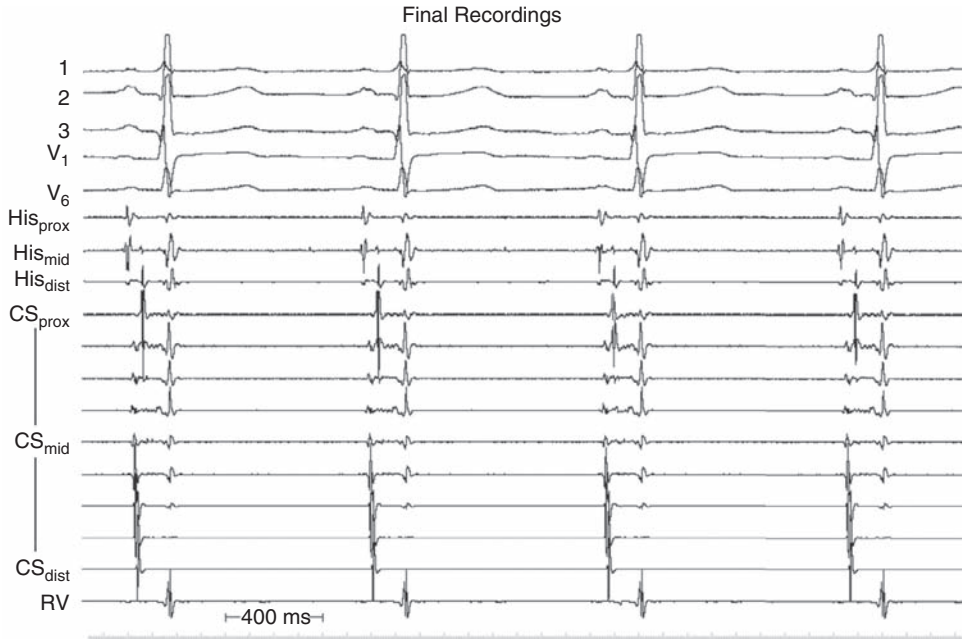

Figure 4-9

As seen in Fig. 4-9, after ablation, sinus rhythm with intact conduction and normal intervals is present, CL 950 to 1000 ms. With isoproterenol, the sinus rate accelerated and AV conduction remained consistent. No accelerated junctional rhythm was observed.

Fluoroscopy of Catheter Positions

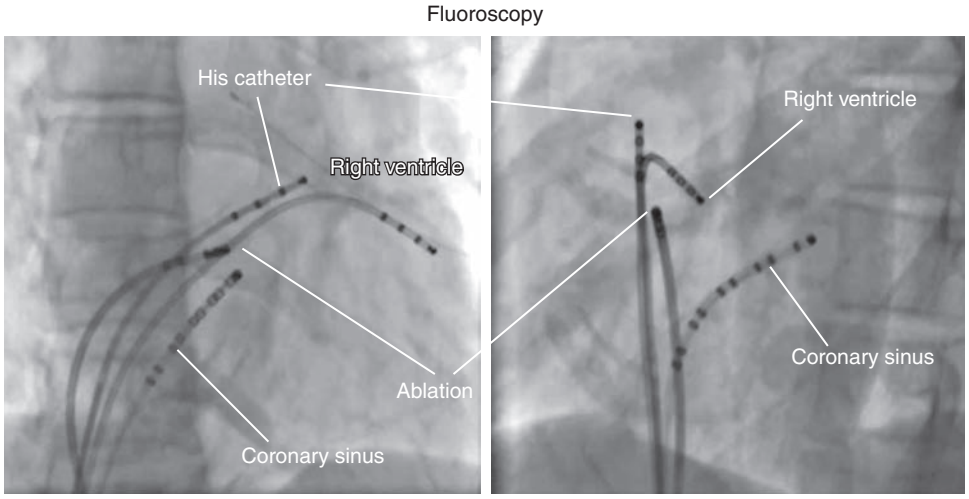

Figure 4-10

Fig. 4-10 displays fluoroscopic images of the ablation catheter at the site of successful ablation, where the compact AV node would be expected to reside.

Summary

- Accelerated junctional rhythm is rare but can be very symptomatic, resulting in functional "pacemaker syndrome"
- It must be distinguished from AV nodal reentry and atrial rhythm with long PR interval
- The site of impulse formation is in the conduction system and must be targeted very carefully to avoid heart block:
  - Site of earliest His potential
  - Often occurs in slow pathway region
  - Further acceleration of junctional rhythm occurs with RF application—a sensitive, but not specific, indicator
  - Atrial pacing to monitor anterograde conduction can help avoid heart block

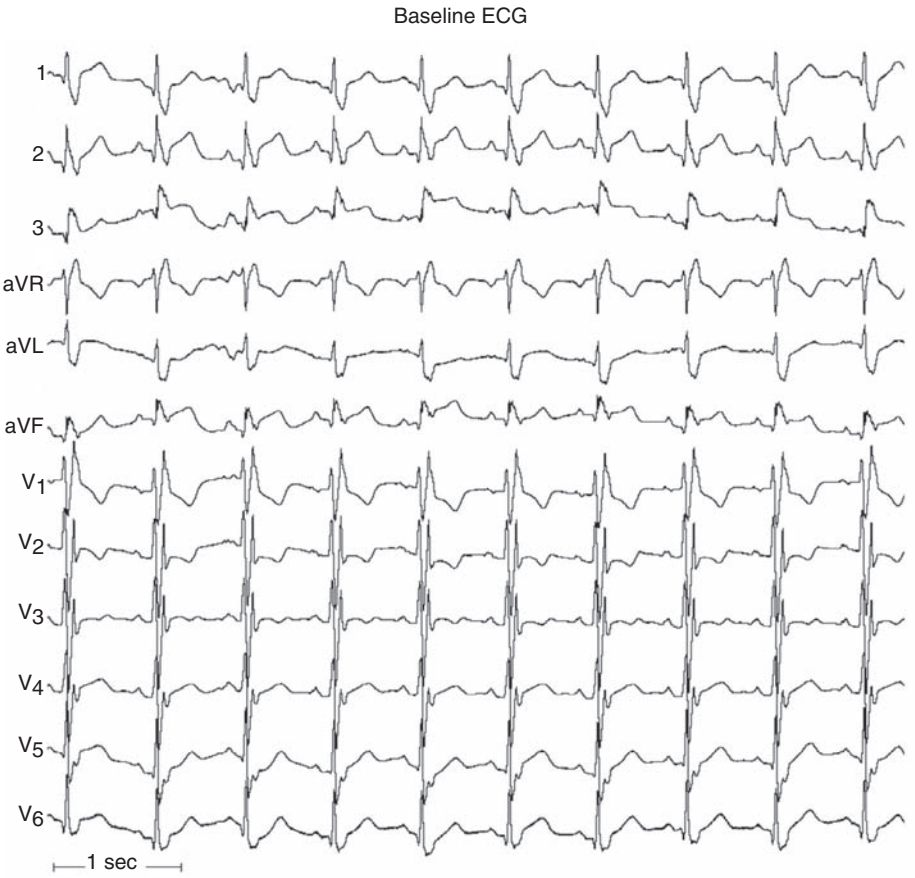
5 Left Lateral Concealed Pathway Supraventricular Tachycardia

Case Presentation

A 21-year-old man with a lifelong history of palpitations and supraventricular tachycardia (SVT) was referred for catheter ablation. He began having episodes as a child, only occasionally at first but more frequently as a teenager. He was diagnosed with SVT at age 10; episodes were characterized as sudden onset with palpitations, lightheadedness, and dyspnea. Medical therapy with beta blockers failed to control episodes and he underwent an attempt at catheter ablation. A concealed left lateral bypass tract was diagnosed but ablation (retrograde aortic approach) failed despite multiple radiofrequency (RF) applications, and the procedure was stopped because of prolonged fluoroscopy time. Three years later another ablation attempt likewise failed (retrograde aortic approach).

He also had a history of cyanosis and a heart murmur at birth and was diagnosed with tetralogy of Fallot. A Blalock-Taussig shunt was constructed at age 2 weeks and he underwent complete intracardiac repair at age 15 months (shunt taken down at that time). He has had progressive pulmonic regurgitation in the ensuing years but a normal physical capacity.

Baseline ECG in Sinus Rhythm: SVT ECG



What Questions Should You Ask About History and Prior Procedures?

Figure 5-1

In Fig. 5-1, right bundle branch block (RBBB) is evident during sinus rhythm, consistent with right ventriculotomy for tetralogy repair.

Figure 5-2

In Fig. 5-2, SVT has the same QRS configuration and no discernible P waves. This could thus be atrioventricular (AV) nodal reentry or atrial tachycardia with P waves hidden in the QRS complex. Orthodromic SVT using a left-sided bypass tract could also appear the same way (P wave inside the widened, RBBB QRS complex). However, the P wave should be visible after the RBBB QRS in orthodromic SVT using a right lateral pathway.

Baseline Intracardiac Recordings in Sinus Rhythm

Figure 5-3

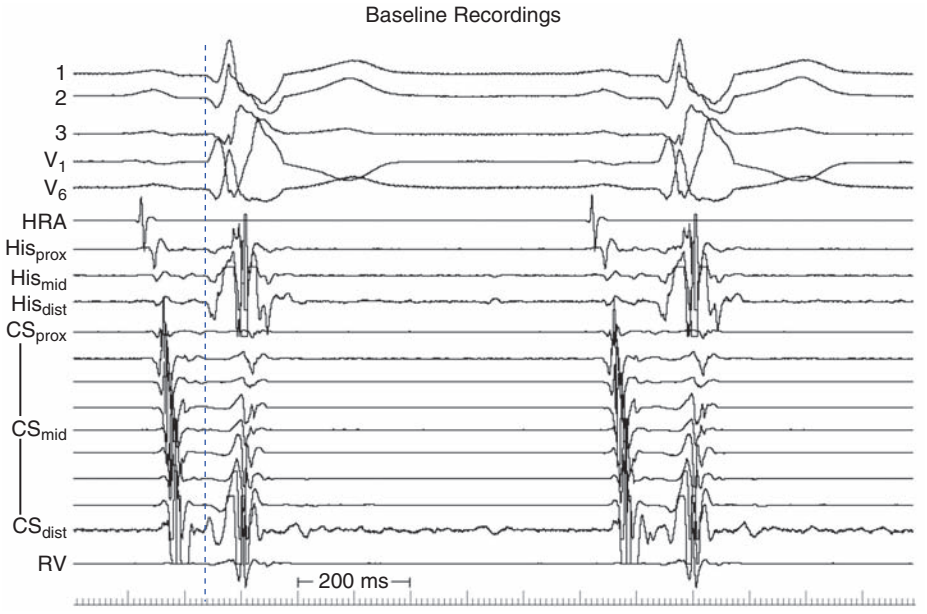


Fig. 5-3 shows no evidence of left lateral (or other location) preexcitation on intracardiac recordings in sinus rhythm; *dashed line* denotes QRS onset.

Ventricular Pacing at Progressively Rapid Rates During Sinus Rhythm

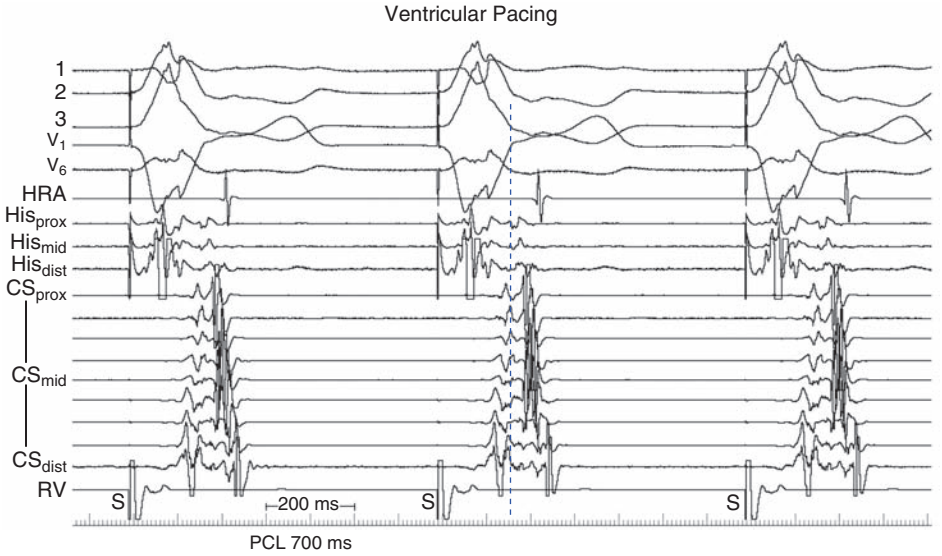

Figure 5-4

With ventricular pacing at 700 ms (Fig. 5-4), it is evident that retrograde conduction is present; the His bundle atrial activation appears earliest *(dashed blue line)*, but the distal coronary sinus (CS) recordings are difficult to interpret (likely because of prior ablation in this area).

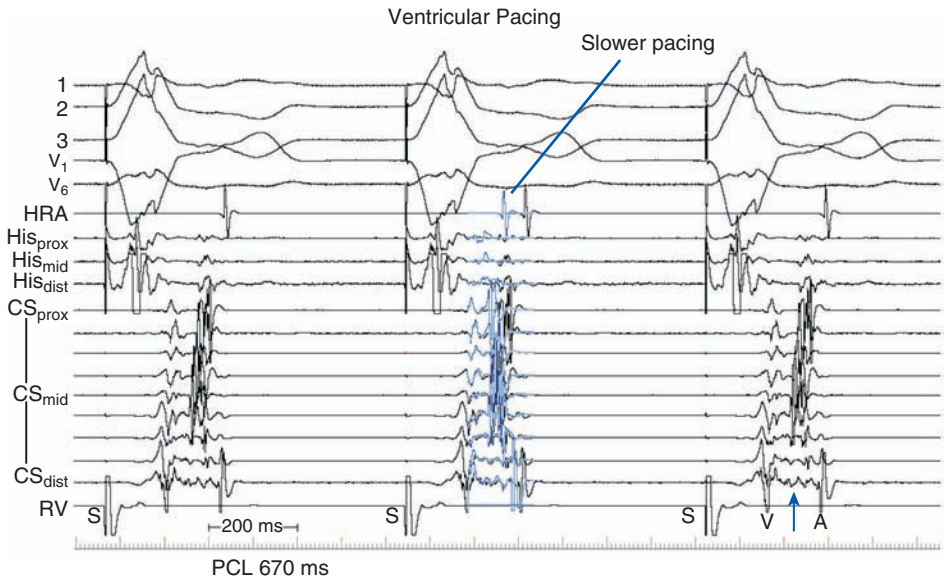

Figure 5-5

With slightly more rapid pacing (670 ms; Fig. 5-5), there is a change in the atrial activation sequence (slower pacing sequence shown superimposed in *blue*). The most obvious change is in the high right atrium (HRA) and His atrial recordings, which are delayed with more rapid pacing, signifying loss of AV nodal conduction, whereas most of the CS recordings are largely unchanged (consistent with conduction over a left lateral bypass tract). A series of complex signals *(blue arrow)* is present in between what is clearly ventricular (V) and what is clearly atrial activation (A); because of prior ablation, these could represent slow conduction in either ventricular or atrial tissue, or recordings from the bypass tract itself.

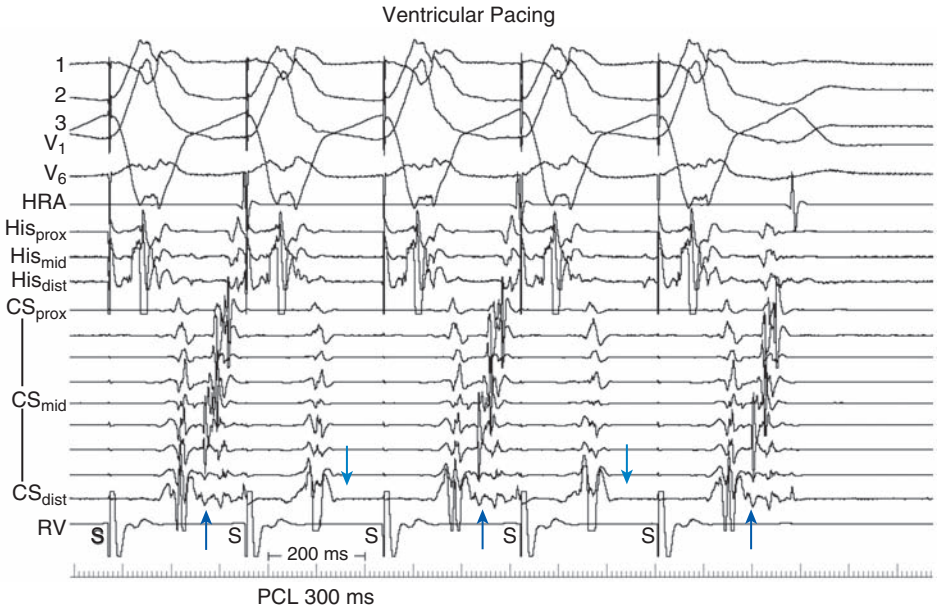

Figure 5-6

To investigate the nature of these signals, some way must be devised to clearly separate atrial from ventricular activation. In Fig. 5-6, rapid ventricular pacing at 300 ms results in 2:1 retrograde conduction. On cycles without atrial recordings *(light blue downward arrows)*, the signals in question are absent *(upward blue arrows)*—signifying that they are not ventricular in origin, because there is a ventricular electrogram on each of the paced complexes.

Ventricular Pacing Initiates SVT

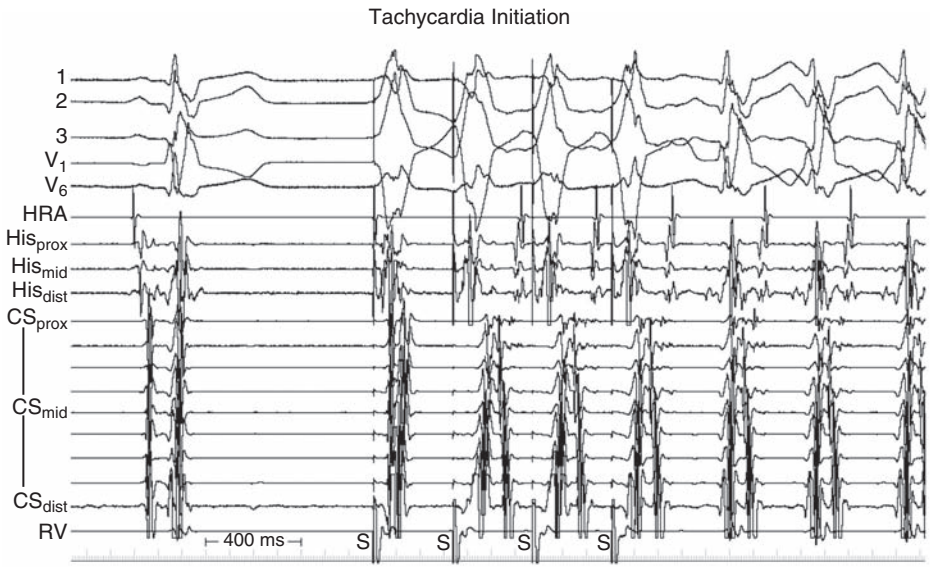

Figure 5-7

Fig. 5-7 shows a burst of rapid ventricular pacing initiating an episode of SVT.

Ventricular Extrastimuli in SVT

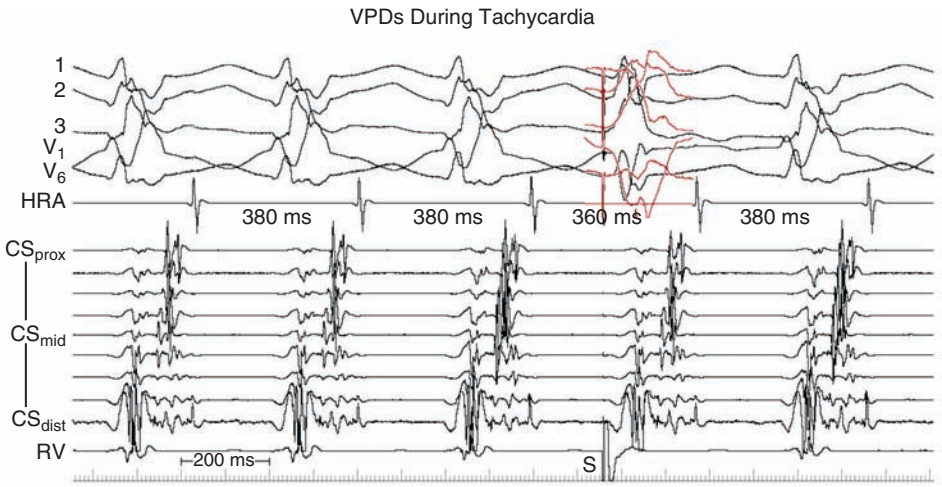

Figure 5-8

In Fig. 5-8, a single extrastimulus (S) is delivered from the right ventricle during SVT. A-A intervals in the HRA recordings are as indicated. The A-A interval surrounding the premature complex is shorter than any other during tachycardia, suggesting bypass tract conduction; however, this is only valid if the His bundle is refractory at the time the extrastimulus is delivered. A complex of pure right ventricular pacing is superimposed in red atop the complex associated with the extrastimulus. It is clear that simulation during tachycardia yields a QRS complex different from both pure pacing and SVT, and is thus a fusion complex between these two. Because the fusion derives from some element of a conducted QRS complex, the His bundle must have already been activated on that complex, and thus by definition the extrastimulus is His-refractory. Thus the fact that the A-A interval surrounding this complex is shorter than all others can be interpreted to indicate that a bypass tract is present, but not necessarily participating in tachycardia.

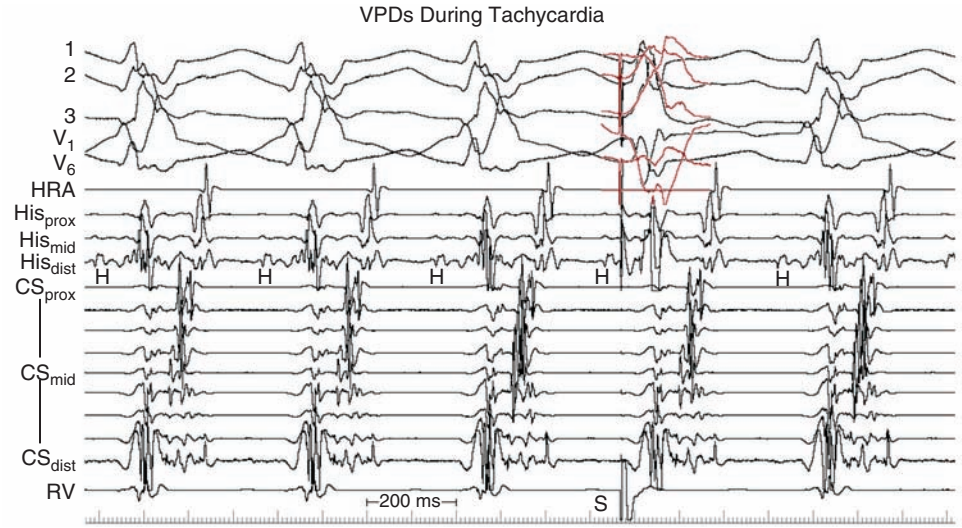

Figure 5-9

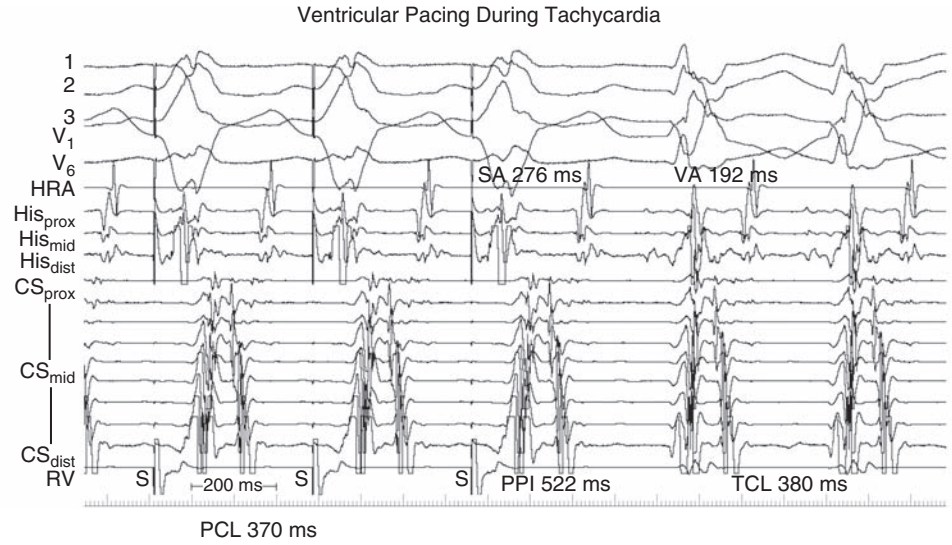
The same event is shown in Fig. 5-9, this time including the His recordings where it can be seen that the His bundle (H) had indeed already been activated on the complex in question and was thus refractory.

Ventricular Overdrive Pacing in SVT

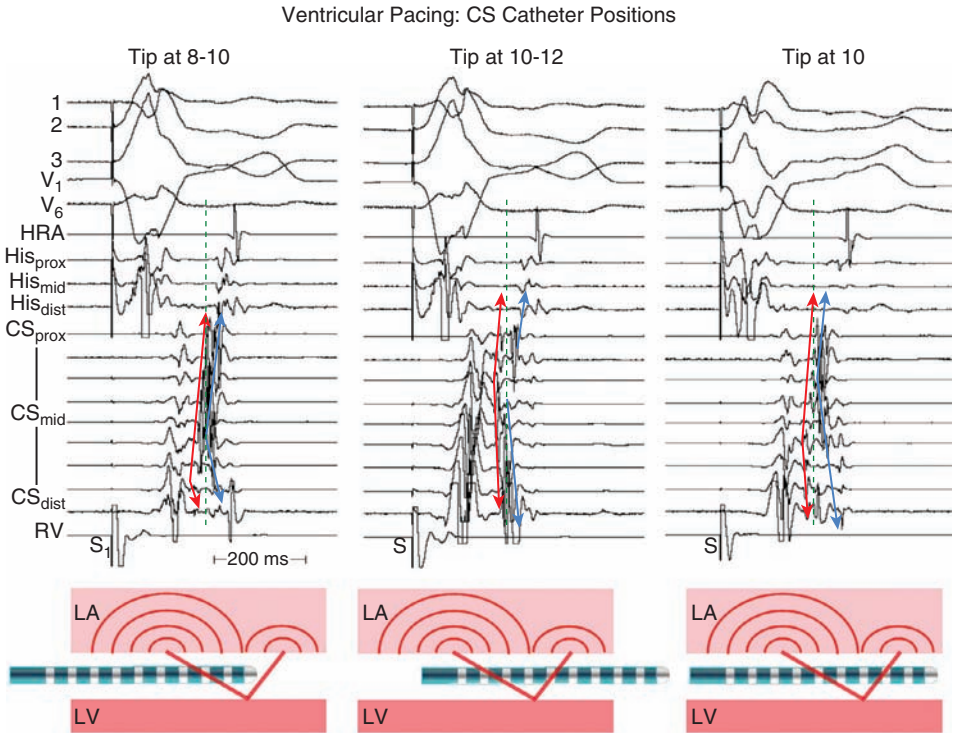
Figure 5-10



The results of ventricular overdrive pacing during SVT are shown in Fig. 5-10; the stimulus-atrial minus ventricular-atrial (SA-VA) difference (84 ms) is just less than 85 ms and suggests orthodromic SVT, whereas the post-pacing interval–tachycardia cycle length (PPI-TCL) difference (158 ms) is more suggestive of AV nodal reentry. Some of the disparity can be accounted for by the longer AH interval after the last paced complex, but the conflicting numbers is one reason that these intervals should be interpreted with caution in situations in which a far left-sided bypass tract is involved. Note also that the CS activations have changed—the catheter has been advanced somewhat (more distally in the CS). Finally, the SA interval during right ventricular pacing—simulating left bundle branch block (LBBB)—is much longer than the VA during SVT, strongly suggesting participation of a left free wall bypass tract during tachycardia.

Ventricular Pacing with Different Coronary Sinus Catheter Positions

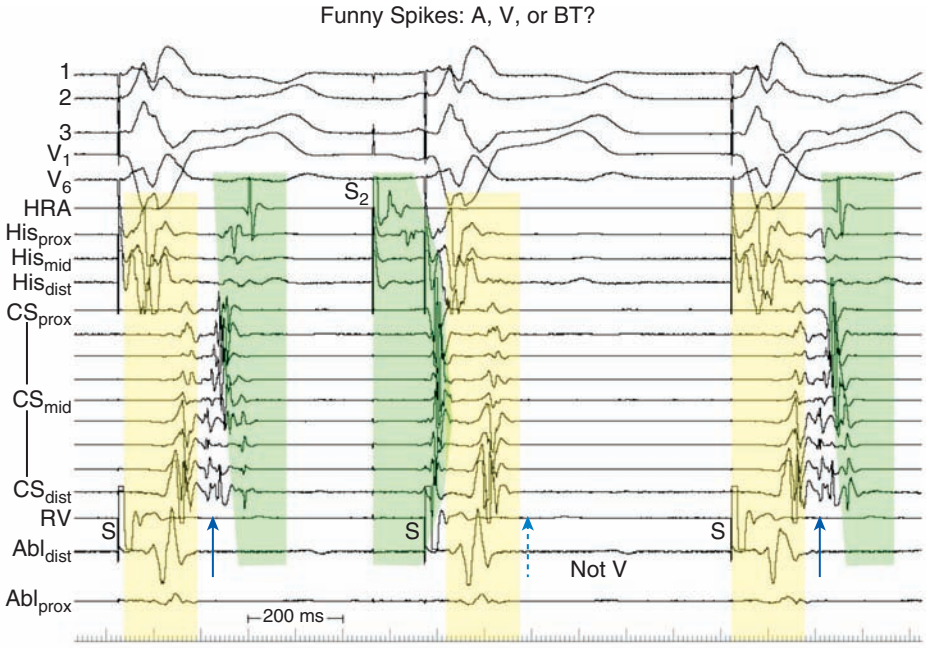
Figure 5-11



It is sometimes useful to "bracket" the site of earliest atrial activation in CS recordings. In Fig. 5-11A, recordings are shown with the catheter tip at site "8-10" (directly lateral on the mitral annulus), site "10-12" (anterolateral mitral annulus), and site "10" (intermediate between these two). A *dashed green line*, placed at the same interval before the HRA recordings in each panel, serves as a reference for comparison of activation sequences (Fig. 5-11B). Two activation sequences are evident within the coronary sinus recordings, indicated by *red arrows* and *blue arrows* (Fig. 5-11C). Whether these represent propagation over a bypass tract or partially insulated strands of atrial muscle within scar from prior ablation is not clear. One possible resolution to the different propagation patterns is shown in the diagram at bottom, where a multipolar electrode catheter is moved along the mitral annulus between the left atrium (LA) and left ventricle (LV). It is possible that there are two atrial insertions of the bypass tract, as indicated.

Nature of "Funny Spikes" Explored

Atrial Extrastimuli During Fixed-Rate Ventricular Pacing



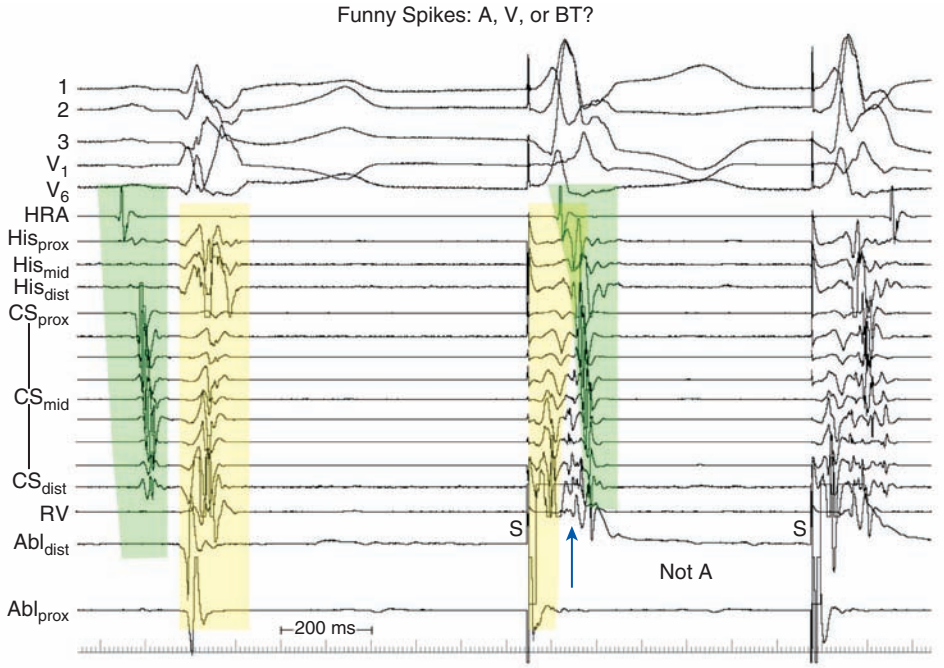
Are the Funny Spikes A, V, or BT? [Fig. 5-12]

Figure 5-12

In Fig. 5-12, to further investigate the nature of the peculiar signals (*blue)* between what is thought to clearly ventricular *(shaded yellow)* and clearly atrial *(shaded green)*, an atrial extrastimulus (S2) is introduced during fixed-rate ventricular pacing (S). This draws the atrial electrograms earlier, whereas the ventricular electrogram is unaffected. Because the complex potentials are no longer seen, they cannot be part of the ventricular recording.

Onset of Ventricular Pacing at Time of Sinus Complex

Figure 5-13



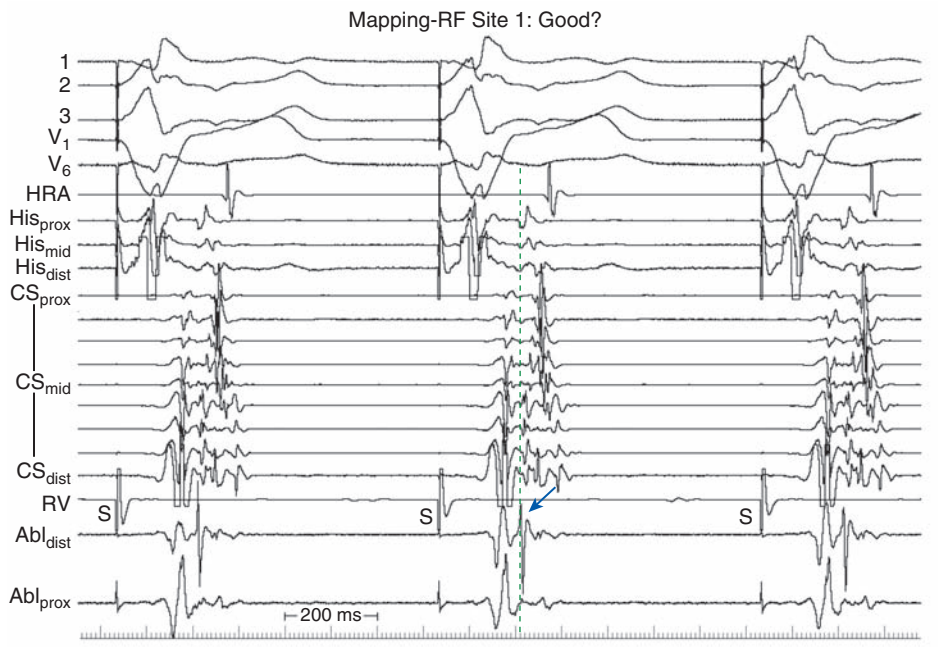
Similarly, a ventricular stimulus introduced during atrial pacing (or, as in Fig. 5-13, sinus rhythm) that causes the potentials in question to appear while the atrial recording is unchanged indicates that the questionable potentials are also not atrial in origin. Because they are neither atrial nor ventricular, they must be bypass tract recordings.

Mapping and Ablation Sites and Results

First Ablation Site

Is This Mapping Site a Good Site to Deliver RF Energy? [Fig. 5-14]

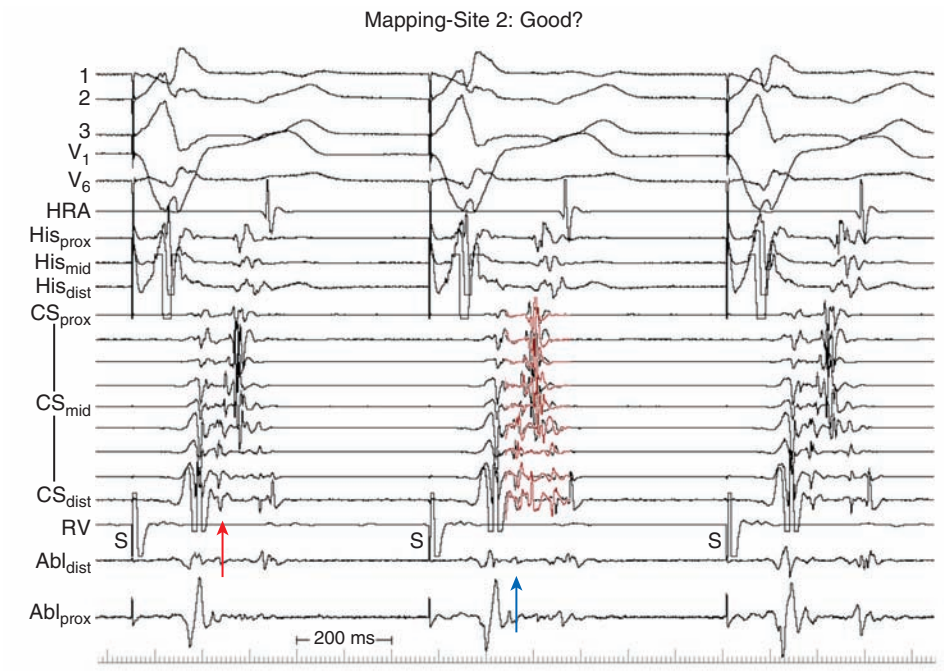
Figure 5-14



Now that the nature of the potentials in the CS recordings is clear, mapping can begin, targeting the bypass tract potentials as the most vulnerable site. Notice in Fig. 5-14, after transseptal catheterization, the ablation catheter records a sharp potential *(arrow)* that

precedes all others in the CS *(dotted green line)*. With a large, stable electrogram, this looks like a good site to deliver RF energy.

Effect of First Ablation, Second Mapping Site



Is This Mapping Site a Good Site to Deliver RF Energy? [Fig. 5-15]

Figure 5-15

After ablation at the first site, retrograde conduction remains; however, the atrial activation sequence has changed (prior sequence superimposed in red on Fig. 5-15). The early bypass tract potentials *(red arrow)* persist, but atrial electrograms in the more distal CS recordings have been delayed. This could be because of ablation of one of two atrial insertions of the pathway, or of a branch of the pathway itself. The mapping site is not particularly attractive because of the small, far-field appearance of the bypass tract potential recording *(blue arrow)*.

Mapping Site No. 4 and Ablation

Is This Mapping Site a Good Site to Deliver RF Energy? [Fig. 5-16]

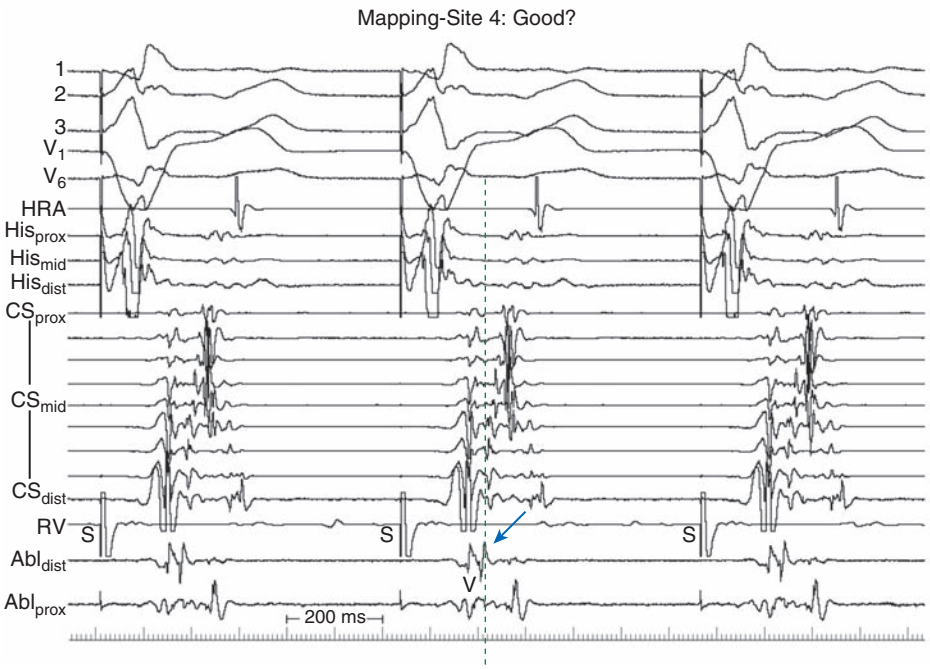


Figure 5-16

Other nearby sites were sampled, this one showing sharp ventricular (V) and bypass tract (*blue arrow*, Fig. 5-16) recordings during ventricular pacing. The *dashed green line* indicates timing of bypass tract potentials recorded in CS electrodes.

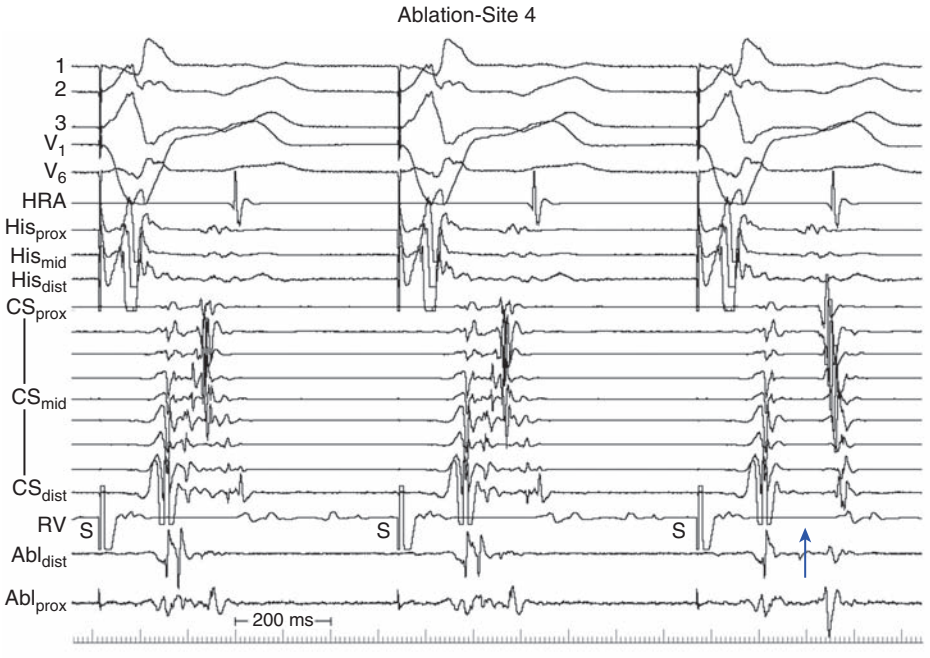

Figure 5-17

During RF energy delivery at this site (Fig. 5-17), retrograde conduction over the bypass tract suddenly fails *(arrow)*, instead now proceeding over the AV node.

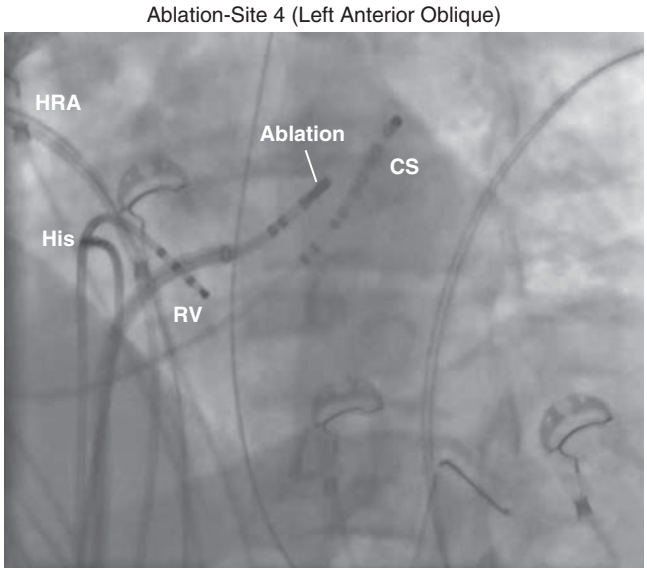

Figure 5-18

A left anterior oblique fluoroscopic image of the ablation site is displayed in Fig. 5-18.

Ventricular Pacing Postablation (AV Nodal Conduction Only)

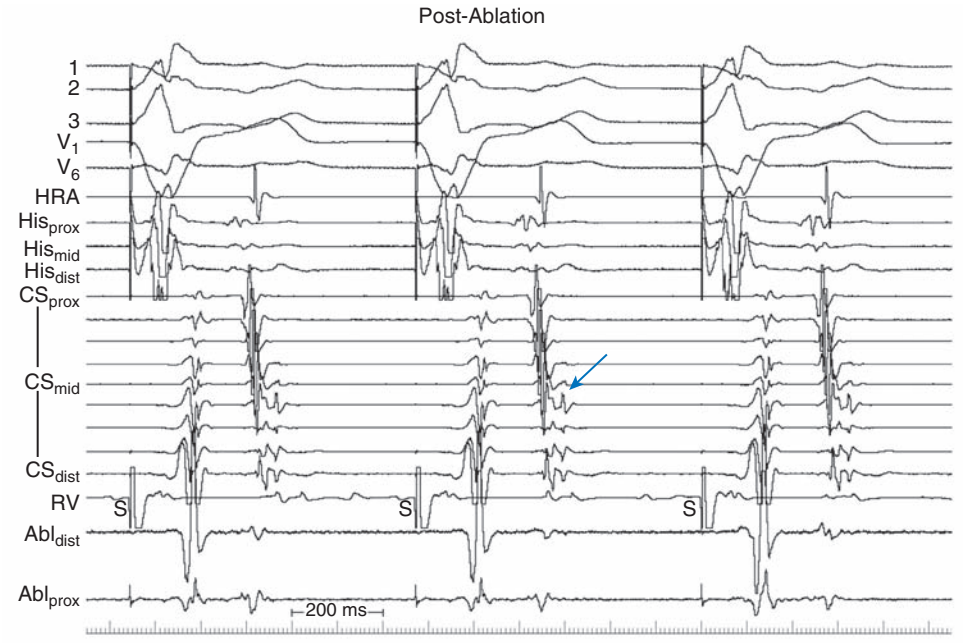

Figure 5-19

After ablation, ventricular pacing in Fig. 5-19 shows retrograde conduction with a midline activation sequence. In addition, small potentials *(arrow)* are now seen after the atrial electrogram in the middle and distal CS, possibly representing activation of the bypass tract after (rather than before) atrial activation. Retrograde conduction over the pathway did not recur during a 45-min waiting period or after isoproterenol provocation. The patient has not had recurrent tachycardia.

Summary

- AV bypass tracts typically cross the AV groove at an angle, with the ventricular insertion more proximal along the coronary sinus than the atrial insertion
- Prior ablation disrupts atrial electrograms, sometimes making interpretation of electrograms difficult
- Searching for and proving the identity of a bypass tract potential may be preferable to looking for earliest atrial activation, especially after prior ablation
- In general, the retrograde and transseptal approaches yield equivalent outcomes, but in any given case, one might be better suited to success than the other

Antidromic Supraventricular Tachycardia

6

Case Presentation

A 52-year-old man developed wide-complex tachycardia (WCT) after coronary artery surgery. He had a history of refractory hypertension and complained of palpitations and chest discomfort. Evaluation ultimately showed an anomalous left coronary artery from the right sinus of Valsalva, coursing between great vessels. He underwent open surgical reconstruction of the left main coronary artery. He reportedly had both severe bradycardia and tachycardia (possibly ventricular fibrillation) coming off the heart-lung machine. He was given amiodarone, and a dual-chamber pacemaker. He had an episode of wide QRS complex tachycardia 5 days postoperatively and was asymptomatic with this; pacemaker interrogation showed a 1:1 A:V relationship in tachycardia. He was treated with metoprolol but continued to have palpitations and tachycardia episodes on pacemaker interrogation. He was referred for electrophsyiology study.

ECG in Sinus Rhythm

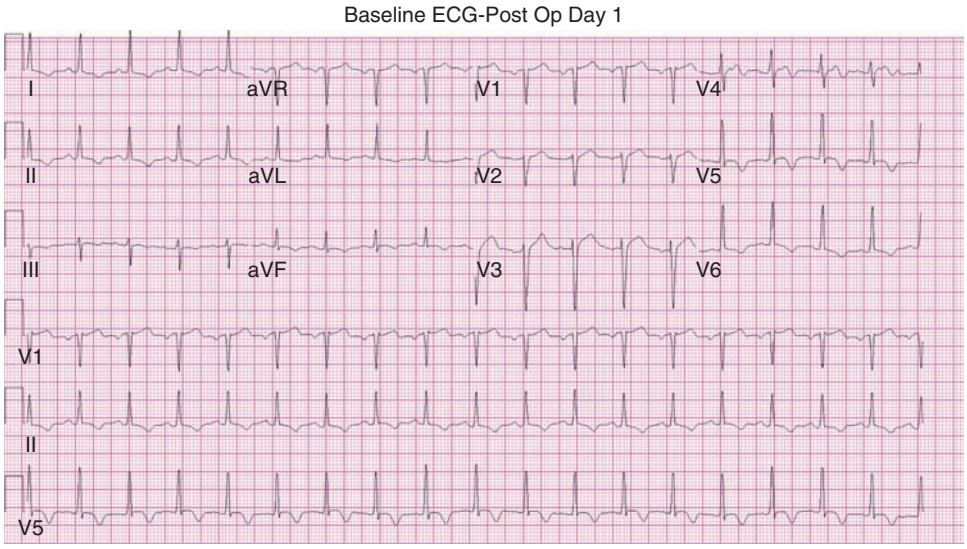

Figure 6-1

The early postoperative sinus rhythm ECG (Fig. 6-1) is relatively normal; there are no normal septal q waves, probably because of longstanding hypertension. Nonspecific ST and T-wave abnormalities may be related to the postoperative state. There is certainly no infarct pattern.

Wide-QRS Tachycardia ECG

Figure 6-2

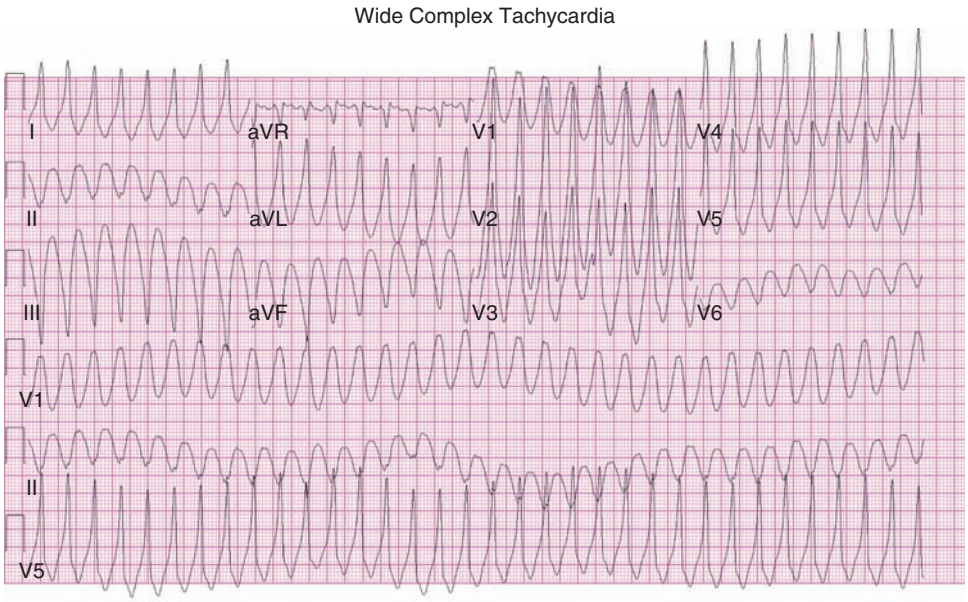

Fig. 6-2 displays the WCT recorded on day 5 postoperatively. It has a right bundle branch block (RBBB), left superior axis morphology, and no clearly discernible P waves. Q waves are evident in the inferior leads as well as V6 (slightly suspect as to its location because of the great disparity between V5 [all positive] and V6 [all negative]; this may be because of postoperative bandaging). The differential diagnosis of this WCT consists of broad categories, including supraventricular tachycardia (SVT) with aberration, a preexcited tachycardia, or ventricular tachycardia. The pattern is not particularly consistent with aberration of any form, and he does not have a reason to have either ventricular tachycardia (no prior scar) or preexcited tachycardia (no delta waves during sinus rhythm). He does have a pacemaker, which can pace the ventricle rapidly in response to atrial flutter or fibrillation, and could account for a wide-QRS tachycardia; however, the pacing lead is in the right ventricle and should yield a left bundle branch block pattern (also, no pacemaker stimulus artifacts are evident).

At this time, additional history from the patient revealed that he had Wolff-Parkinson-White syndrome and had undergone ablation about 12 years earlier that was thought to have been successful. He had nearly forgotten this in all the events surrounding his bypass surgery.

Intracardiac Recordings and Atrial Pacing

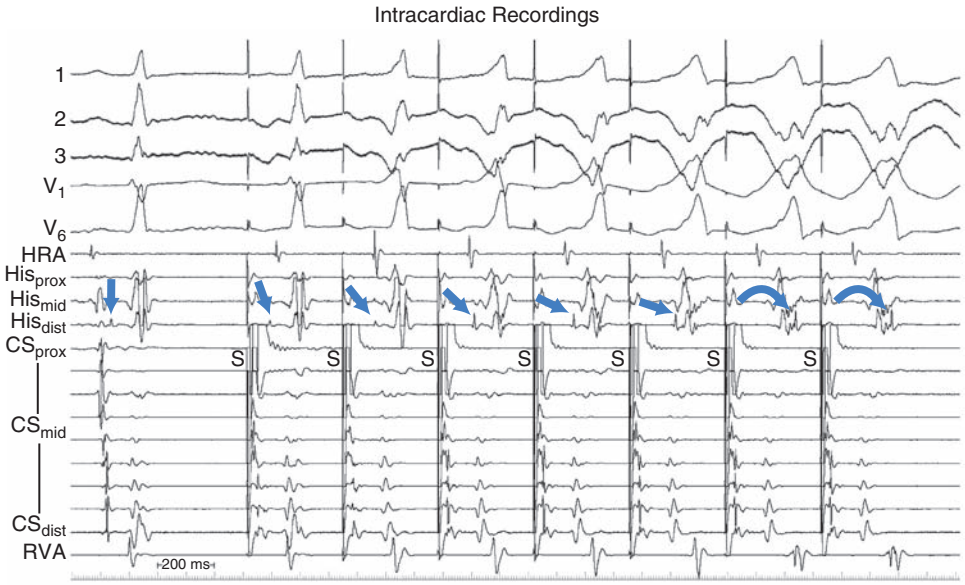

Figure 6-3

At the time of electrophysiologic study 2 months after surgery, catheters were placed in standard intracardiac locations as shown in Fig. 6-3. There is no strong evidence of preexcitation on the surface or intracardiac recordings during the sinus rhythm complex shown at left (*blue arrows* indicate His potential with normal AH and HV intervals on this complex). However, with rapid atrial pacing, the QRS complex shows progressive widening until it assumes a configuration similar to that of the WCT. In addition, the interval from stimulus to the His potential *(blue arrow)* shows progressive delay, with the His potential occurring at or after the QRS onset following the third to last stimulus. Furthermore, the His potential actually becomes retrograde, occurring toward the end of the QRS complex after the last two stimuli *(curved arrows)*. This behavior (progressive widening of the QRS complex with His potential occurring after QRS onset) is seen with ventricular tachycardia or preexcitation. Here, it seems most consistent with preexcitation.

WCT Initiation (Atrial and Ventricular Pacing)

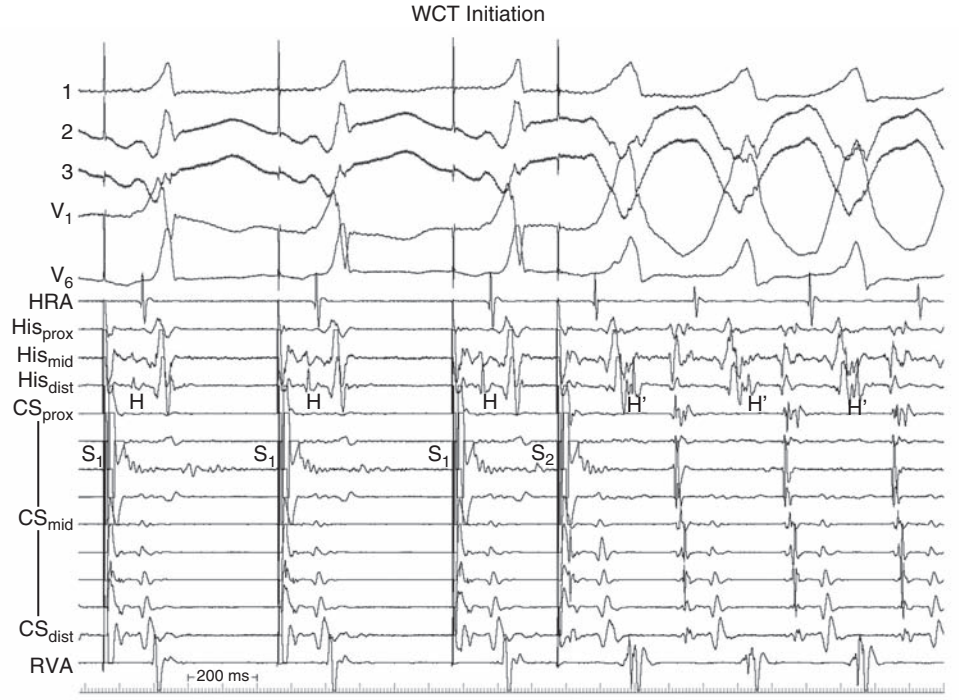

Figure 6-4

With an atrial drivetrain from the proximal coronary sinus, a preexcited QRS complex is evident in Fig. 6-4. An anterograde His potential (H) is still seen. After the extrastimulus (S2), WCT is initiated. A His potential (H′) is seen after the local ventricular electrogram in each complex. This preexcited tachycardia could be true antidromic reentry or the pathway may be a bystander with preexcited AV nodal reentry or atrial tachycardia.

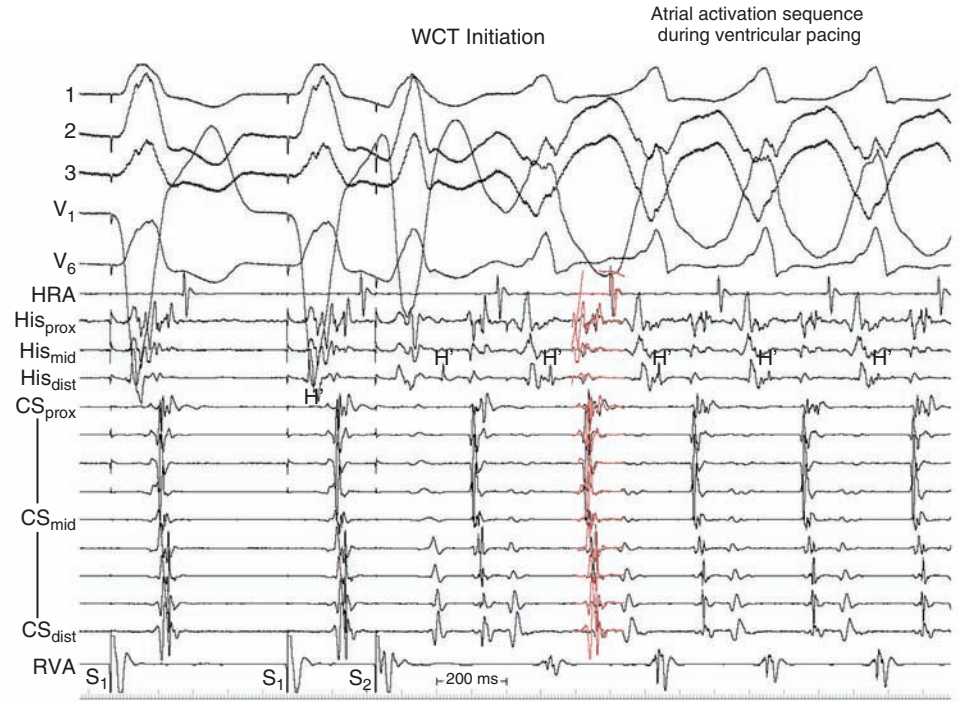

Figure 6-5

The tachycardia was also inducible with ventricular pacing and extrastimuli. In Fig. 6-5, an atrial activation sequence during ventricular pacing is superimposed in red over the atrial activation during tachycardia, showing an identical pattern. Thus it is reasonable to assume that conduction in each instance is over the same pathway, which is compatible with the

AV node (evidenced by His potential [H′] occurs at the same interval before each atrial recording; midline activation sequence; relatively long VA interval).

WCT vs Right Ventricular Pacing at Tachycardia Cycle Length

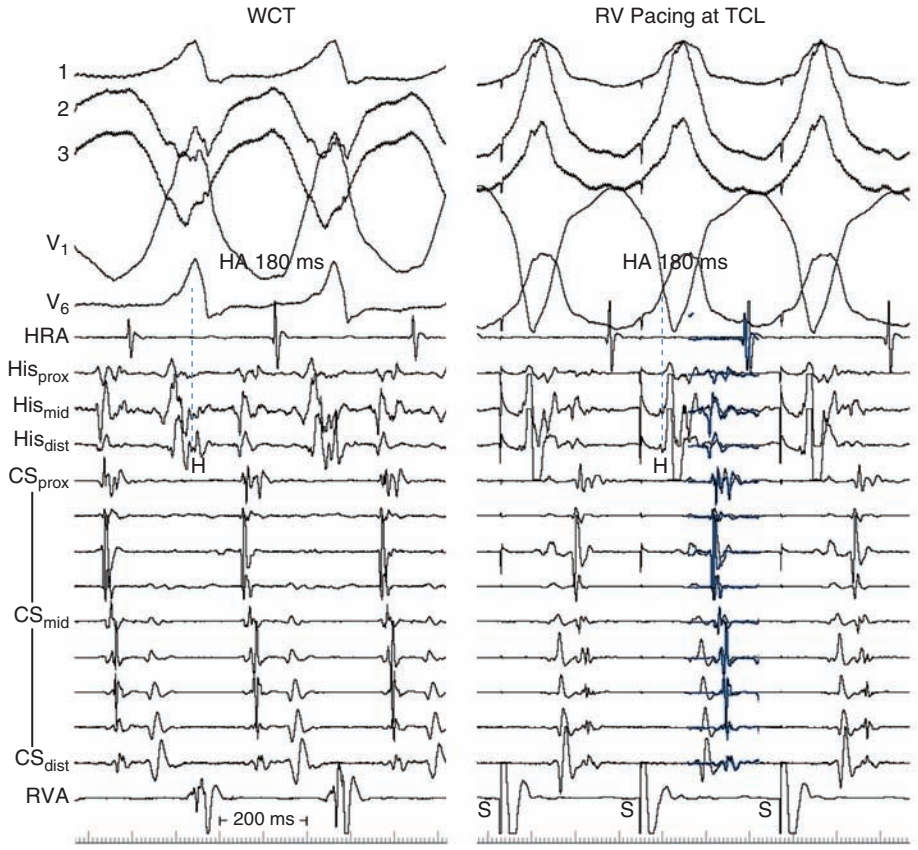

Figure 6-6

In Fig. 6-6, comparison of HA intervals (H denotes His potential) during tachycardia and ventricular pacing at the tachycardia cycle length shows the same atrial activation sequence (WCT activation sequence *superimposed in blue* over that during ventricular pacing at right) and identical HA intervals. If another bypass tract were used in the retrograde direction in either situation, the His and atrium would be activated in parallel during ventricular pacing (in series during tachycardia), leading to an artificially shorter apparent HA interval. Because the HA intervals are identical, conduction is probably proceeding over the same pathway in each situation.

Para-Hisian Pacing

These Findings:

A. Exclude a retrogradely conducting bypass tract (BT)
B. Demonstrate exclusive BT conduction
C. Show AV nodal and BT conduction
D. Show AV nodal conduction
E. Show atrial capture [Fig. 6-7]

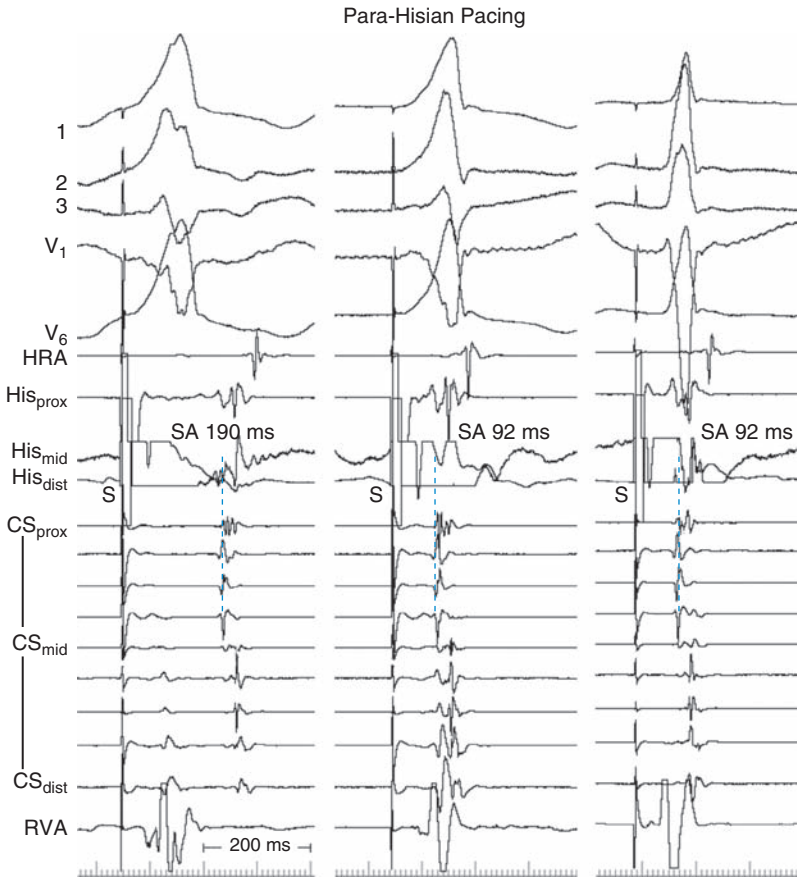

Figure 6-7

Para-Hisian pacing is performed from the His catheter (Fig. 6-7). At left, the widest resulting QRS complex is associated with a stimulus-A (SA) interval 280 ms. The complex at center shows a slightly narrower QRS complex, indicating His + ventricular capture; the SA interval is much shorter (180 ms). At right is an almost totally normal QRS complex, with a long stimulus-QRS interval likely indicating no or minimal ventricular capture ("pure" His capture). Here, the SA interval is also 180 ms. These findings are compatible with retrograde conduction over the AV node, but do not exclude the presence of a bypass tract, especially one with a long conduction time (longer than the retrograde AV nodal conduction time).

Atrial Extrastimuli (Premature Atrial Complex [PAC]) in WCT

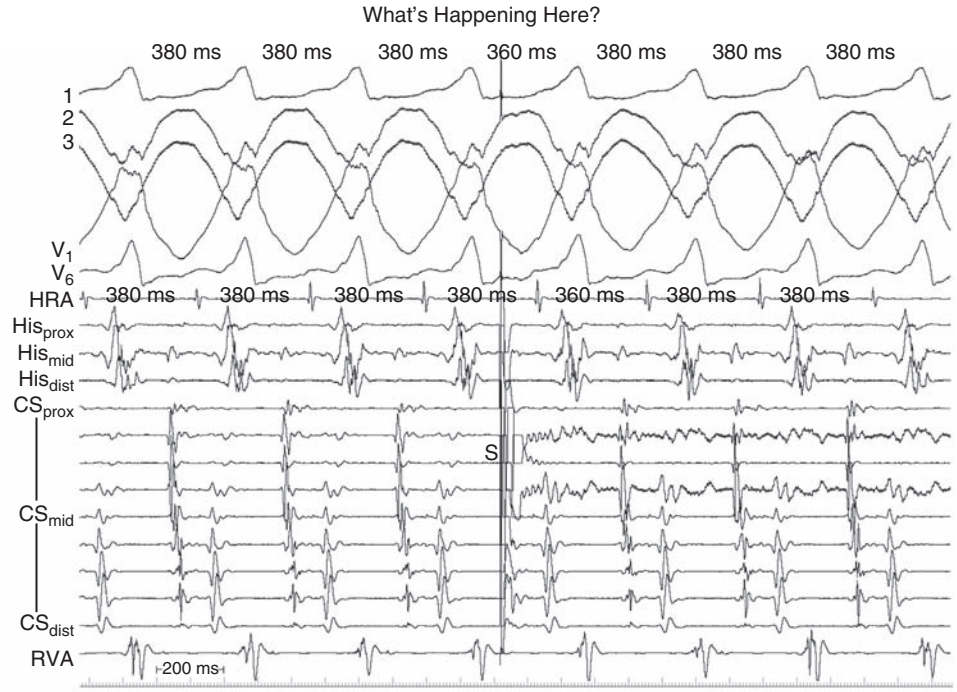

Figure 6-8

During sustained, stable WCT (Fig. 6-8), a single atrial extrastimulus (S) is introduced from the coronary sinus at a time when the atrial electrogram in the His bundle region is being inscribed (and that tissue is thus refractory). Intervals shown at the top are QRS-QRS intervals, showing that the QRS complex immediately after the extrastimulus is advanced by it. This cannot happen with ventricular tachycardia, but can with a preexcited tachycardia. In addition, the intervals shown in the middle are A-A intervals measured in the high right atrium (HRA) recording. These show advancement of the timing of the subsequent atrial electrogram, after the QRS complex that had been advanced. This indicates dependence of atrial activation on the prior QRS complex, and thus an atrial tachycardia is excluded. In addition, the fact that the stimulus occurred while the AV nodal region was refractory shows that this cannot be preexcited AV nodal reentry. Thus true antidromic tachycardia (anterograde bypass tract, retrograde AV node) is favored.

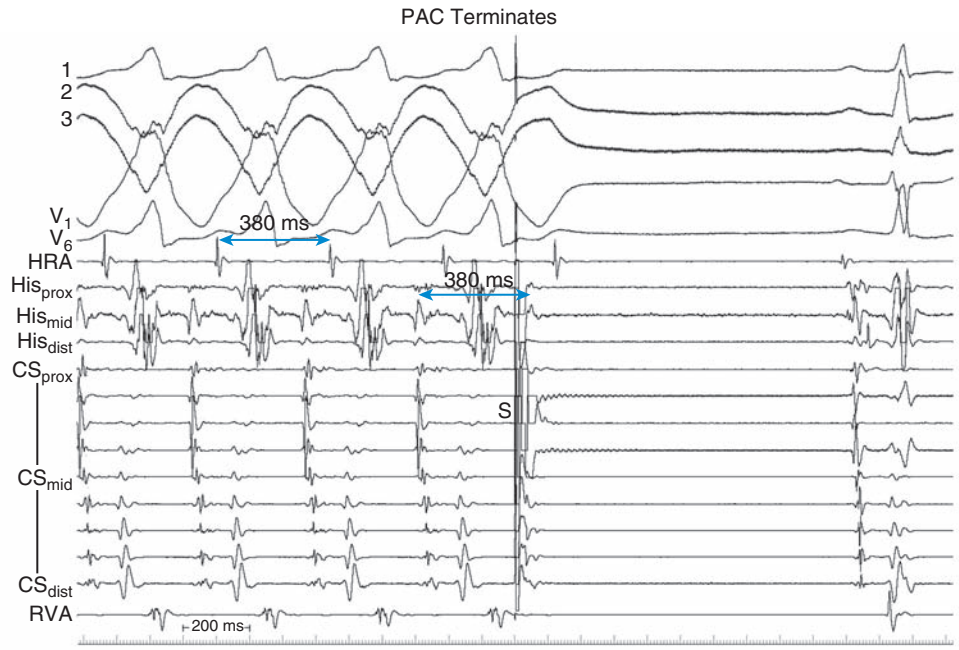

Figure 6-9

As shown in Fig. 6-9, another atrial extrastimulus delivered during stable tachycardia again occurs at a time when the AV nodal region is refractory (*arrows* on atrial recordings). In this case, atrial capture occurs (as indicated by HRA recording), but tachycardia terminates without ventricular activation. This again excludes ventricular tachycardia, as well as forms of SVT in which the bypass tract was a bystander (such as atrial tachycardia or AV nodal reentry), because simply blocking in the bypass tract with the atrial extrastimulus should eliminate preexcitation but the tachycardia should continue with narrow QRS complexes. Thus antidromic tachycardia is the diagnosis.

Investigating Possible Accessory Pathway Potential

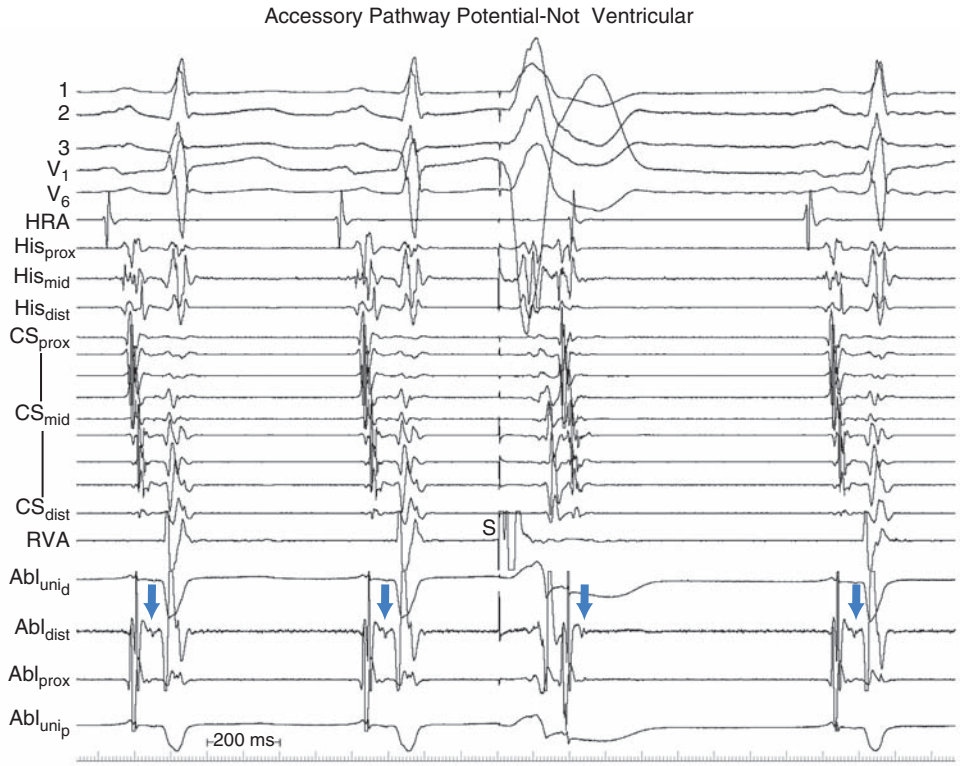

Figure 6-10

Now that a diagnosis has been established, mapping can proceed. At a site around the coronary sinus os, a recording is made that has a large atrial potential, a large ventricular potential, and a small potential between these (*blue arrows*, Fig. 6-10) that may represent the bypass tract. This is tested by introducing a ventricular extrastimulus (S) during sinus rhythm. The small potential remains with a fixed relationship to the atrial recording and is thus not part of the ventricular electrogram.

Preexcited SVT Initiation

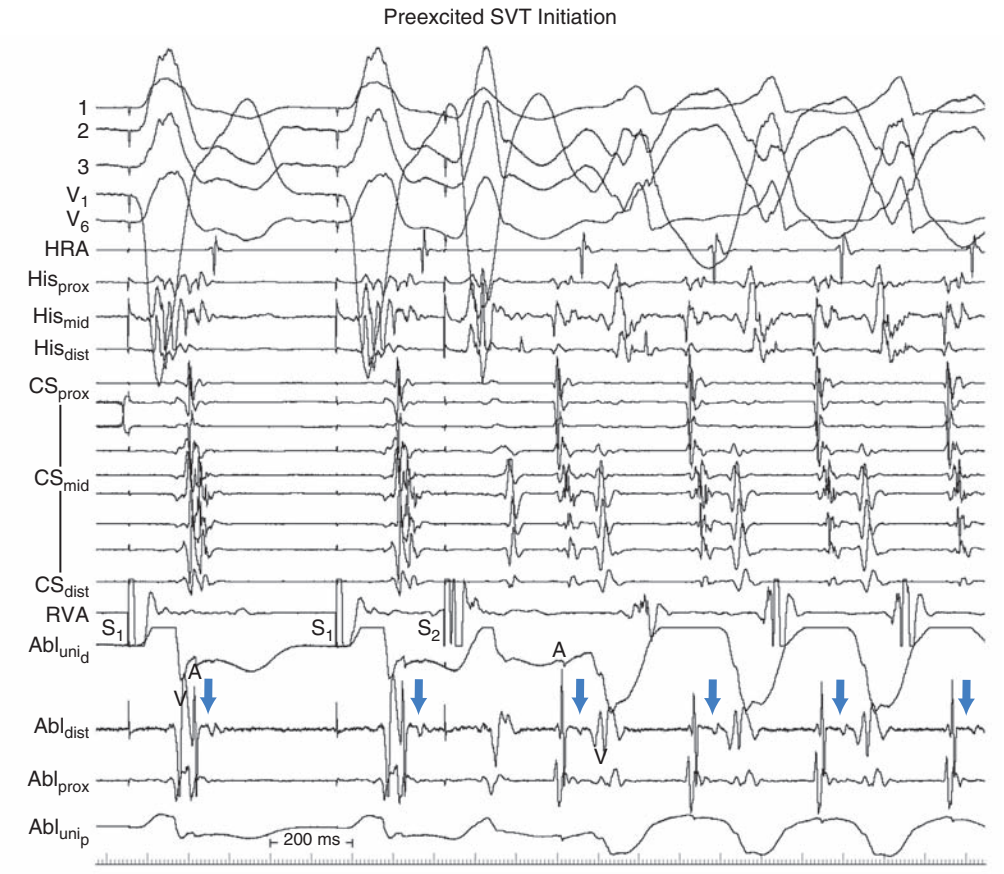

Figure 6-11

During another induction of preexcited tachycardia (Fig. 6-11), the interesting potential *(blue arrow)* remains between atrial (A) and ventricular (V) electrograms during preexcited tachycardia. However, during ventricular pacing, the potential follows the atrial electrogram. This indicates that the pathway has no retrograde conduction (retrograde conduction occurs through the AV node and activates the atrium and the pathway thereafter).

Ablation Site and Ablation Delivery

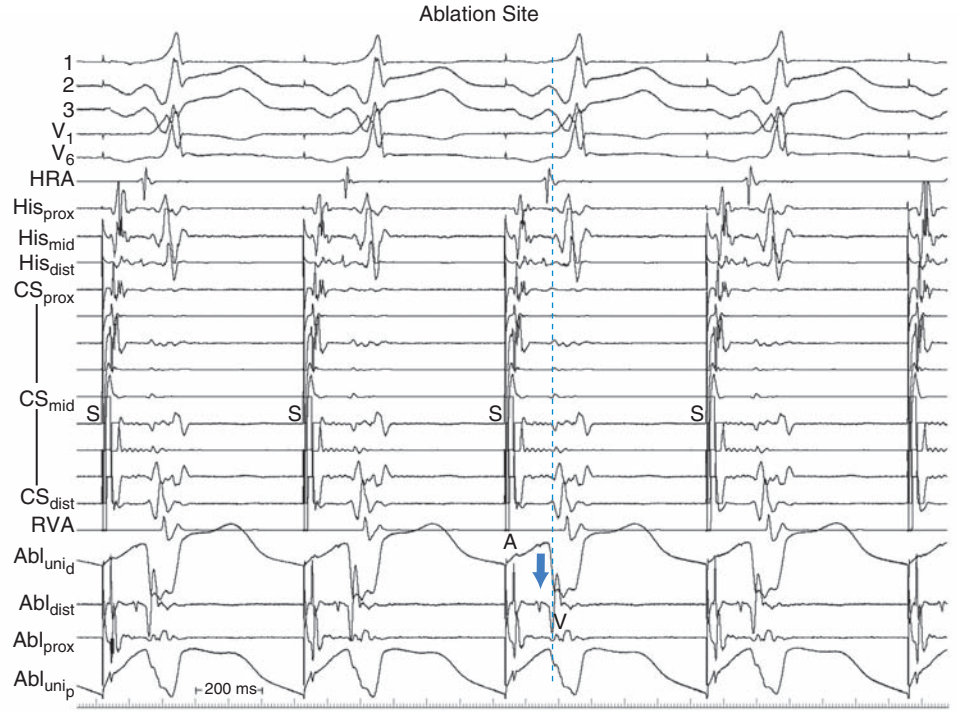

Figure 6-12

A site for possible ablation is chosen as indicated in Fig. 6-12. The surface QRS/delta wave onset is shown by a *dashed blue line*; the recording at this site shows a large atrial potential (A), bypass tract potential *(blue arrow)*, and ventricular electrogram (V). In addition, the unipolar recording shows a "QS" configuration; this and the bipolar ventricular recording precede the onset of the delta wave by about 20 ms.

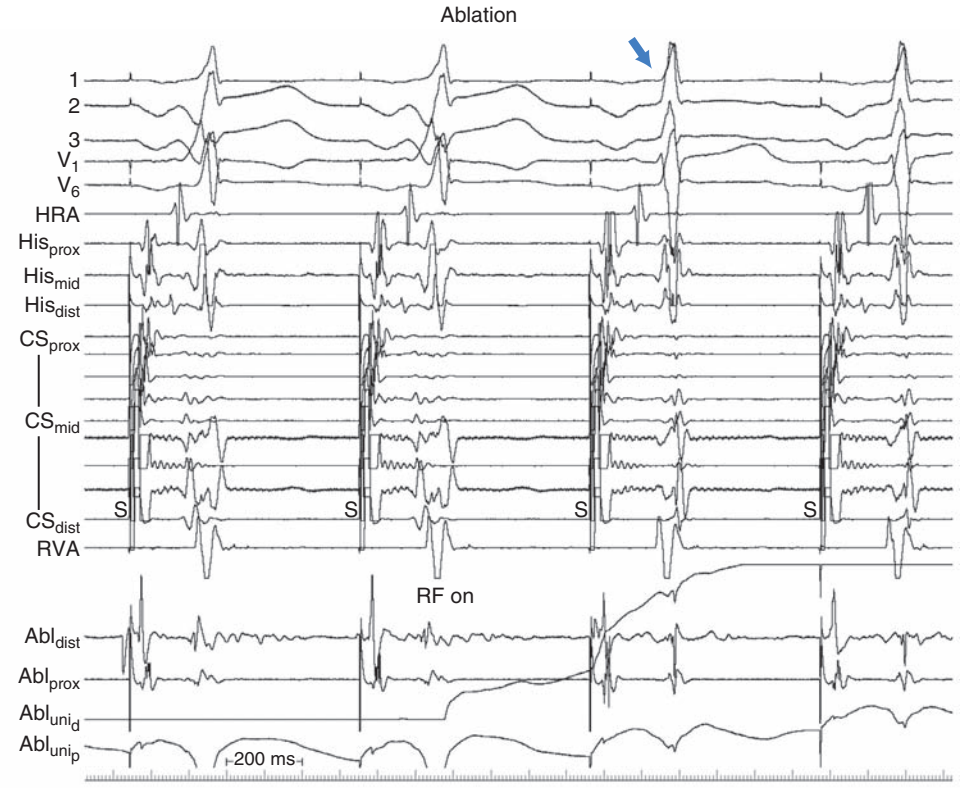

Figure 6-13

Radiofrequency energy application at this site (as indicated in middle of Fig. 6-13) during atrial pacing to maximize the delta wave shows a nearly immediate loss of preexcitation (see surface ECG leads, *arrow*).

Pre- and Postablation ECGs Compared

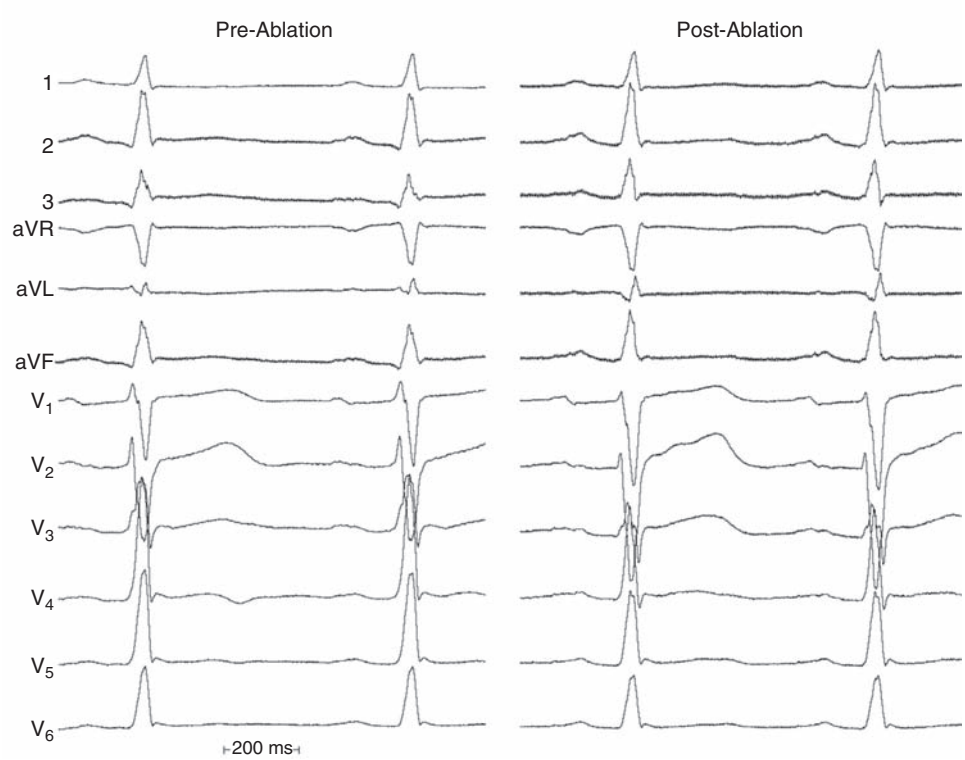

Figure 6-14

In Fig. 6-14, 12-lead ECG recordings before ablation and immediately postablation show subtle differences, suggesting that preexcitation really was present to a very minor degree before ablation (small Q wave in leads 2, 3, and aVF, and larger R wave before ablation in leads V1 and V2).

Bypass tract conduction did not recur during a waiting period, with or without isoproterenol provocation. Electroanatomic mapping was not used during this procedure (only electrogram-based mapping). The patient has done well on long-term follow-up without recurrence of preexcitation or tachycardia for several years.

Summary

- Not all WCTs after coronary artery surgery are ventricular tachycardia
- History is important (remote ablation recalled)
- Usually, partially successful ablation eliminates anterograde pathway conduction; here, it was retrograde conduction that had been ablated successfully at the first procedure. The patient still had the capability of having preexcited tachycardias such as atrial flutter/fibrillation, atrial tachycardia or AV nodal reentry (in which the bypass tract is a bystander), or, as here, antidromic tachycardia
- It is both possible and important to distinguish true antidromic SVT (which will be eliminated by successful pathway ablation) from other preexcited tachycardias (which need additional ablation of the cause of the tachycardia, not just of the pathway, which is a bystander)

7 Atriofascicular Pathway Supraventricular Tachycardia

Case Presentation

A 30-year-old woman had been bothered by sustained palpitations for the last 8 years; there had been a recent (2 years) increase in frequency of episodes. She had several emergency room (ER) visits for palpitations; ECGs consistently showed left bundle branch block (LBBB) tachycardia at ~200/min that terminated reliably with adenosine. Following tachycardia termination, the QRS was normal. She was diagnosed with supraventricular tachycardia (SVT) with LBBB aberration. Physical examination and non-invasive evaluation were completely normal. Because of increased frequency of episodes refractory to beta blockers, an electrophysiology (EP) study and ablation were performed:

EP study 1/11: Atrioventricular (AV) nodal reentrant SVT was diagnosed, leading to extensive slow pathway ablation; the operator noted that the catheter kept falling into a large coronary sinus ostium. A long vascular sheath was used but tachycardia was still inducible at the end of the procedure.

EP study 5/11: AV nodal reentrant SVT was again diagnosed, further ablation in the slow pathway region was performed with "transient success".

In the months following her second ablation, she experienced a "crescendo" in frequency of episodes, resulting in 16 ER visits (each with tachycardia having LBBB pattern, almost all readily terminated with adenosine). She was referred for repeat EP study and possible ablation.

ECG During Tachycardia

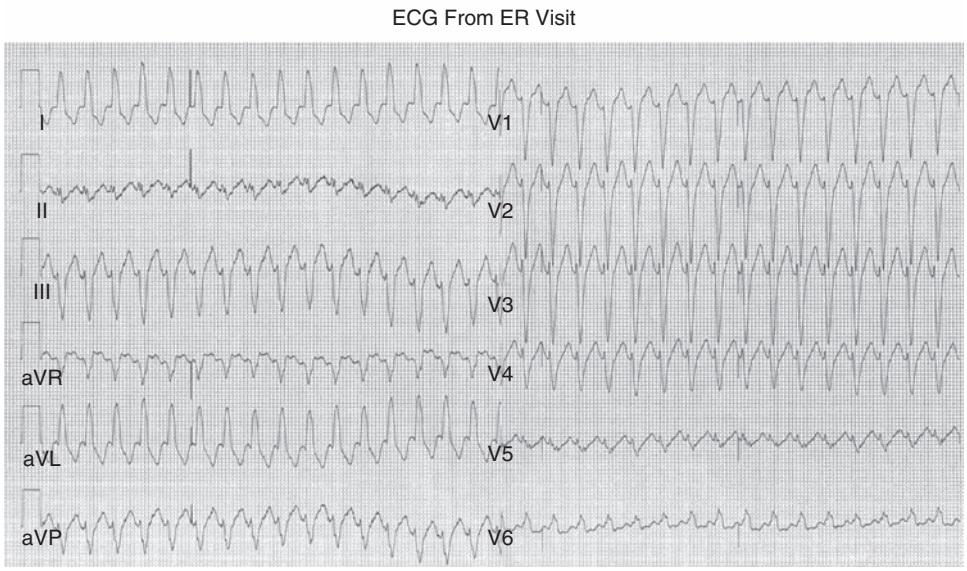

Figure 7-1

The ECG in Fig. 7-1 is representative of those obtained at each of several emergency room visits over the prior months, showing a regular tachycardia with a left bundle branch block pattern. This was reliably terminated with adenosine injection, resulting in a sinus rhythm ECG that showed no abnormalities (narrow QRS complex).

Differential Diagnosis of LBBB-Appearing Tachycardia

What About Left Bundle Branch Block (LBBB) Tachycardias?

Although right bundle branch block (RBBB) aberration is more common in younger individuals, LBBB-type tachycardias can certainly occur, with a certain relatively short list of possibilities as noted below:

- Differential diagnosis of typical LBBB tachycardia in patients with a normal resting ECG and no structural heart disease includes the following:
  - Orthodromic supraventricular tachycardia (SVT) with left lateral concealed bypass tract
  - Any type of SVT with LBBB aberration
  - Antidromic SVT using atriofascicular pathway
  - Right ventricular papillary muscle focal VT
- Typical LBBB tachycardia in patients *with* structural heart disease includes the following:
  - SVT of any type and preexisting LBBB
  - Bundle branch reentry
- *Atypical* LBBB may be seen in the following:
  - Preexcited SVT using an atrioventricular pathway anterogradely
  - VT

Baseline ECG and Intracardiac Recordings

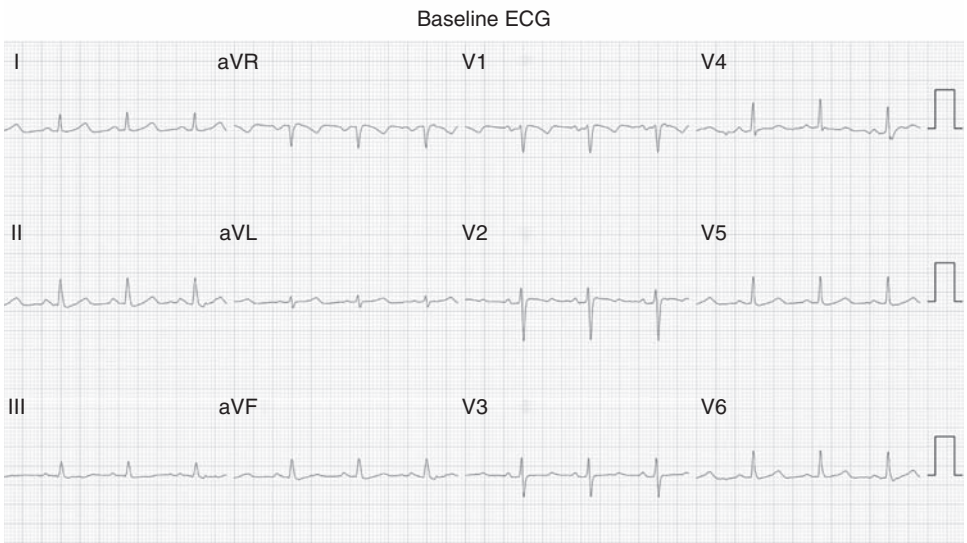

Figure 7-2

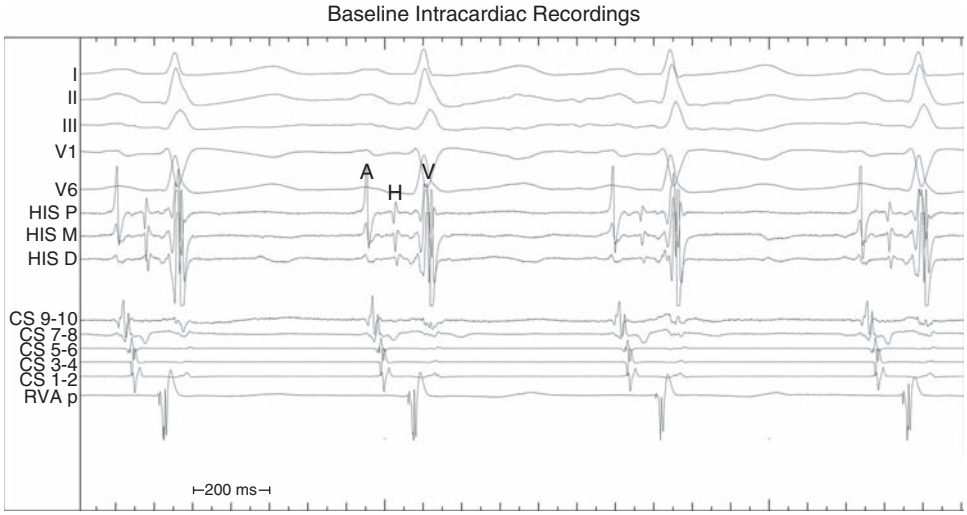
The baseline ECG (Fig. 7-2), as indicated previously, was entirely normal without bundle branch block.

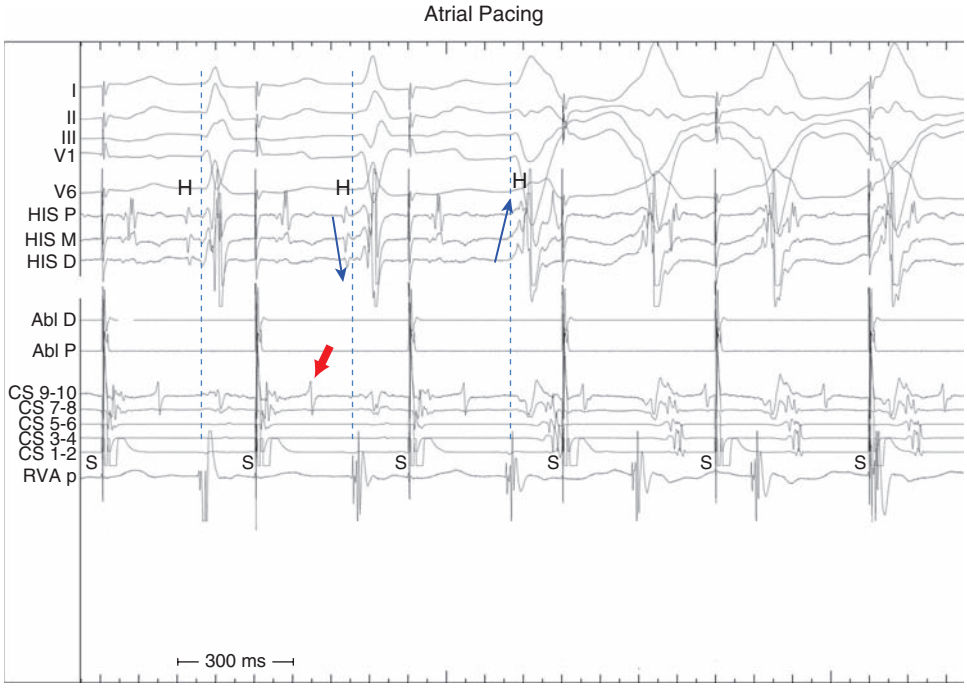
Figure 7-3



Baseline intracardiac recordings (Fig. 7-3) were likewise entirely normal, with AH and HV intervals within the normal range.

Atrial Pacing with Change in QRS and Tachycardia Induction

Figure 7-4



With atrial pacing from the distal coronary sinus, some unusual features are observed in Fig. 7-4. The *red arrow* indicates an odd potential in the region of the coronary sinus ostium; this may have been a "split potential" caused by repeated ablation in this region. Additionally, the surface ECG shows changes with a progressive increase in QRS duration until tachycardia with a left bundle branch block pattern ensues. Before this, while the AH interval changes little, the His potential (H) moves further toward and even into the QRS complex (*dashed line* denotes onset) until its direction of propagation becomes retrograde *(upward blue arrow)*. Note also that the right ventricular recording, which has a right bundle branch potential, precedes the onset of the surface QRS complex as well as the His potential. All of these taken together make a strong case for the presence of an atriofascicular bypass tract (BT); gradual development of left bundle branch block is related to progressive delay in the atrioventricular (AV) node, allowing slow conduction

down the atriofascicular pathway to its insertion in the distal right bundle branch; conduction is then retrograde to the His bundle, recording of which occurs after the onset of the QRS complex. Conduction back to the atrium is typically over the normal AV node, and tachycardia then proceeds with conduction through the atrium to the atriofascicular pathway's atrial portion (which behaves physiologically like an AV node).

Wide QRS Tachycardia

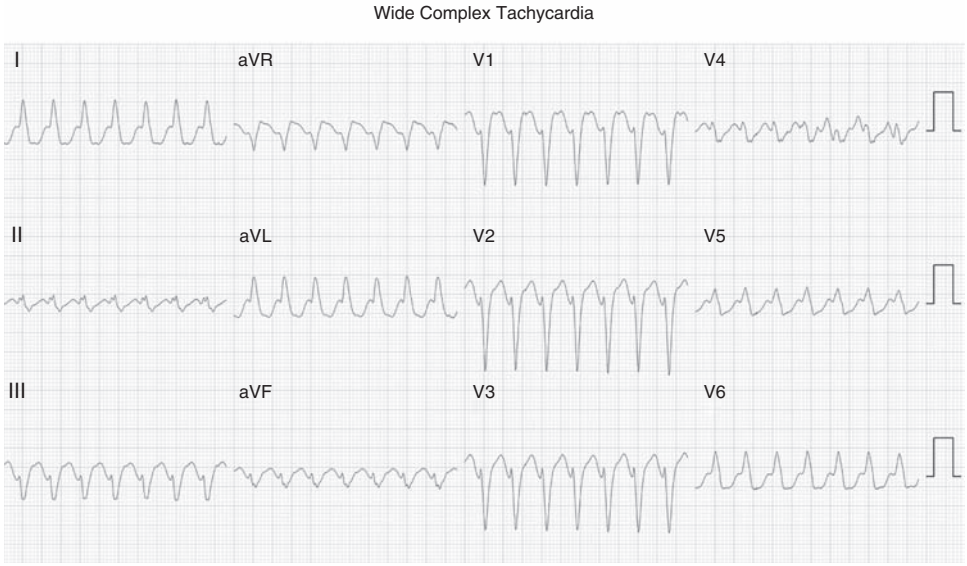


Figure 7-5

A full ECG of the induced tachycardia is shown in Fig. 7-5, matching that of spontaneously occurring episodes with left bundle branch block.

Atrial Extrastimuli During Tachycardia

Is Any Diagnosis Excluded? [Fig. 7-6]

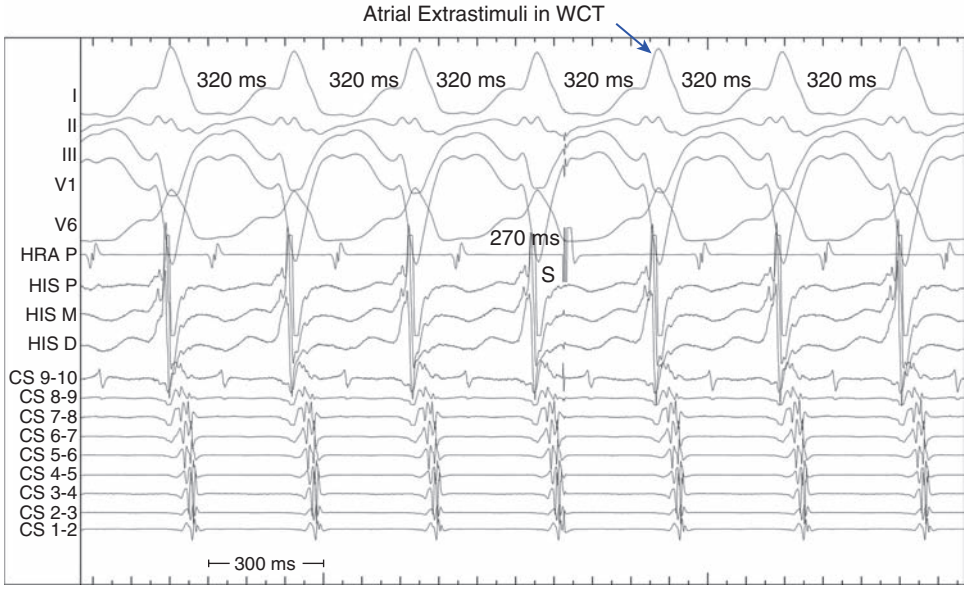

Figure 7-6

To prove that an atriofascicular pathway is present and participating in tachycardia, as well as to exclude other potential causes, atrial extrastimuli are introduced (Fig. 7-6) along the lateral tricuspid annulus at a time when the atrial electrogram in the region of the normal AV node is refractory (such that the AV node cannot be affected by the extrastimulus). The location at which the extrastimuli are delivered is important, because it is desirable to have a relatively small amount of atrium to traverse before arriving at the pathway. In the example shown, numbers of the top indicate intervals between QRS complexes. When the extrastimulus (S) is delivered at 270 ms from the prior atrial recording, the next QRS complex *(arrow)* occurs exactly on time (320 ms). Because there was no effect on the tachycardia, no conclusions can be drawn as to its nature and none of the potential causes is excluded.

Next QRS Advanced While AVJ-A is Refractory: [Fig. 7-7A]

- Excludes ventricular tachycardia
- An accessory pathway present
- Not nodofascicular or nodoventricular

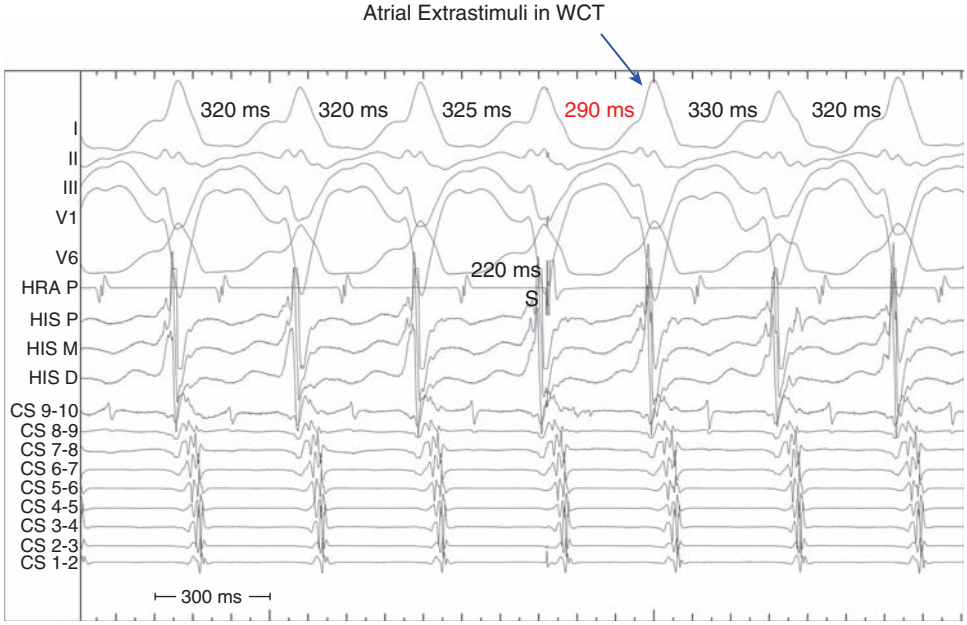

Figure 7-7A

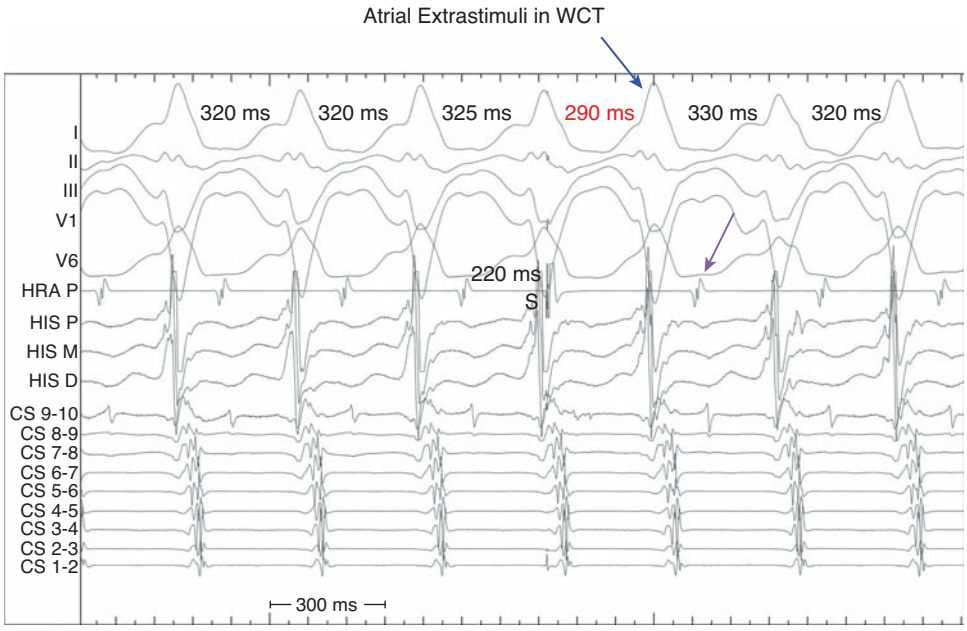
When the atrial extrastimulus (S) is delivered at an interval of 220 ms, the subsequent QRS complex *(blue arrow)* is advanced (290 ms) (see Fig. 7-7A). This excludes ventricular tachycardia, because there is no way an atrial premature event should affect the timing of ventricular activation when the AV node is refractory.

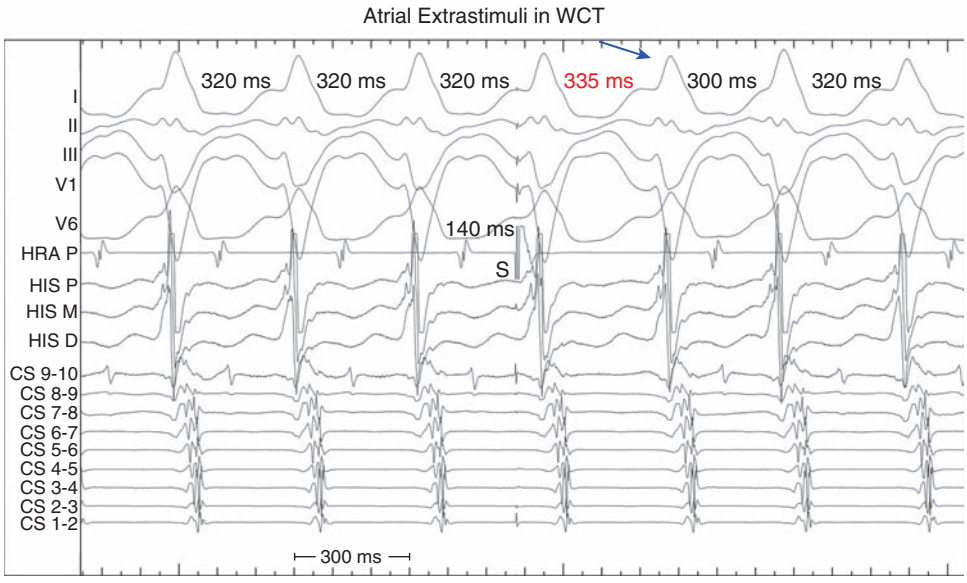


Next A Advanced Only to Same Extent as QRS:

- Not preexcited AVNRT [Fig. 7-7B]
- Not preexcited atrial tachycardia
- Second BT not excluded

Figure 7-7B

In addition, the first atrial event (*purple arrow*, Fig. 7-7B) after the QRS complex that was advanced *(blue arrow)* is likewise earlier than expected. If this tachycardia were AV nodal reentry or an atrial tachycardia, the atrial complex indicated by the *purple arrow* should have occurred exactly on time. However, because its occurrence appears to depend on the timing of the prior QRS complex, this appears to be true antidromic atrioventricular reentry proceeding down the atriofascicular pathway and up the AV node. In addition, a nodofascicular or nodoventricular pathway cannot be involved, because the AV node was refractory when the extrastimulus was delivered.



Next QRS Delayed (Not While AVJ-A is Refractory): [Fig. 7-8A]

- Excludes ventricular tachycardia

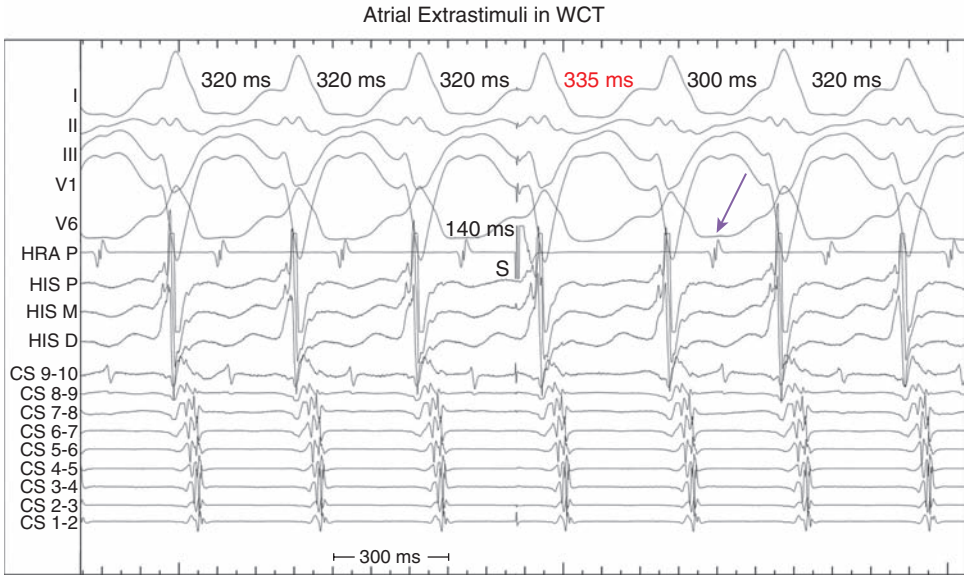
Figure 7-8A

As the atrial extrastimulus (S, Fig. 7-8A) is made to be more premature (140 ms now), the subsequent QRS complex *(blue arrow)* is actually delayed from when it would be expected to occur. This atrial stimulus is so premature that the AV node cannot be considered to be refractory; however, the fact that the next QRS complex is delayed again excludes ventricular tachycardia.

Next A Linked to Next QRS: [Fig. 7-8B]

- Not preexcited AVNRT
- Not preexcited atrial tachycardia
- Second BT not excluded

Figure 7-8B

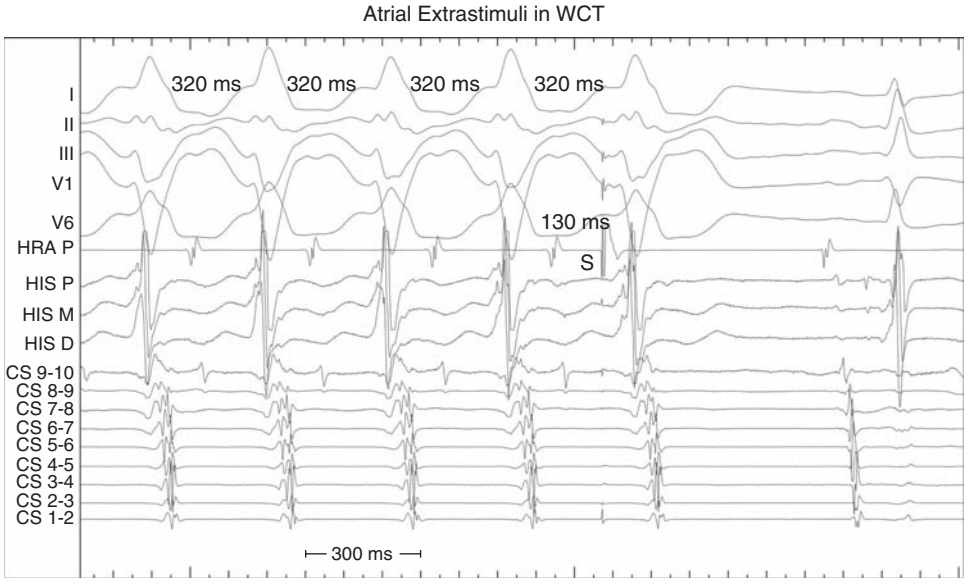


As seen previously, the first atrial complex (*purple arrow*, Fig. 7-8B) that follows the delayed QRS complex *(blue arrow)* occurs at a time later than expected and is linked to the prior QRS complex. This once again excludes atrial tachycardia or a bystander atriofascicular pathway with AV nodal reentry as the main arrhythmia diagnosis. However, retrograde conduction over a second, septal bypass tract is not necessarily excluded thereby.

Next QRS Absent (Not While AVJ-A is Refractory): [Fig. 7-9]

- Excludes ventricular tachycardia

Figure 7-9



Finally, as shown in Fig. 7-9, with an even more premature atrial extrastimulus (S), at 130 ms from the prior atrial complex, the atrium is captured but there is no subsequent QRS complex. Again, this excludes ventricular tachycardia as a potential diagnosis. Because the AV node is not refractory at the time this extrastimulus is delivered, AV nodal-dependent tachycardias could conceivably have been terminated with this and cannot be excluded on the basis of this finding alone.

Atriofascicular Pathways

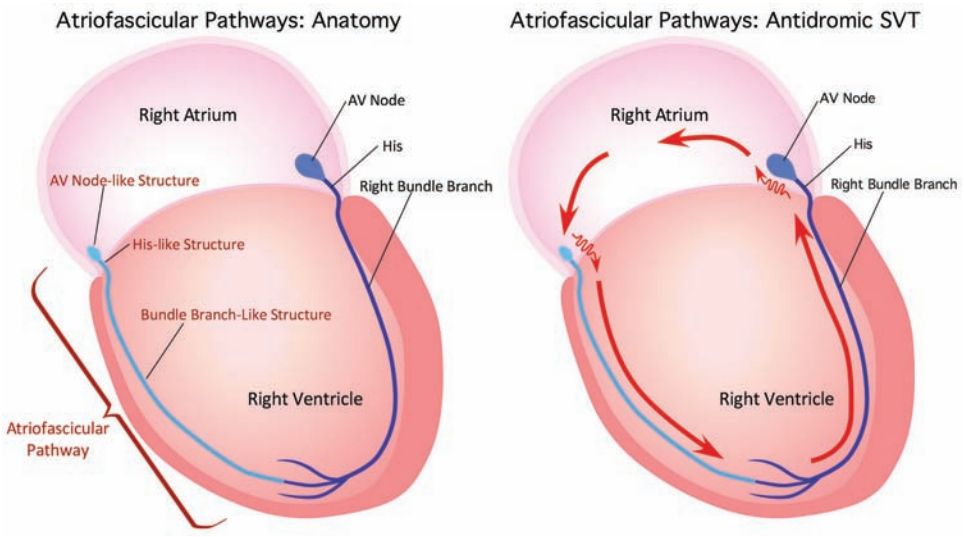


Figure 7-10

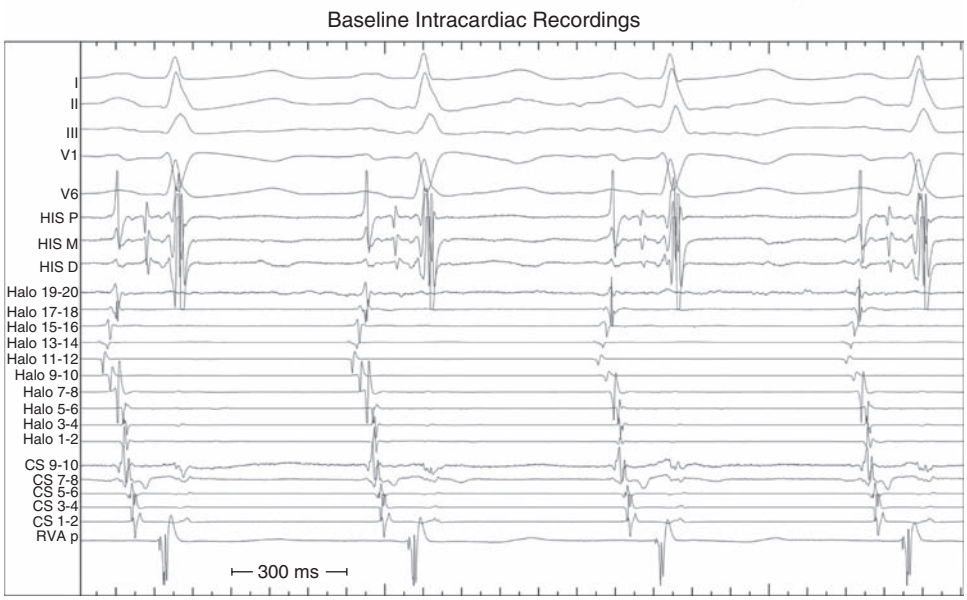
The diagram on the left in Fig. 7-10 shows the anatomy of atriofascicular pathways that have several components: an AV node–like structure in the lateral right atrium near the tricuspid annulus, a His bundle–like structure that crosses the annulus, and a long fiber-like right bundle that connects the His-like portion to the true distal right bundle. In this sense, the entire pathway is like a duplication of the normal conduction system. During antidromic tachycardia, as shown at right, the impulse travels down the atriofascicular pathway and up the normal conduction system. Zigzag lines denote slow conduction encountered in the normal AV node and the node-like part of the atriofascicular pathway.

More Baseline Recordings (with Halo Catheter)

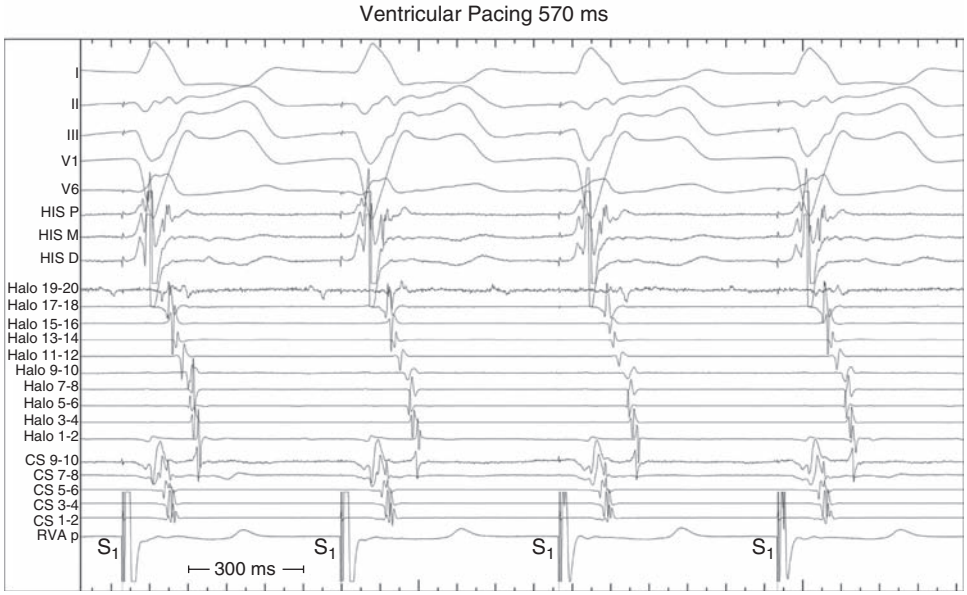
Figure 7-11



Now that a diagnosis of an atriofascicular pathway–mediated atrioventricular reentrant tachycardia has been made, selection of target sites for ablation can begin. At the beginning of the procedure, a multipolar electrode catheter ("Halo") was placed around the tricuspid annulus to facilitate mapping. The recording that had been labeled "HRA" in prior figures was in fact one of the electrodes of this catheter. During sinus rhythm as shown in Fig. 7-11, it is not possible to determine the atriofascicular pathway's location.

Ventricular Pacing

Figure 7-12



Ventricular pacing at a slow rate shows an atrial activation pattern consistent with retrograde conduction over the AV node (Fig. 7-12).

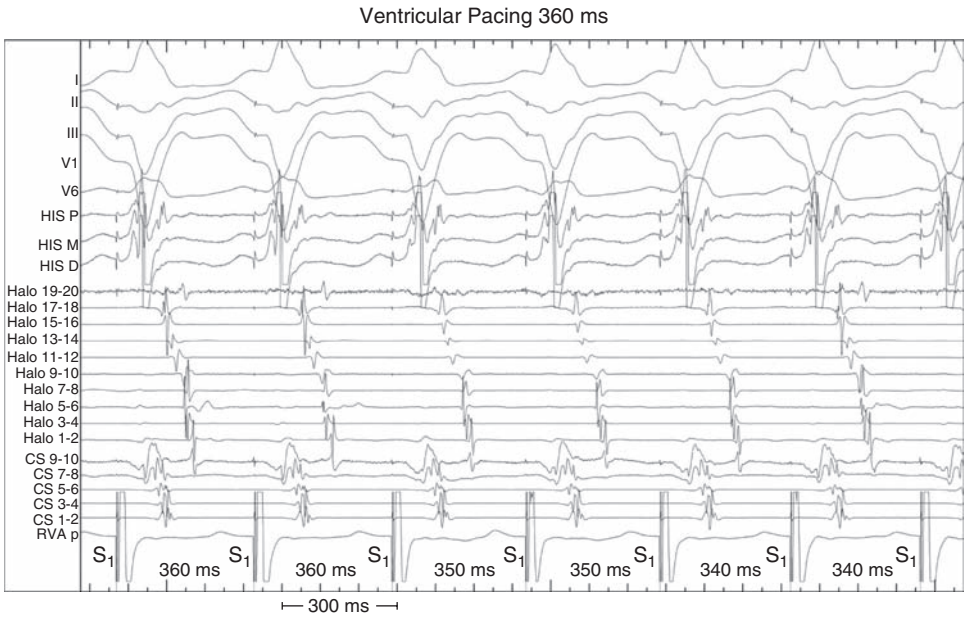


Figure 7-13

The same atrial activation pattern is maintained with ventricular pacing at a more rapid rate in Fig. 7-13.

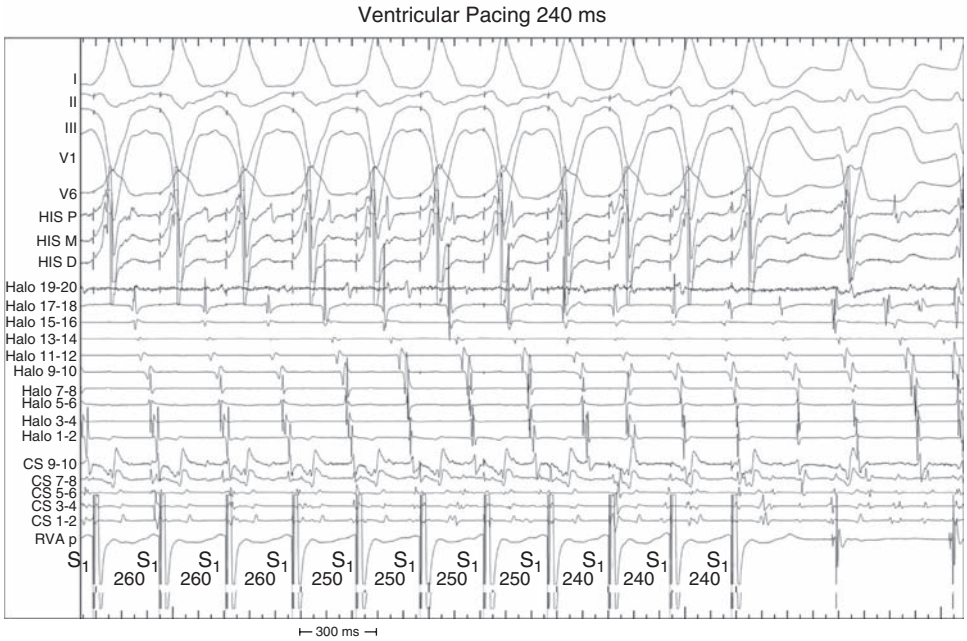

Figure 7-14

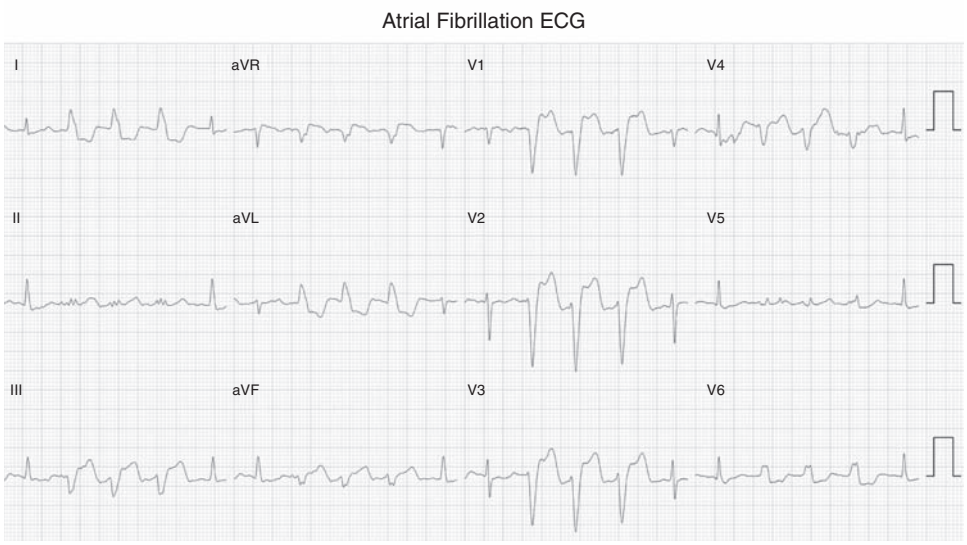
With still more rapid ventricular pacing (Fig. 7-14), conduction over the AV node persists. However, atrial fibrillation ensues.

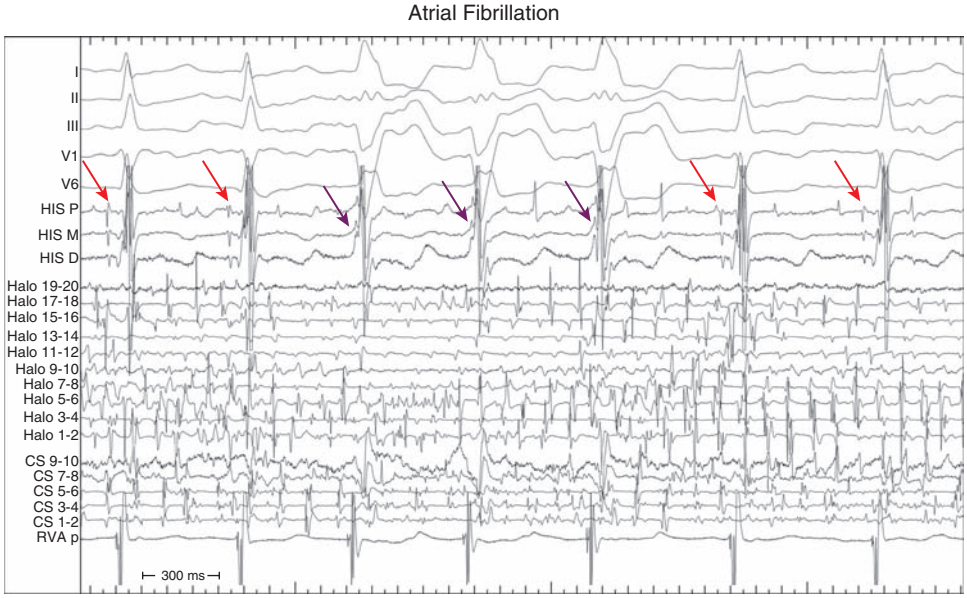
Atrial Fibrillation ECG and Intracardiac Recordings

Figure 7-15A



An ECG of atrial fibrillation, partially conducted over the atriofascicular pathway, is shown in Fig. 7-15A.

Figure 7-15B



In Fig. 7.15B, intracardiac recordings during atrial fibrillation show narrow QRS complexes with an anterogradely activated His potential *(red arrows)*, as well as wide QRS complexes with retrogradely activated His recordings *(purple arrows)*, because of anterograde conduction over the atriofascicular pathway on these complexes rather than the AV node.

Atrial Pacing and Premature Stimulation

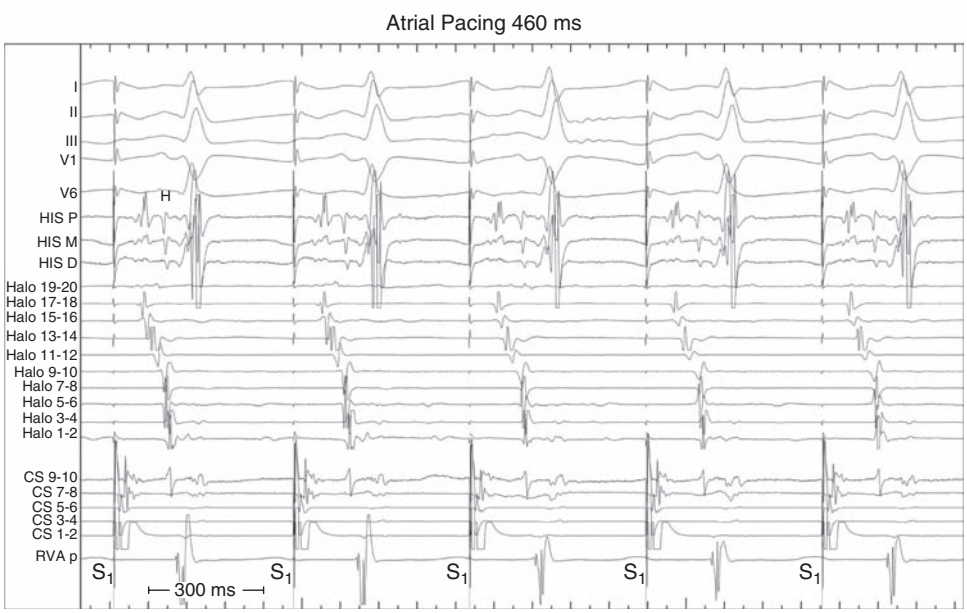


Figure 7-16

Cardioversion was necessary to terminate atrial fibrillation and continue with the procedure. Thereafter, with atrial pacing at 460 ms, ventricular activation is still largely mediated over the normal AV node-His Purkinje system (H), with a relatively narrow QRS complex (Fig. 7-16).

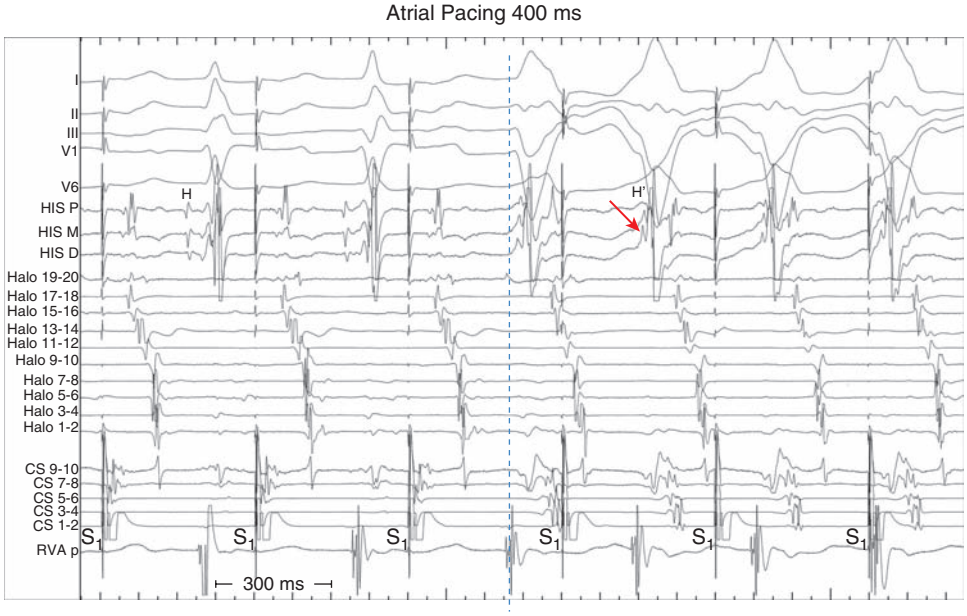

Figure 7-17

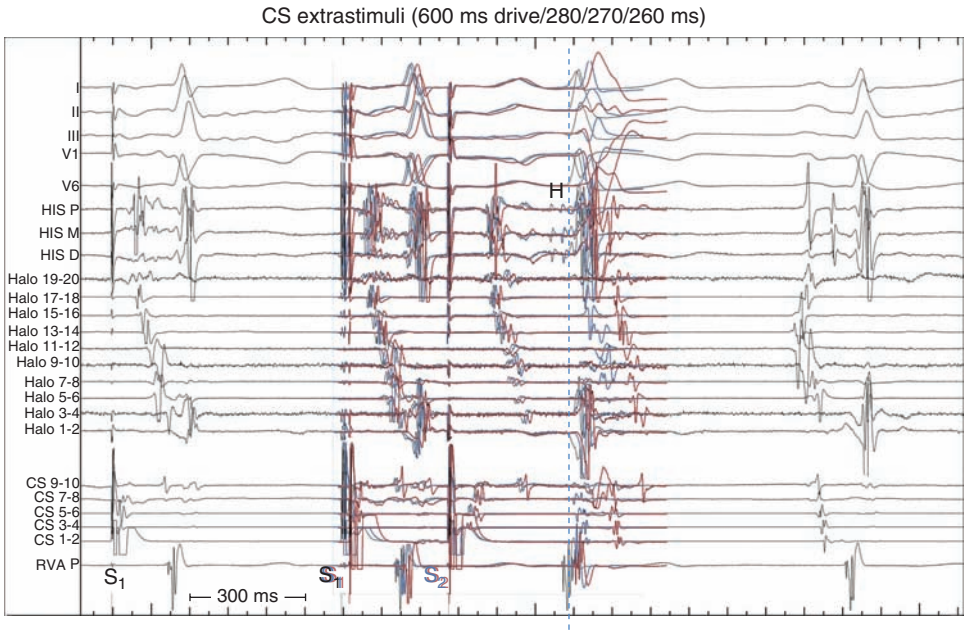
As the atrial pacing cycle length is decreased to 400 ms (Fig. 7-17), the AV node fatigues and the atriofascicular pathway becomes the mode of ventricular activation. The His potential (H′, *red arrow*) is activated retrogradely. The onset of the first preexcited QRS is indicated by a *dashed line*; note the RV electrogram and sharp spike (right bundle branch potential) precede the QRS onset.

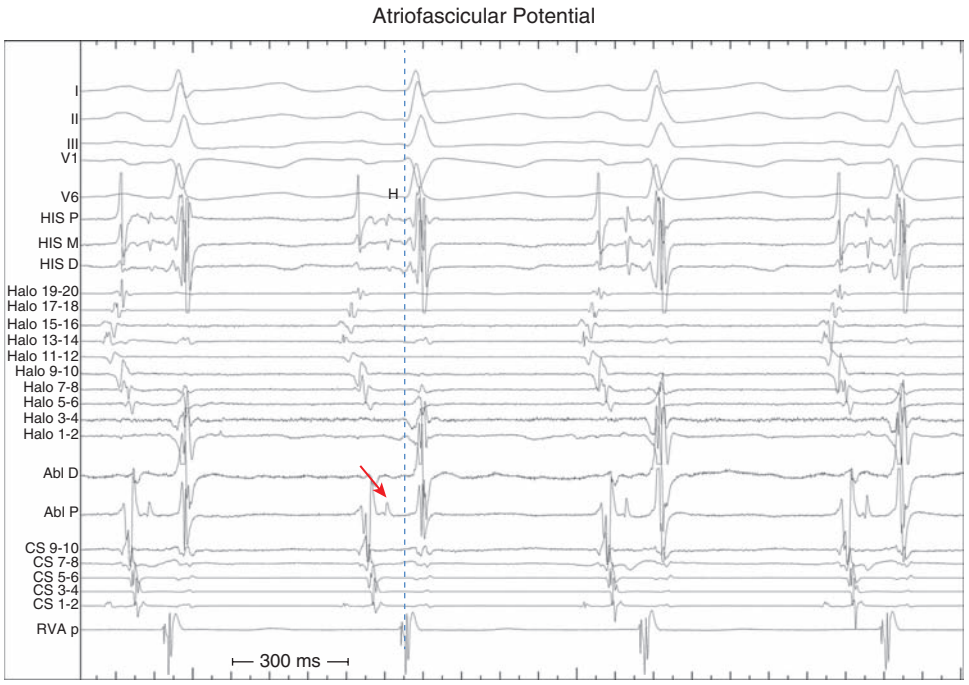
Figure 7-18



The effect of increasing prematurity of atrial stimulation on atrioventricular conduction is illustrated in Fig. 7-18 by superimposing successive coupling intervals (black, 280 ms; blue, 270 ms; red, 260 ms). It can be seen that the His bundle recording (H) is progressively delayed while the timing of the onset of the QRS complex *(dashed line)* does not change significantly, and the QRS duration progressively increases as more of the ventricular muscle is activated over the atriofascicular pathway and less over the AV node.

Mapping Atriofascicular Potential

Figure 7-19



A site along the lateral tricuspid annulus is sampled, at which a recording is obtained (Fig. 7-19) that looks very much like the recording from the His catheter at the septum (atrial electrogram, His-like potential *[red arrow]*, ventricular electrogram). This is compatible with the atriofascicular pathway potential.

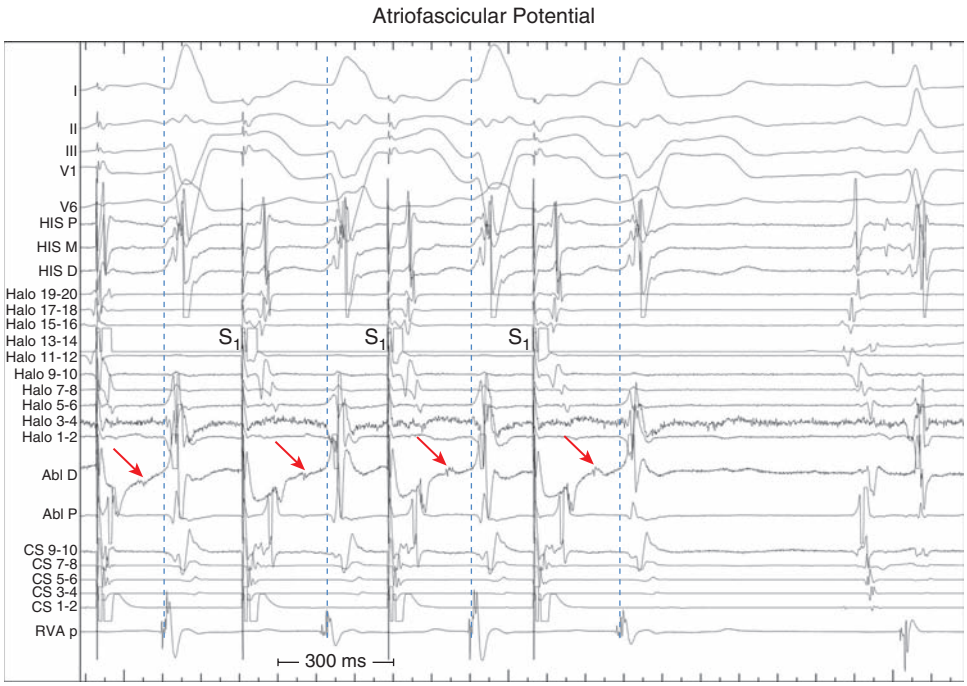


Figure 7-20

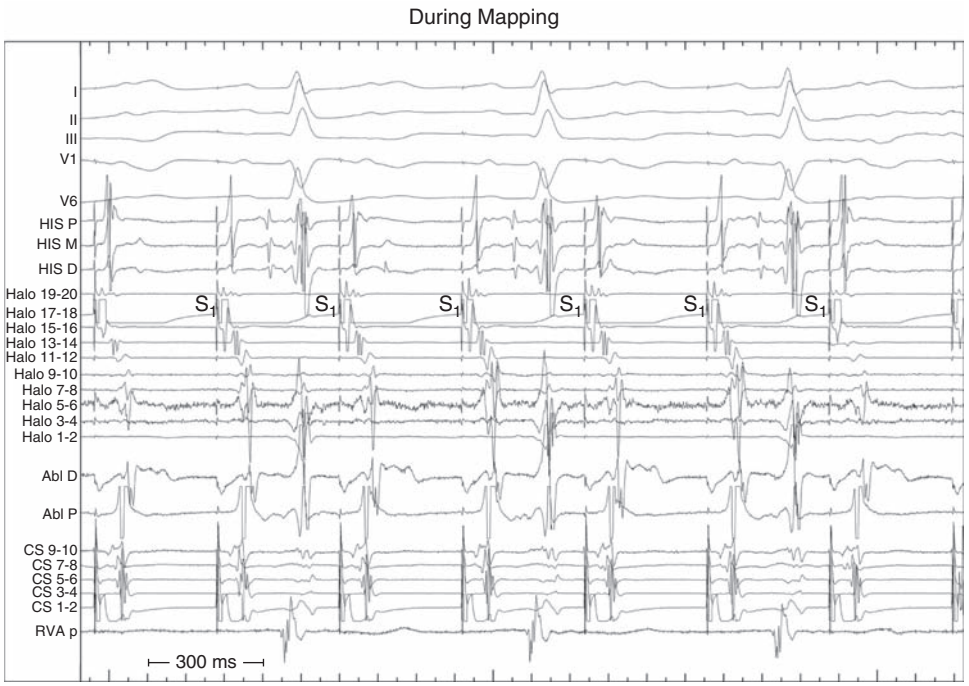
To validate the signal at the *red arrows* as a true atriofascicular pathway potential, pacing is performed (Fig. 7-20). If an actual atriofascicular potential, it should always be present during preexcited complexes and at a consistent interval before the QRS onset *(dashed line)*, which it does appear to be.

Figure 7-21



As often occurs in cases of atriofascicular pathways, small movements of the catheter tip in the vicinity of the pathway can "bump" into it and render it unexcitable for extended periods. In Fig. 7-21, under the same conditions as in Fig. 7-20, preexcitation is suddenly lost as is recording of the pathway potential. Although this is further corroboration of being at the correct site, it is not very helpful if pathway conduction does not resume. It is thus important to be very careful and deliberate with movement of the ablation catheter as it nears the anticipated location of the pathway, either to not cause trauma that temporarily eliminates conduction or, if it occurs nonetheless, to be able to ablate at the site where it occurred if the catheter has not moved from that site. Too often, however, the ablation catheter bumps the pathway while brushing past its location, and when the operator observes this and then looks at where the catheter tip is, it is no longer at the location at which mechanical interruption of pathway conduction occurred. Obviously, ablation at this other site will do no good.

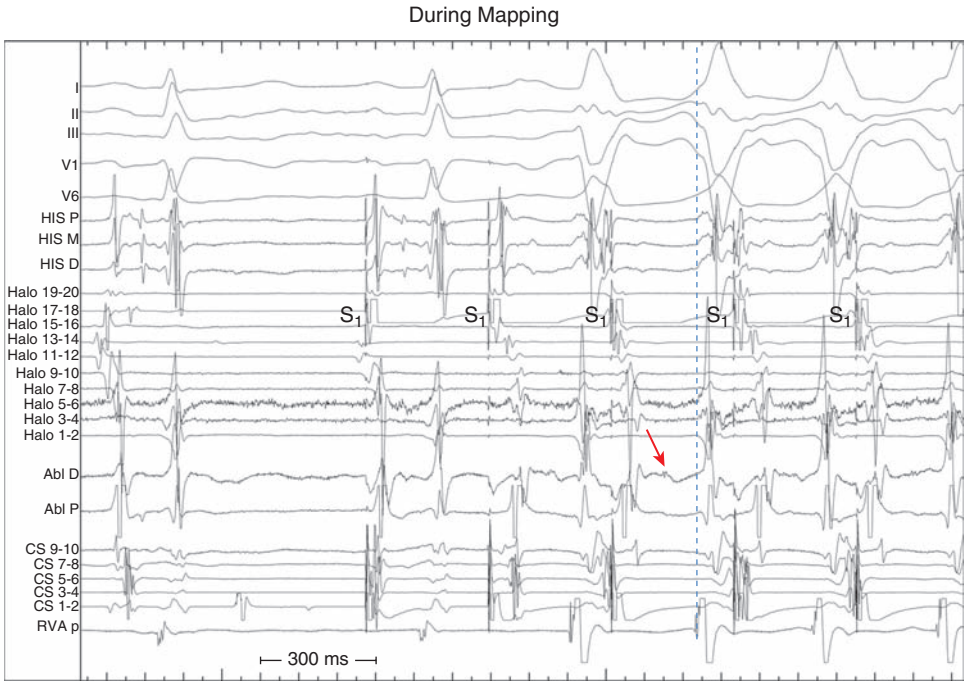


Figure 7-22

Fortunately, pathway conduction did come back a few minutes later, and the catheter was at the same location as shown (Fig. 7-22; *red arrow* shows pathway potential before preexcited QRS with *dashed line* at onset). If it had not resumed, moving the catheter away from there or administering isoproterenol or even adenosine may facilitate resumption of pathway conduction.

Pacing Ablation Site

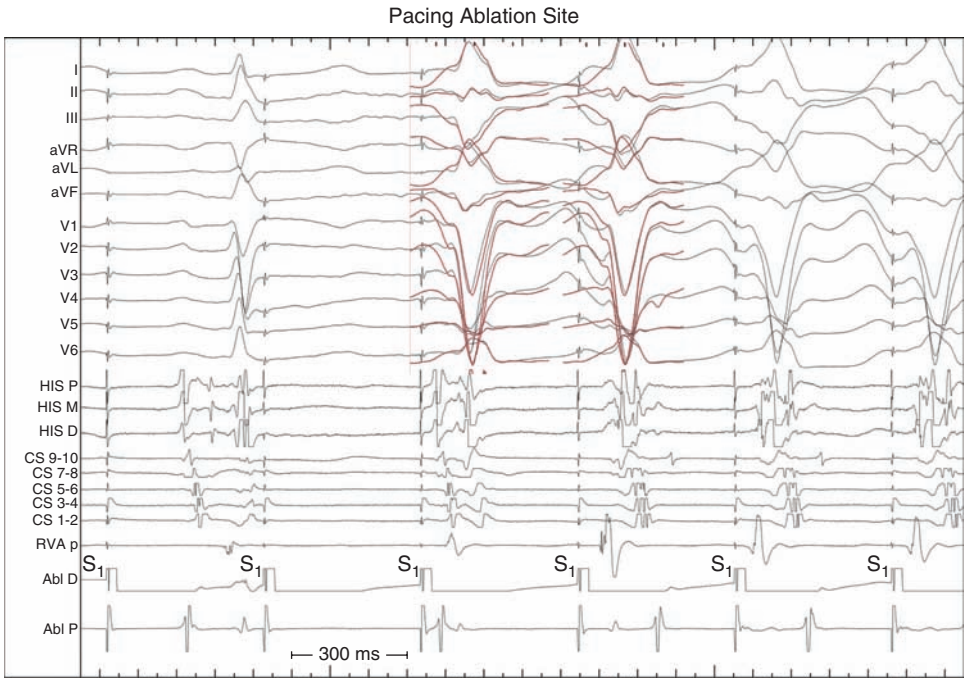

Figure 7-23

As one final corroboration, pacing from the ablation catheter nearly entirely mimicked QRS complexes during SVT (superimposed in red, Fig. 7-23), indicating that the catheter was at the site of the pathway. Importantly, if a significant amount of local ventricular capture had occurred, the QRS complex (pacing from the tricuspid annulus) would be significantly different from SVT complexes (with activation beginning closer to the apex).

Ablation Site and Radiofrequency Delivery

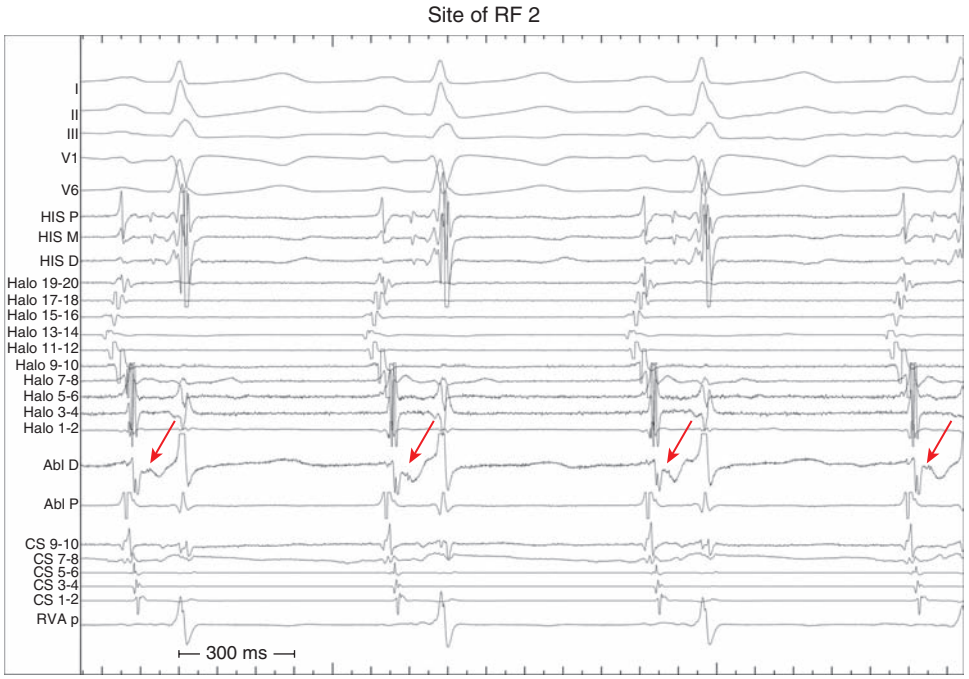

Figure 7-24

The first radiofrequency (RF) application was stopped after a few seconds because of catheter movement. The catheter was repositioned as shown in Fig. 7-24, for a second attempt at RF application. The *arrow* shows a tiny potential, indicating the atriofascicular pathway recording, just after the atrial signal at an annular site (both atrial and ventricular recordings clearly seen).

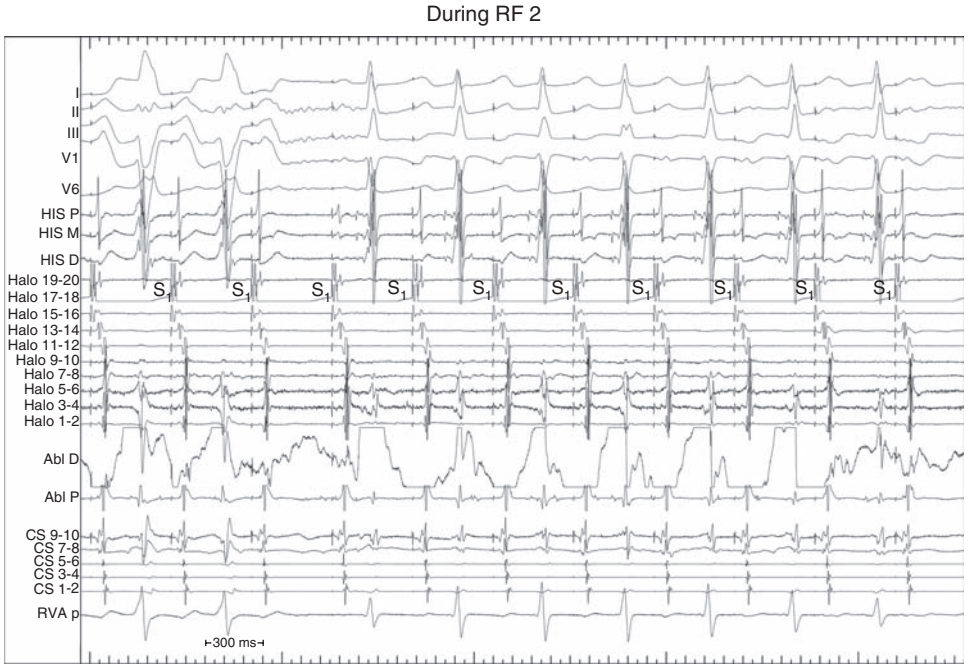

Figure 7-25

Shortly after beginning RF application during atrial pacing, preexcitation suddenly disappears as the pathway has been eliminated (Fig. 7-25).

Atrial Pacing Postablation

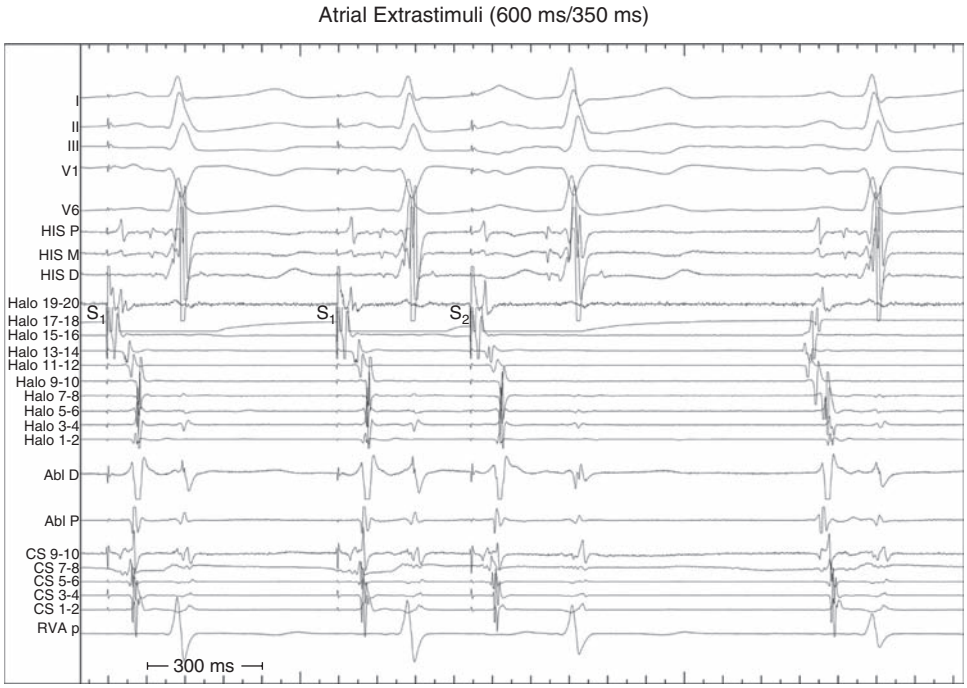

Figure 7-26

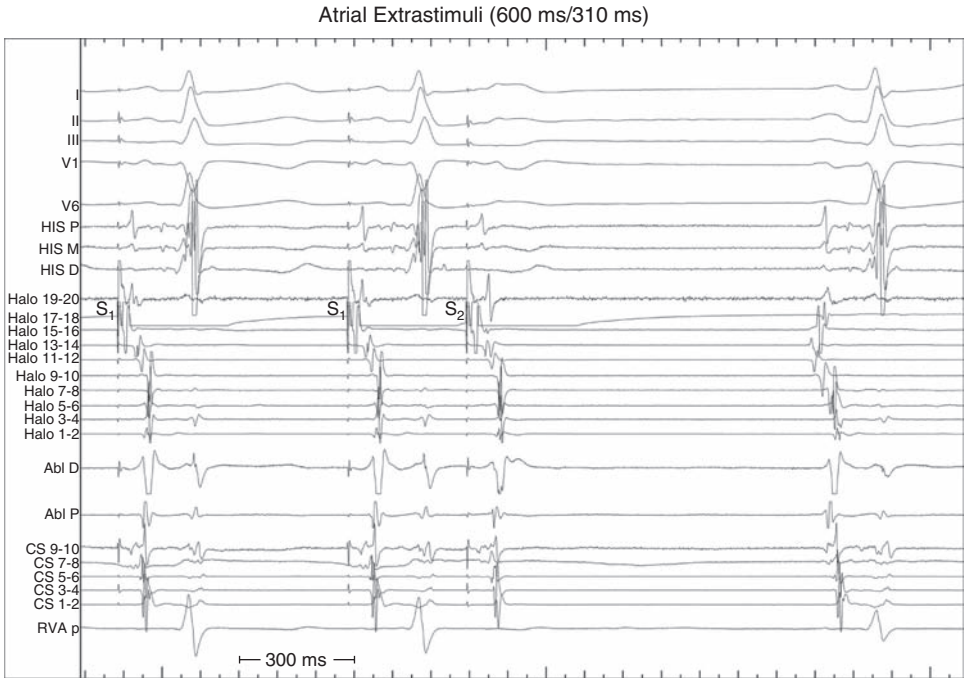
In Fig. 7-26, atrial extrastimuli delivered after successful ablation show only conduction over the AV node–His-Purkinje system and no preexcitation.

Figure 7-27

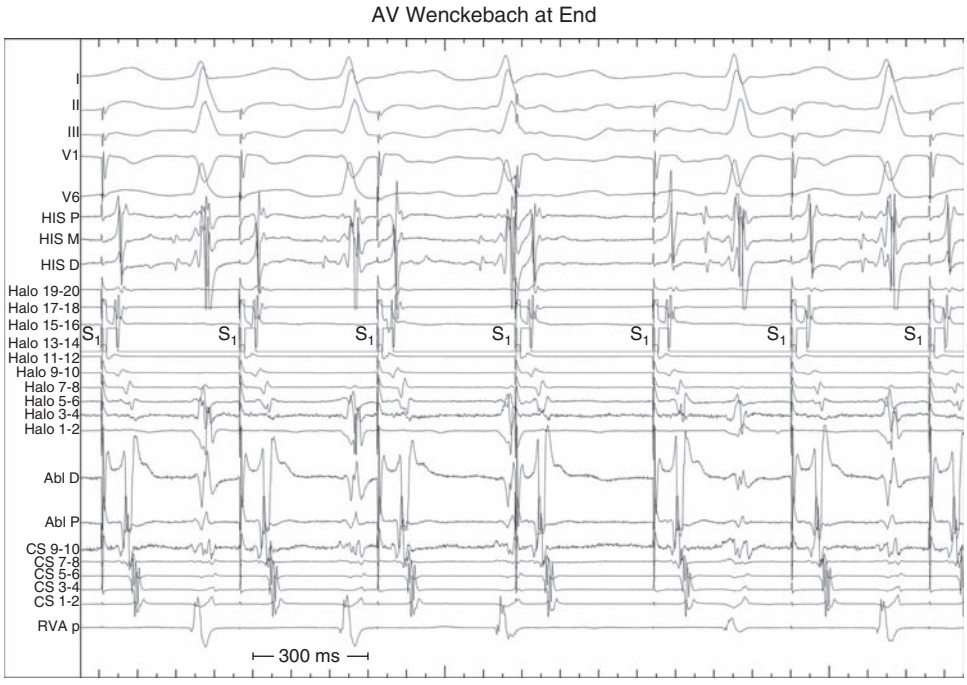
The same coupling intervals as had shown preexcitation before ablation no longer do so, as shown in Fig. 7-27.

Figure 7-28



An atrial extrastimulus results in AV nodal refractoriness; before successful ablation, this would have conducted over the atriofascicular pathway to the ventricle (Fig. 7-28).

Figure 7-29



At the end of the procedure, AV conduction was exclusively over the AV node–His-Purkinje system. Atrioventricular Wenckebach is shown in Fig. 7-29.

Final Fluoroscopy

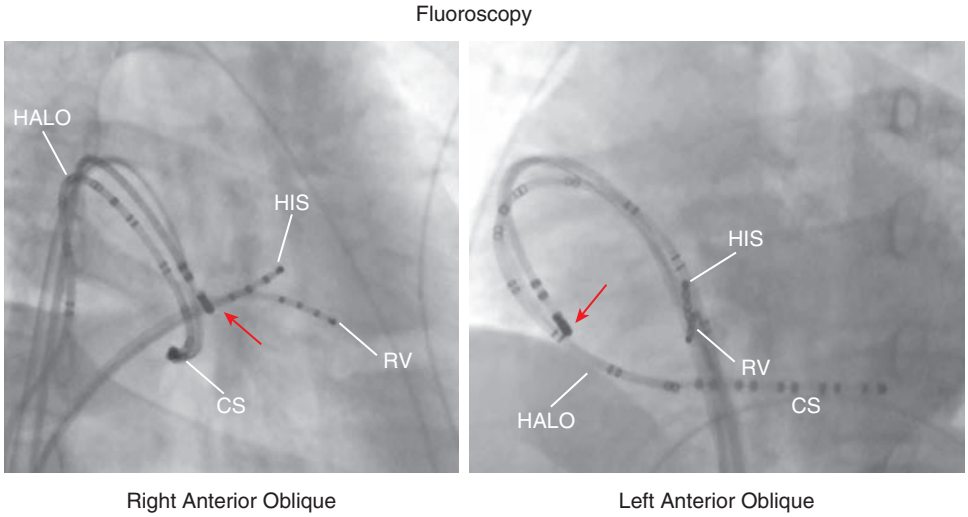


Figure 7-30

Fluoroscopic views of catheter positions at the time of successful ablation are shown in Fig. 7-30. The mapping/ablation catheter (tip indicated by a *red arrow*) is looped around the tricuspid annulus, a technique that is sometimes helpful for maintaining catheter stability. The coronary sinus catheter was also looped around the tricuspid annulus, as was the Halo catheter.

Principles of Mapping Atriofascicular Pathways

Methods for mapping/ablation of atriofascicular pathways include targeting the following:

- Pathway potential
  - At tricuspid annulus
  - In ventricle, be careful (if RBBB occurs this results in longer path length, incessant SVT)
- Site at which longest atrial extrastimulus coupling interval during SVT advances next QRS
- Site at which shortest S-QRS with atrial pacing is seen
- Site at which pace mapping at tricuspid annulus exactly replicates preexcitation pattern
- Site at which catheter manipulation damages pathway
  - Be VERY careful—trauma may somnify pathway for prolonged periods

Summary

- Atriofascicular pathways are rare but full of physiology
- Clues to diagnosis:
  - Multiple episodes of LBBB SVT
  - Delayed R-wave progression in LBBB SVT
- Antidromic reciprocating tachycardia (ART) can mimic AVNRT with LBBB
  - ECG looks like LBBB; His position may be unstable (thus not consistently seen)
  - Earliest retrograde activation is at AVN fast pathway
  - Differentiation:
    - His occurs before (AVNRT) or after (ART) QRS onset
    - ΔHA interval (AVNRT $>$ +10 ms, ART $\approx$ 0 ms)
      - His activation in ART is retrograde (anterograde in AVNRT)
      - Second bypass tract is excluded by ΔHA interval (ART $\approx$ 0 ms, preexcited ORT $<$ −10 ms)

8 Slowly Conducting Bypass Tract Supraventricular Tachycardia

Case Presentation

A 20-year-old woman had been experiencing palpitations and near syncope with increasing frequency over the last 2 years. Beta blockers were used in the past but to no avail. She had several emergency room (ER) visits in the interim where supraventricular tachycardia (SVT) episodes were terminated with intravenous adenosine termination. The electrophysiologist was called at 2 AM one day when the patient was in incessant SVT at an outside hospital ER (despite multiple adenosine doses) and hypotensive. She was also 30 weeks pregnant with her third child. She was transferred to our hospital for further therapy. Options considered: medical therapy (but what medications are effective and safe during pregnancy?) or catheter ablation (but what about fluoroscopic exposure to the unborn child?).

Prior SVT ECG

What Is the Differential Diagnosis? [Fig. 8-1]

Figure 8-1

Figure 8-1 displays a so-called "long-RP" supraventricular tachycardia with inverted P waves in inferior leads. The differential diagnosis for this rhythm includes atrial tachycardia from the low septum/region of the coronary sinus ostium; atypical "fast-slow" AV nodal reentry; automatic junctional tachycardia; and orthodromic SVT using a slowly conducting bypass tract. She clearly needs some treatment not only for her but also for her baby's health.

Her SVT stopped by the time of arrival to our hospital, without recurrence for several hours. She and her family were uncertain about ablation. Medical therapy with sotalol (relatively safe in pregnancy) was recommended. After one dose of sotalol (80 mg), nearly incessant SVT occurred, lasting 20 to 30 min at a time, stopping for a few seconds and resuming; episodes started with either P or QRS. Because of the poor response to medical therapy, catheter ablation was then recommended.

Electroanatomic "Shell" [Fig. 8-2]

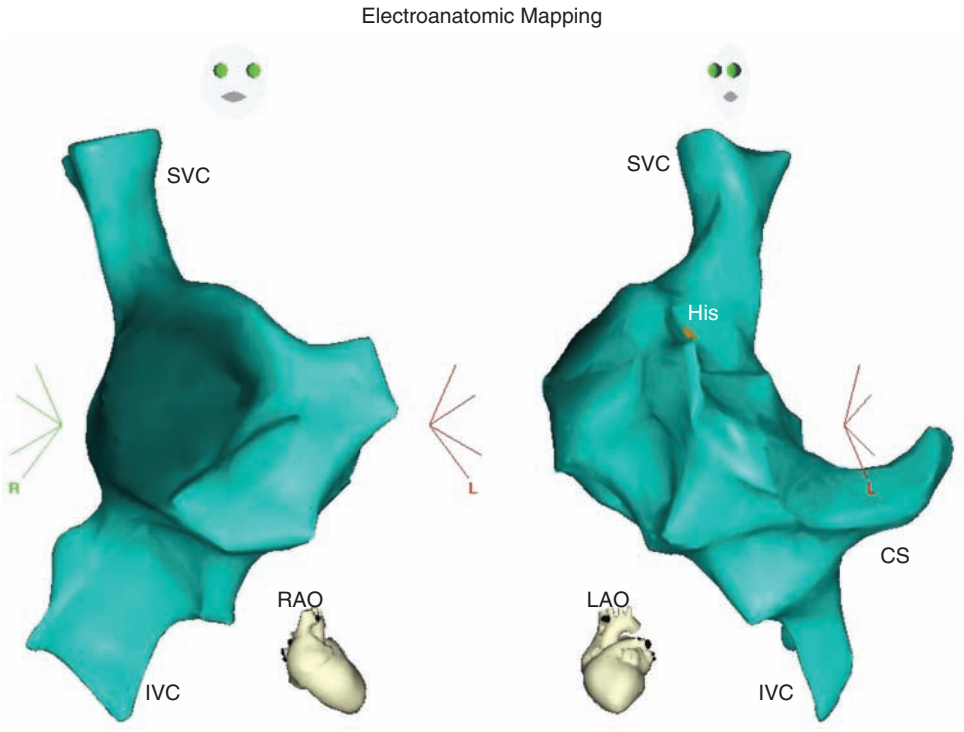

Figure 8-2

At the electrophysiology (EP) study, electroanatomic mapping and stereotactic remote magnetic catheter navigation were used. First, the mapping/ablation catheter was used for delineation and recording of anatomy on an electroanatomic mapping system (navigating to His, coronary sinus (CS), and characterizing the extent of the RA chamber; Fig. 8-2). SVC, superior vena cava; IVC, inferior vena cava; CS, coronary sinus; RAO, right anterior oblique; LAO, left anterior oblique.

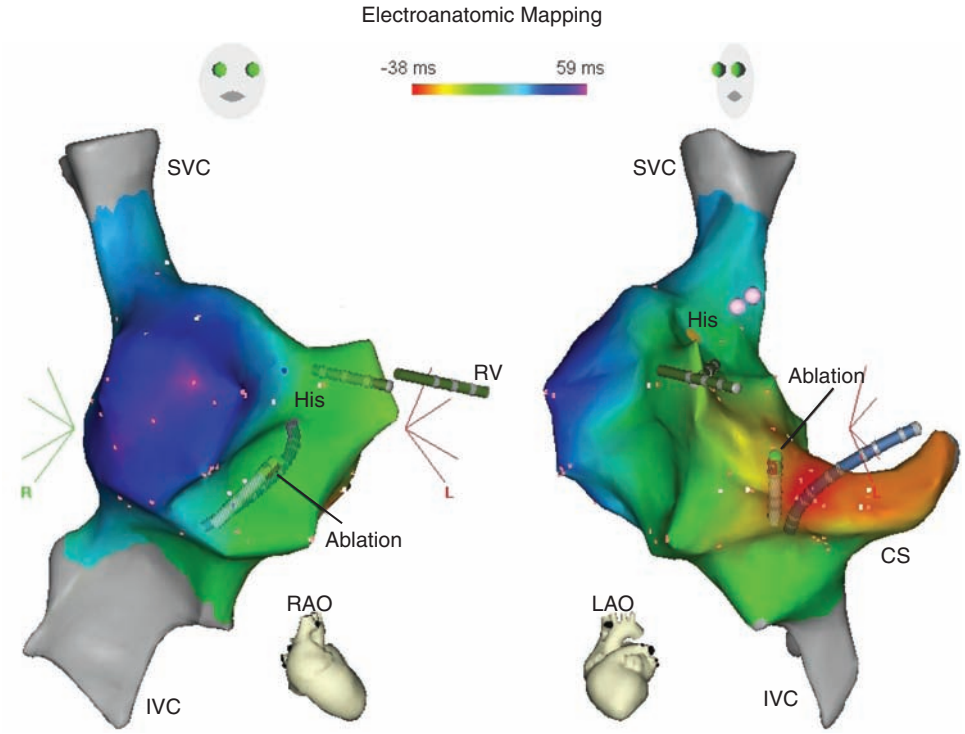

Figure 8-3

Once the anatomy was clear, other electrode catheters were guided into place at previously determined locations (CS, high RA, RV, His) using the electroanatomic map (Fig. 8-3). Representations of the electrode catheters in these locations are as shown. Activation mapping was performed, using a stable CS electrogram as timing reference; all of this was accomplished without use of fluoroscopy. Mapping showed earliest atrial activation at the proximal CS (*red area*). Of note, this is consistent with any of the diagnostic possibilities and does not differentiate among them. Thus EP testing was performed to determine the precise diagnosis. RA, right atrium; RV, right ventricle.

Baseline Intracardiac Recordings During Sinus Rhythm and SVT

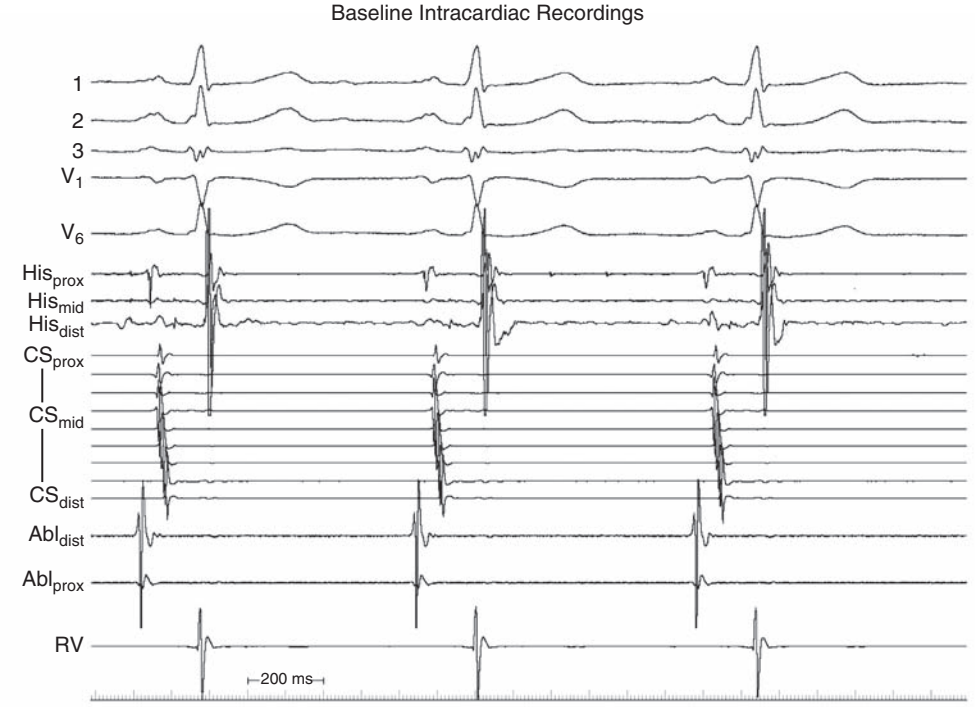

Figure 8-4

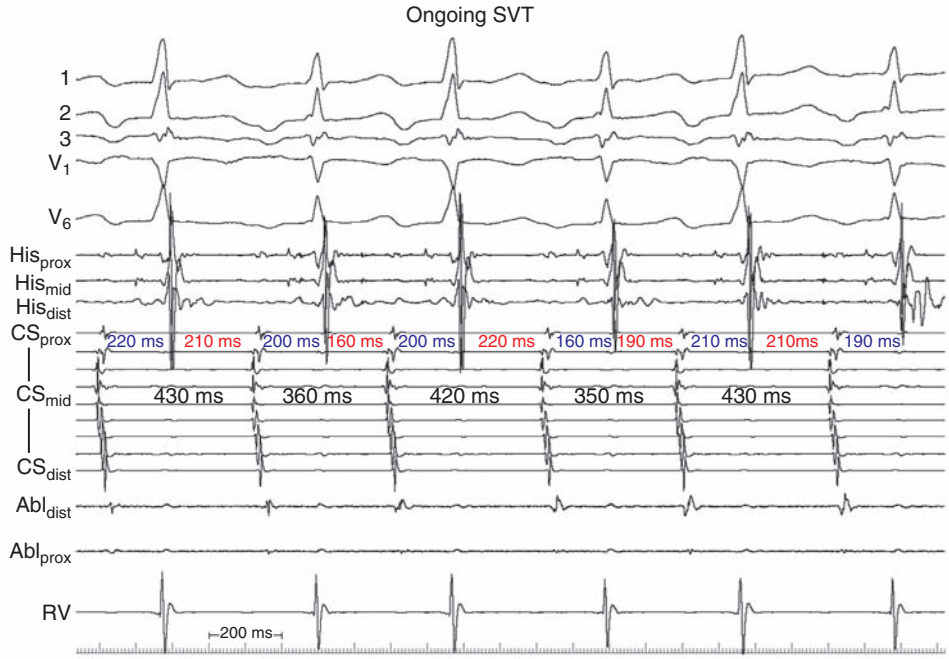
Baseline intracardiac recordings are as shown in Fig. 8-4 during sinus rhythm; as anticipated, SVT was readily initialed by a variety of means including spontaneously or following ventricular (VPC) or atrial (APC) premature complexes.



What Can You Diagnose From This, If Anything? [Fig. 8-5]

Figure 8-5

SVT was rather irregular. Whenever this is the case, it is an opportunity to determine which electrograms depend on others and which are "leaders" that other recordings follow. In Fig. 8-5, cycle length (A-A) intervals are shown in *black*, A-V intervals in *blue*, and VA intervals in *red*. There does not seem to be a consistent relationship of one recording definitely leading to another. Irregularity of tachycardia cycle length significantly hampers use of pacing maneuvers, most of which implicitly rely on a regular cycle length to provide a predictable occurrence of the next SVT complex after a pacing-induced perturbation (such as single extrastimuli or trains of pacing). For instance, if the SVT CL is very irregular, it is very difficult to compare the postpacing interval (PPI) to tachycardia CL (TCL) as an indicator of proximity of the pacing site to a tachycardia circuit.

Ventricular Extrastimuli and Overdrive Pacing in SVT

Does This Help? [Fig. 8-6]

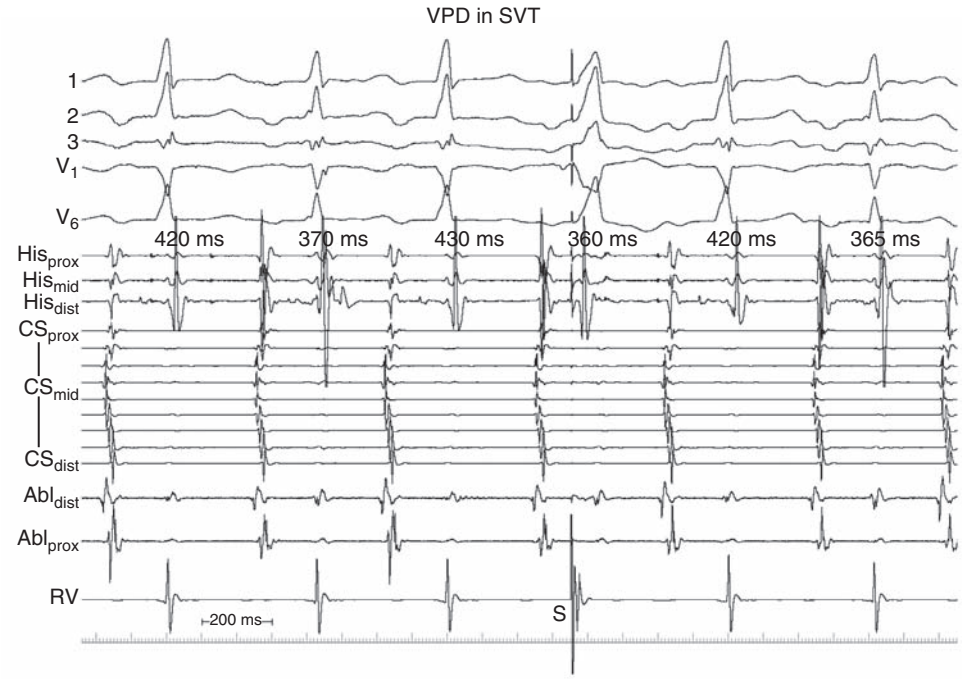


Figure 8-6

In Fig. 8-6, a single ventricular extrastimulus is delivered during SVT. This was difficult to do because the CL was very irregular and timing a ventricular extrastimulus to occur at a time when the His bundle was refractory was a matter of chance. Though one such event is shown here (His-refractory extrastimulus, Fig. 8-6), can anything be inferred from its effect? The atrial recording after the extrastimulus occurs earlier than others and in fact has a slightly shorter A-A interval than any others. The interval surrounding the extrastimulus has to be meaningfully shorter than any other A-A interval in order to use it as evidence for the presence of an atrioventricular bypass tract. The difference between this A-A interval (360 ms) and the shortest spontaneously occurring interval during SVT (365 ms) is very small, and so this should not be the only evidence used to make a diagnosis of a bypass tract.

Does This Help? [Fig. 8-7]

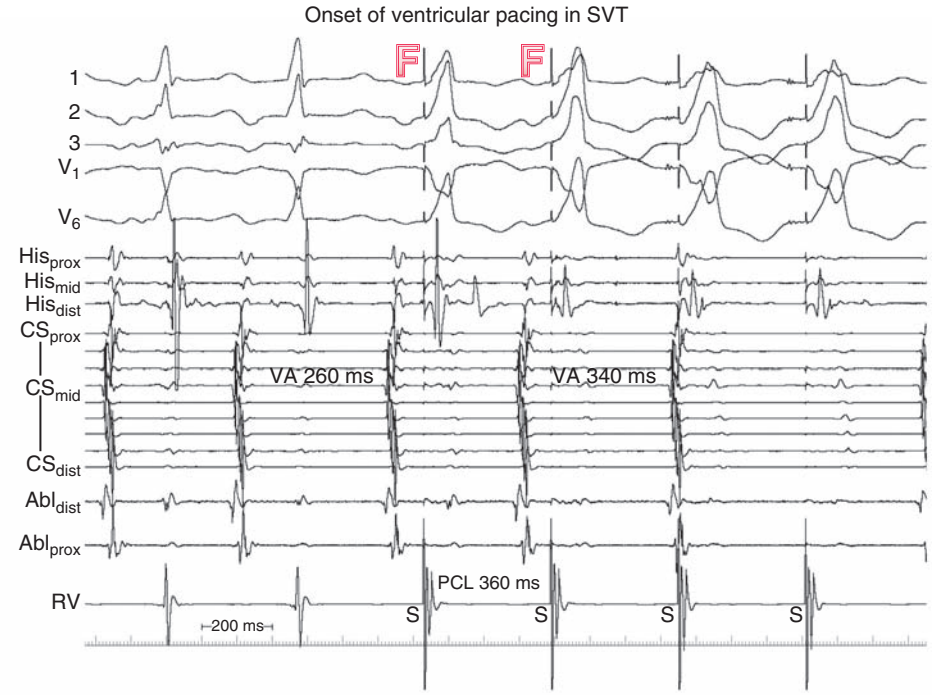

Figure 8-7

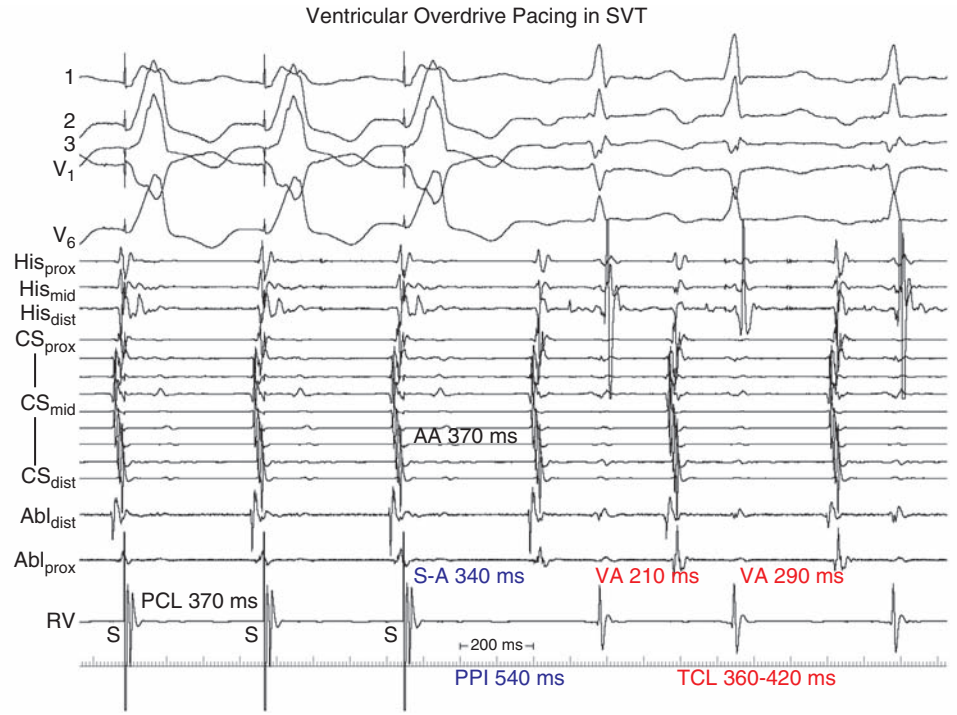
Similarly, interpreting the results of overdrive pacing during SVT can be difficult in the presence of significant CL variability. In Fig. 8-7, at the initiation of overdrive ventricular pacing, the second stimulus is followed by an atrial electrogram that occurs much later than anticipated (VA interval 340 ms). This occurred in response to a paced complex that is a fusion (F) between tachycardia and fully paced complexes (the last two). Because the timing of atrial activation was altered at time when the His had been anterogradely activated, this indicates that there is an extranodal pathway over which atrial activation can occur in response to ventricular stimulation. Further, the fact that the atrial activation is delayed from when it would be expected to occur shows that the pathway is not only present but also participates integrally in SVT. Thus a diagnosis of orthodromic SVT is established (stronger if this is a reproducible finding). Note that SVT terminated during continued pacing (no atrial electrogram after the second to last QRS complex).



Does This Help? [Fig. 8-8]

Figure 8-8

At the end of another attempt at ventricular overdrive pacing, SVT resumes. The usual interval measurements are made, with uninterpretable results: the PPI-TCL difference ranges from 120 ms (consistent with bypass tract SVT) to 180 ms (inconsistent with bypass tract SVT) (Fig. 8-8). Similarly, the stimulus-atrial (SA) minus ventriculoatrial (VA) interval difference ranges from 50 ms (consistent with bypass tract SVT) to 130 ms (not consistent with bypass tract SVT). The problem is that the retrograde limb has cycle length–dependent slowing of conduction ("decremental conduction") that invalidates the measurements.

Atrial Pacing at SVT Cycle Length Compared with SVT

Does This Help? [Fig. 8-9]

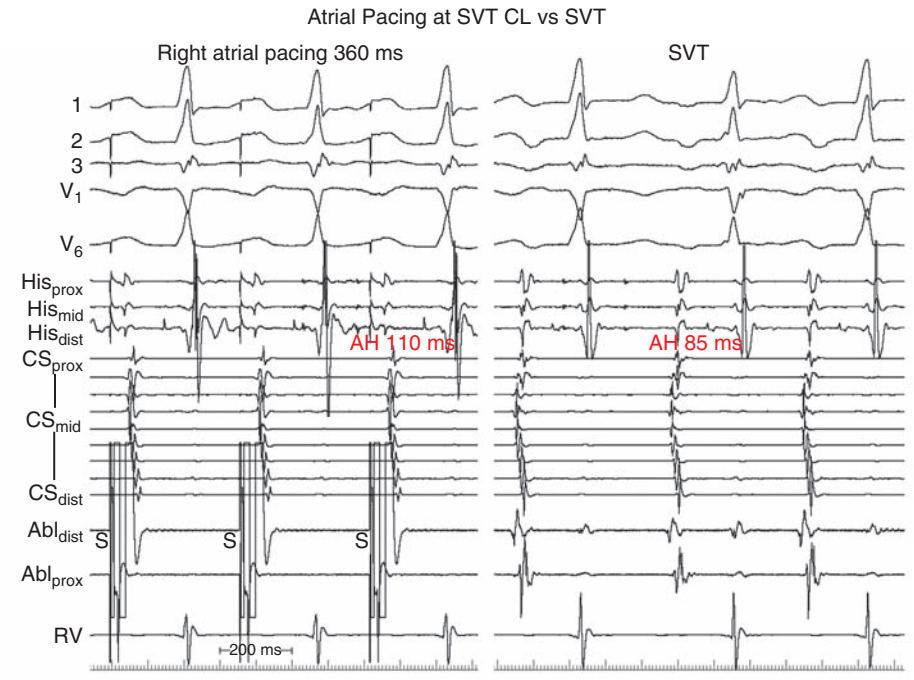


Figure 8-9

To exclude an (unlikely) atrial tachycardia, the atrio-His (AH) interval is compared between that during SVT and during atrial pacing at the SVT CL. If a right atrial tachycardia, the AH intervals should be similar; with orthodromic SVT, the difference between paced and SVT AH intervals is typically 20 to 40 ms, whereas with atypical AV nodal reentry the difference is usually ≥40 ms. Here, the difference of 35 ms is consistent with orthodromic SVT (Fig. 8-9).

Spontaneous SVT Termination

Does This Help? [Fig. 8-10]

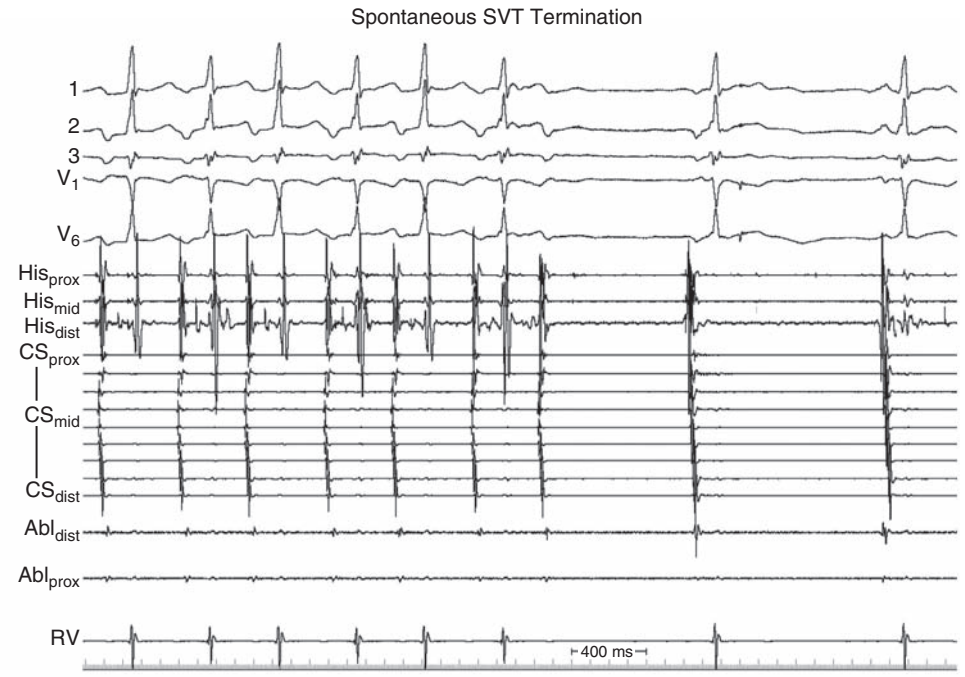

Figure 8-10

Another means of excluding atrial tachycardia as a diagnosis occurred spontaneously here—tachycardia terminates spontaneously with the last event being atrial. An atrial tachycardia with 1:1 AV conduction would not be likely to terminate suddenly at the same instant as AV block occurred (Fig. 8-10).

Comparison of Features and Behavior of Different SVTs

TABLE 8-1 Truth Table

	Atrial Tachycardia	Orthodromic SVT	Atypical (F-S) AVNRT	Junctional Tachycardia
Onset	A first	A or V first	A or V first	V first
Irregularity	A predicts V	V predicts A	V predicts A	V predicts A
His-refract. VPC	No effect	Adv. or delay A	No effect	No effect
Post-V overdrive	No VAC/VAAV	VAV	VAV	VAV
V entrainment	(NA)	SA − VA < 85 ms PPI − TCL < 115 ms	SA − VA > 85 ms PPI − TCL > 115 ms	SA − VA > 85 ms PPI − TCL > 115 ms
Post-A overdrive	AVAV	AVAV	AVAV	AVVA
Delta HA	(NA)	$HA_{SVT} > HA_{Pace}$	$HA_{SVT} < HA_{Pace}$	$HA_{SVT} = HA_{Pace}$
Delta AH	$AH_{SVT} \leq AH_{Pace}$ (10–20 ms)	$AH_{SVT} < AH_{Pace}$ (20–40 ms)	$AH_{SVT} < AH_{Pace}$ (>40 ms)	$AH_{SVT} > AH_{Pace}$
Termination	After V	After A or V	After A or V	After A

A, atrial; AH, atrio-His interval; AHpace, AH during atrial pacing at tachycardia cycle length; AHSVT, AH during SVT; AVAV, sequence of atrial and ventricular events after overdrive pacing; AVNRT, atrioventricular nodal reentrant tachycardia; AVVA, sequence of atrial and ventricular events after overdrive pacing; HA, His-atrial interval; HASVT, HA during SVT; HApace, HA during ventricular pacing at tachycardia cycle length; PPI, post-pacing interval; SA, stimulus-atrial interval; SVT, supraventricular tachycardia; TCL, tachycardia cycle length; V, ventricular; VA, ventriculo-atrial interval; VAV, sequence of atrial and ventricular events after overdrive pacing; VAAV, sequence of atrial and ventricular events after overdrive pacing; VPC, ventricular premature complex.

Table 8-1 is a comparison of features of different types of SVT that are in the differential diagnosis of this SVT. Based on the preponderance of data, orthodromic reentry was diagnosed.

Site of Ablation

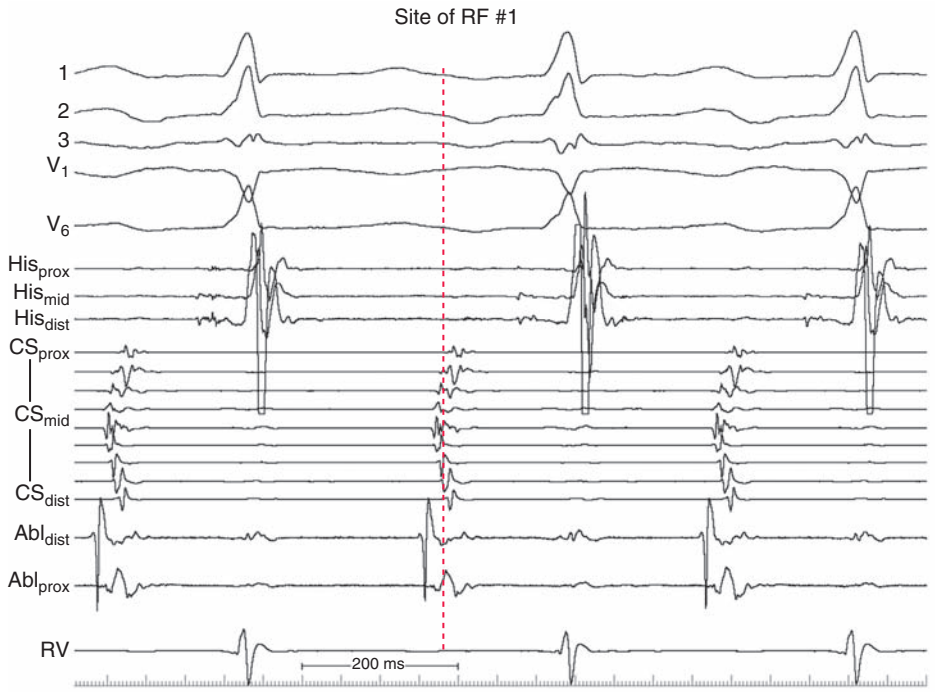

Figure 8-11

With a secure diagnosis, an ablation site may be sought; slowly conducting/decrementally conducting bypass tracts are usually located around the coronary sinus ostium, where more precise mapping began. In Fig. 8-11, a large, sharp potential on the ablation distal recording is seen followed by a more far-field potential. The atrial recording in the proximal electrode suggests that this far-field recording is atrial. The ventricular recording is small and similarly relatively far-field appearing. Because the large potential appears separate from the atrial potential, it is a good candidate for a bypass tract potential. Because of the constraints of cycle length variability, it was not feasible to perform pacing maneuvers to validate this as a true bypass tract potential.

During Ablation SVT Ceases

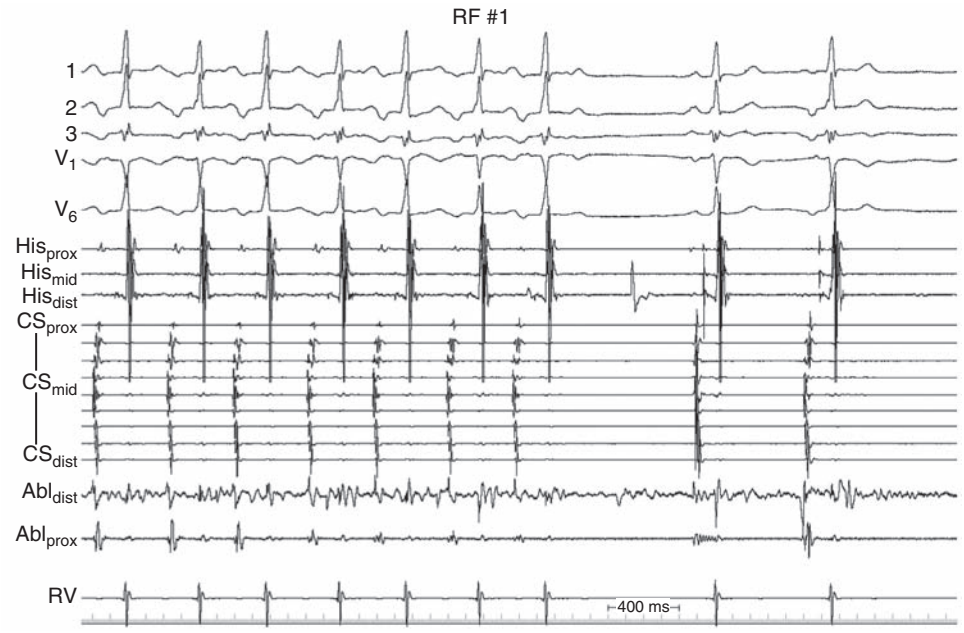

Figure 8-12

RF application at this site terminated SVT within 8 seconds of onset of power delivery (Fig. 8-12). Additional applications were made during sinus rhythm to consolidate the damage.

Ventricular Pacing Postablation

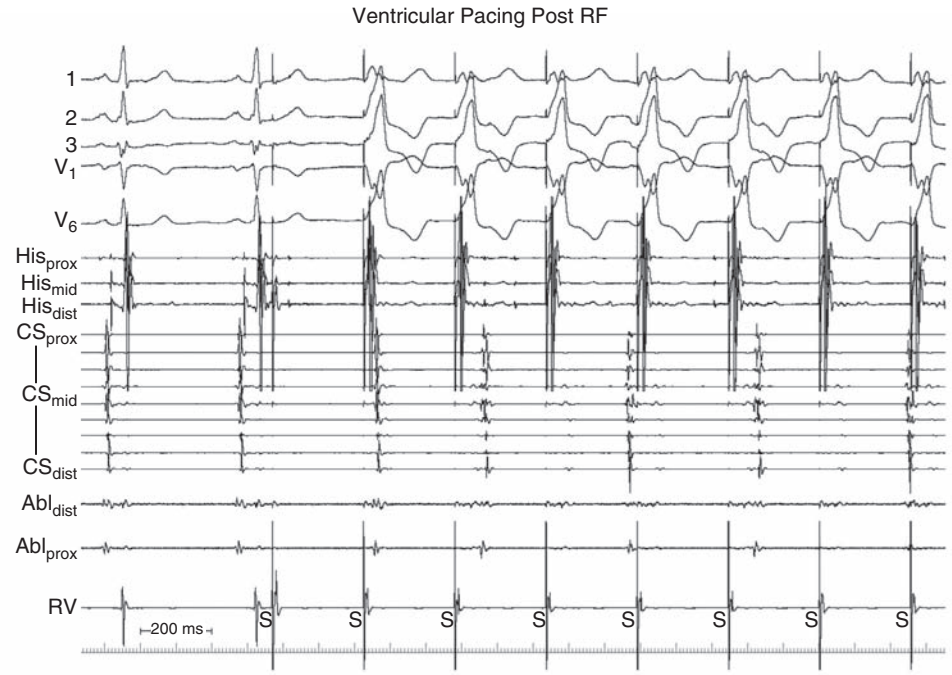

Figure 8-13

After ablation (Fig. 8-13), retrograde conduction was poor and concentric; in contrast to the preablation situation, SVT could not be initiated baseline or after isoproterenol infusion.

Final ECG

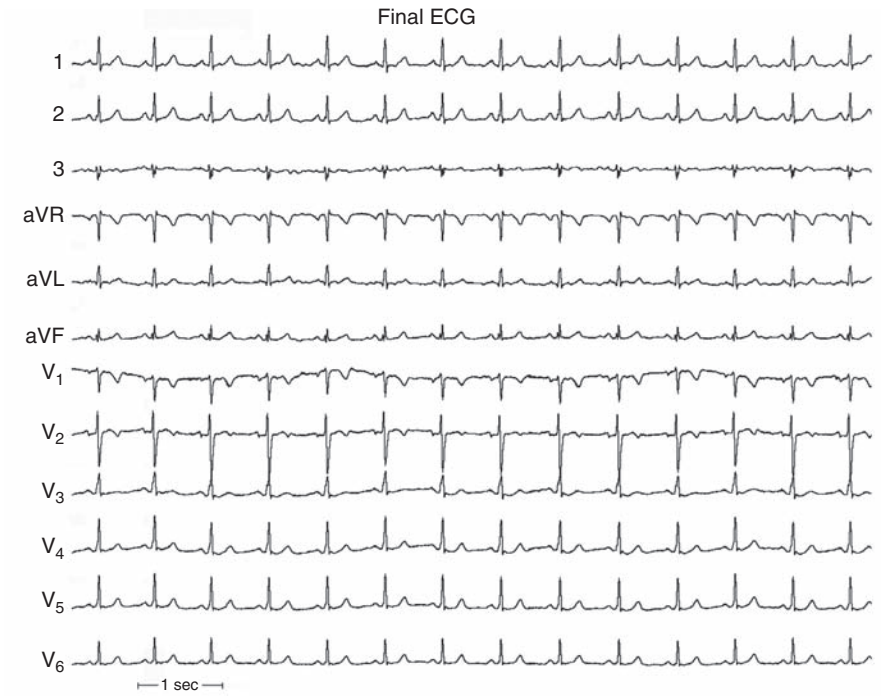

Figure 8-14

Sinus rhythm was present at the end of the procedure and SVT has not recurred (Fig. 8-14). Fetal monitoring throughout the procedure showed no adverse effects on the unborn child (a healthy baby girl, born 8 weeks later).

Electroanatomic Map

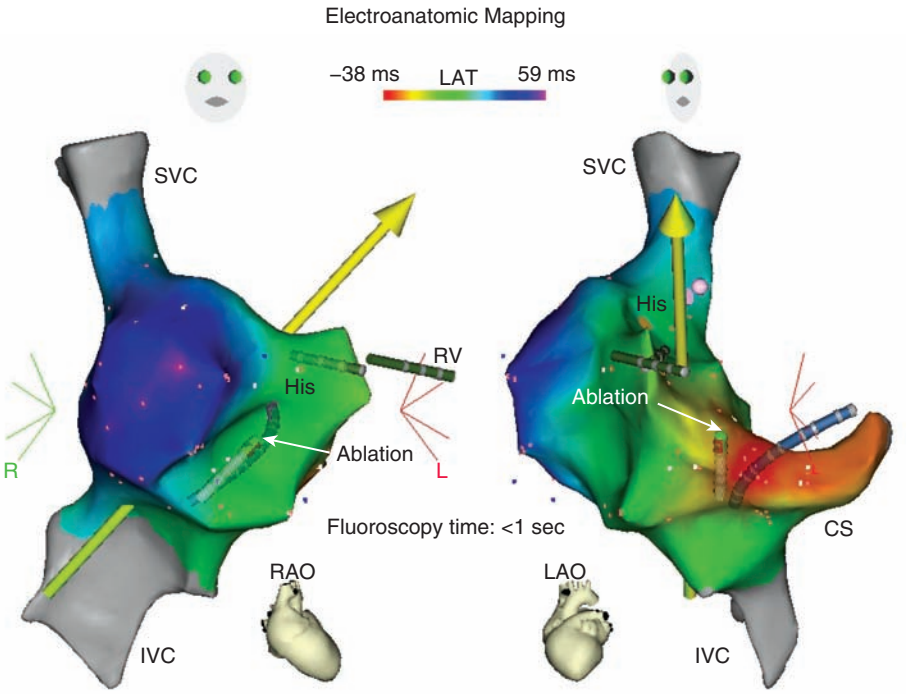

Figure 8-15

The *red area* on the image at the right of the previously shown activation map during SVT (Fig. 8-15) indicates the ablation site. Fluoroscopic exposure was <0.5 seconds (for registration of the patient and electroanatomic system at the beginning of the procedure; no fluoroscopy was used thereafter).

Summary

- A correct diagnosis can almost always be made if the correct tools are used and correct interpretations made
- Significant cycle length variability hampers diagnosis, but can make mapping easier (it is usually clear whether the electrogram of interest leads or follows other recordings)
- Current tools allow drastic limitation in fluoroscopic exposure, including <1 minute in some cases

Fasciculoventricular Pathway 9

Case Presentation

A 13-year-old girl presented with palpitations and lightheadedness for 2 years. She is an orphan, adopted shortly after birth. A muscular ventricular septal defect was detected in early childhood and repaired surgically. She did well until the current syndrome of palpitations developed; these increased in frequency and severity over the 2 years leading up to this evaluation. Physical exam was normal without residual murmur. Her resting ECG showed sinus rhythm with preexcitation. An event monitor was obtained, showing supraventricular tachycardia (SVT) at 250/min. At a prior electrophysiology (EP) study, atrial tachycardia at 250/min was induced, but not mapped or ablated; dual atrioventricular (AV) nodal pathways were observed; preexcitation was noted but not ablated due to proximity to the normal conduction system. Due to continued episodes of palpitations, she was referred for repeat EP study and possible ablation.

Baseline ECG and Intracardiac Recordings

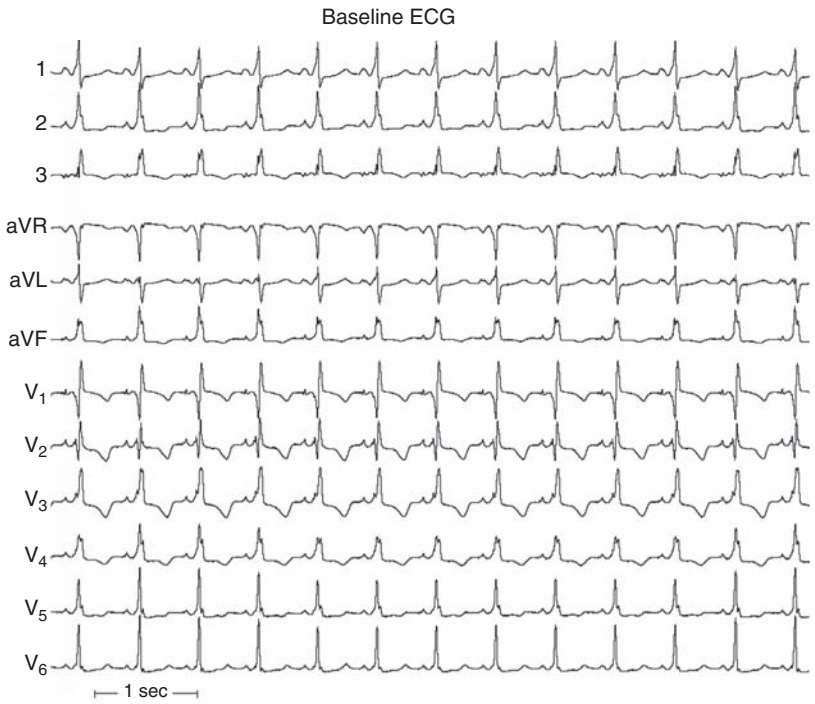

Figure 9-1

The baseline ECG in Fig. 9-1 shows a short PR interval and preexcitation with a pattern suggesting a midseptal pathway insertion. The terminal R′ in V1 and V2 hints that there may be right bundle branch block when preexcitation is absent.

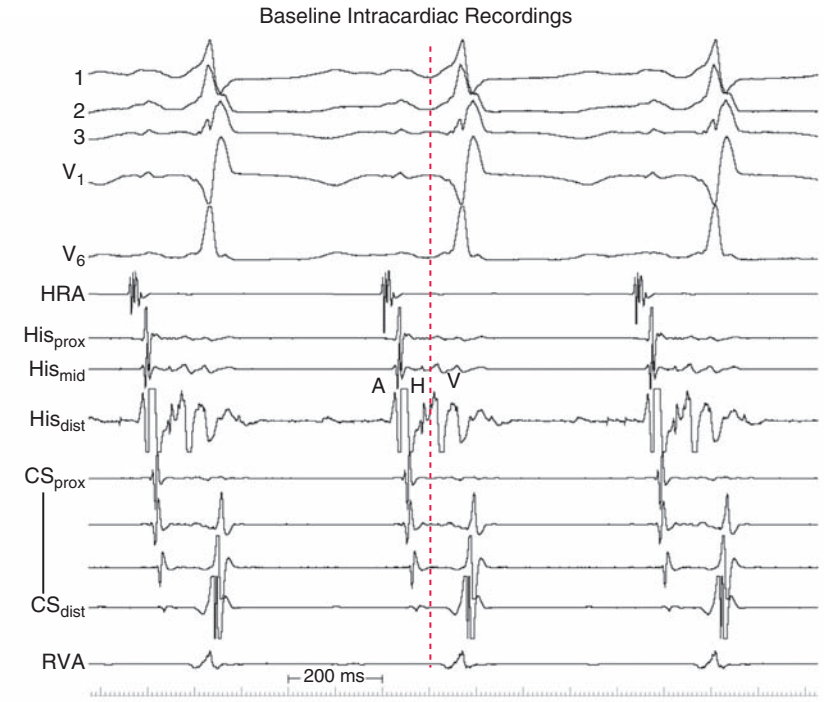

Figure 9-2

Baseline intracardiac recordings confirm preexcitation and show a His potential (H) just before the QRS onset *(dotted line)* with an HV interval 22 ms (Fig. 9-2).

Ventricular Pacing

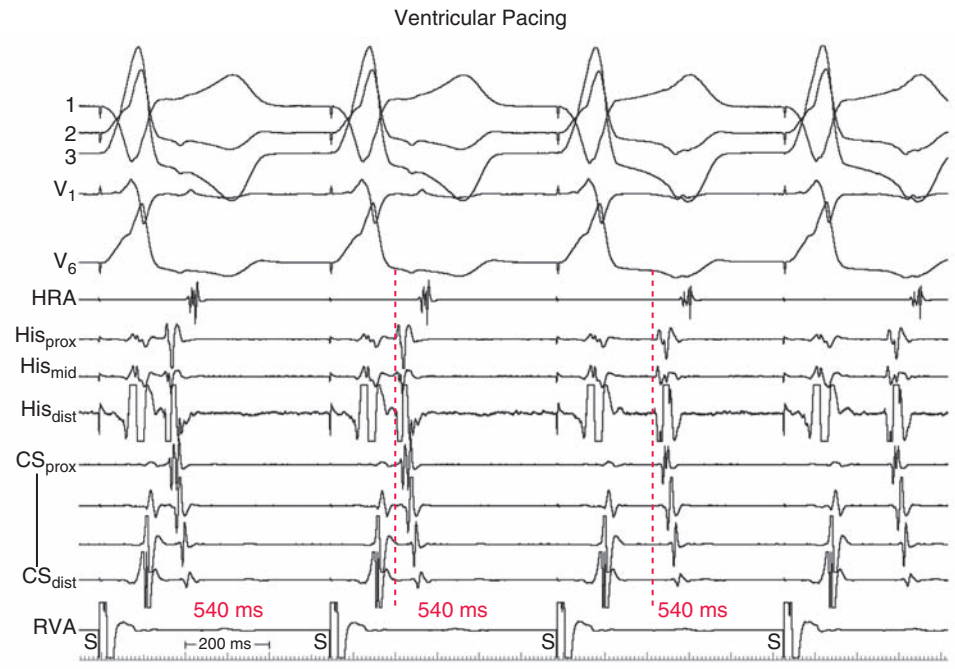

Figure 9-3

Decremental ventricular pacing (Fig. 9-3) shows a concentric activation sequence with a sudden increase in the ventriculo-atrial (VA) interval *(arrows)* without change in pacing rate. Wenckebach VA block occurred at paced cycle length 470 ms. After isoproterenol, VA

Wenckebach block occurred at cycle length 440 ms. Thus because VA conduction characteristics are those of the AV node, the bypass tract either has AV nodal-like properties (very rare) or does not appear to have retrograde conduction.

Atrial Pacing

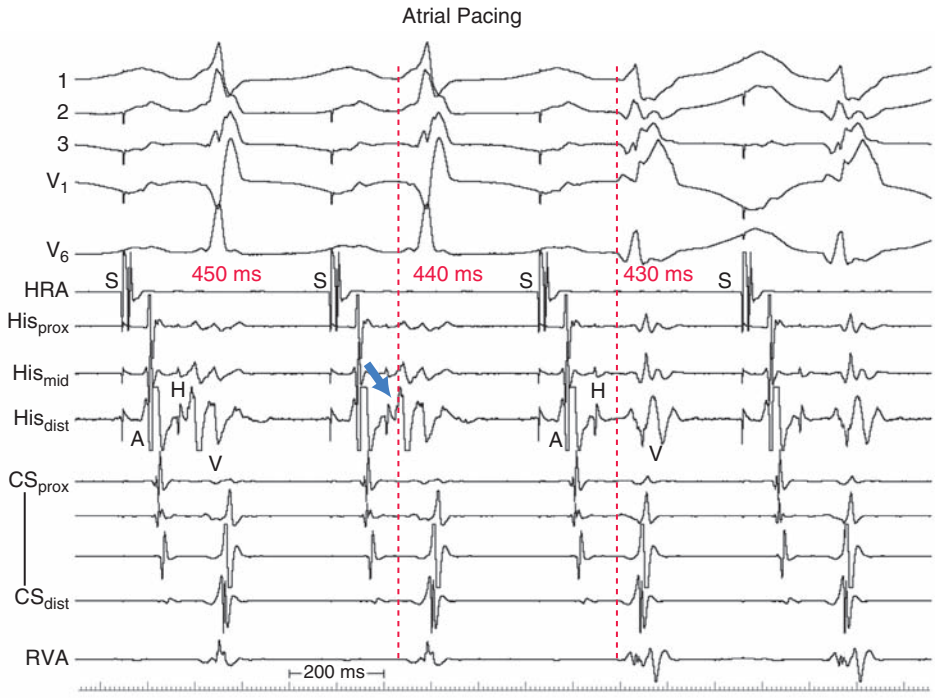

Figure 9-4

With progressively rapid atrial pacing (Fig. 9-4), sudden block in the bypass tract is observed (third and fourth complexes). Coincident with this, the HV interval prolongs from 22 to 50 ms. Of note, right bundle branch block is present in the nonpreexcited beads, as anticipated from the original surface ECG. With the loss of preexcitation, it is evident that early ventricular activation over the pathway had occurred near the His bundle *(arrow)*.

Atrial Extrastimuli

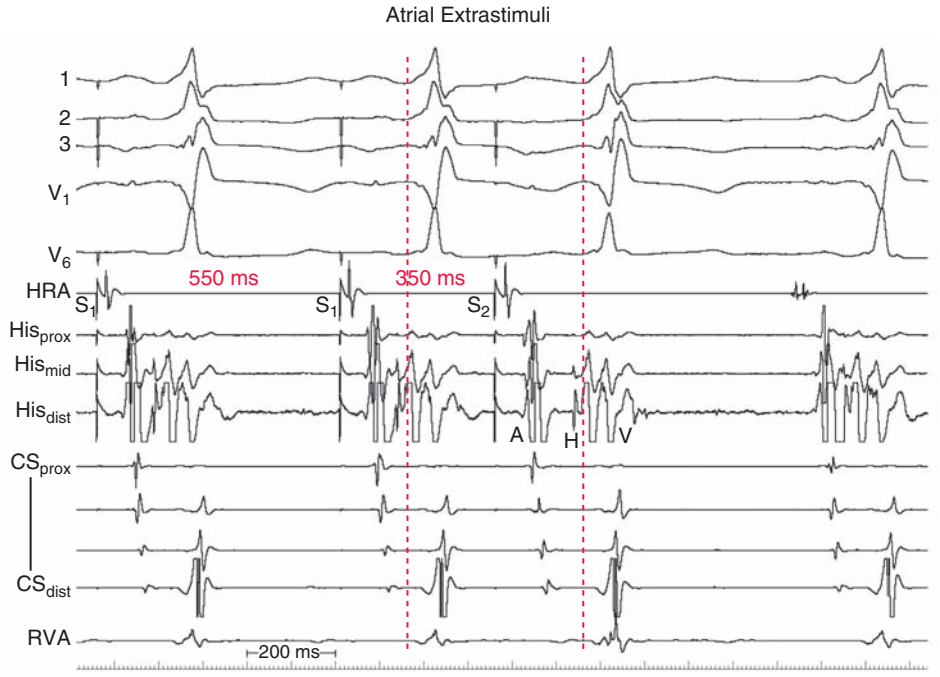

Figure 9-5

In response to atrial premature stimulation, preexcitation persists; the AH interval increases by an anticipated amount consistent with AV nodal behavior (Fig. 9-5). However, the HV interval and preexcitation pattern are unchanged from the drive complexes. *Dashed lines* indicate onset of QRS complexes.

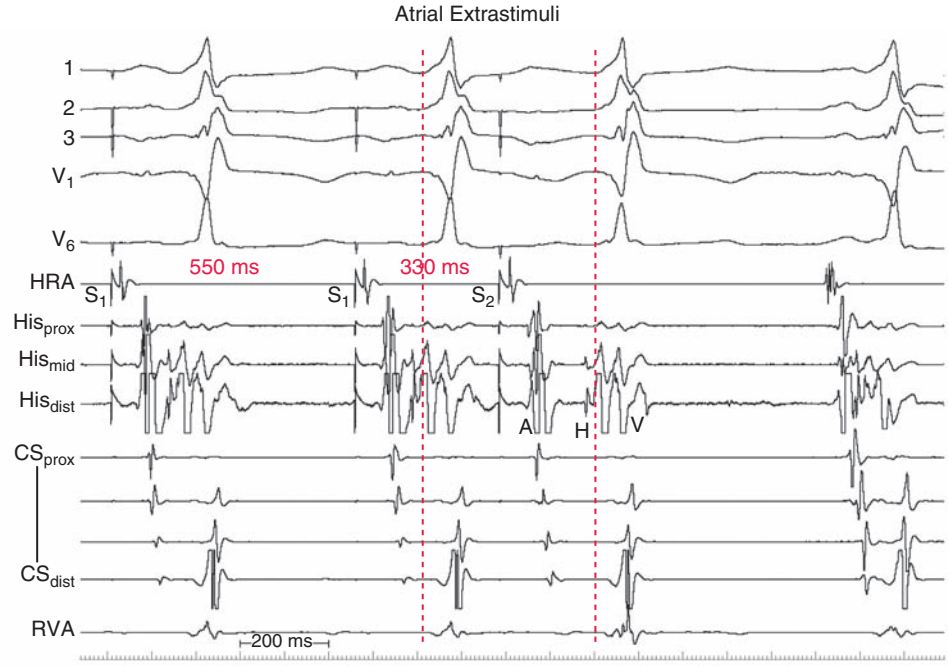

Figure 9-6

With more premature stimulation, preexcitation again persists; the AH interval also increases but the HV interval and preexcitation pattern are unchanged from the drive complexes (Fig. 9-6). This is not typical for the usual atrioventricular pathway, with which the stimulus-delta interval is largely fixed, such that prolongation of the AH interval results in a greater degree of preexcitation and shorter (or even negative) HV interval. Instead, in this case, the HV remains fixed and short, and preexcitation is constant regardless of the AH

interval. These are characteristics of a fasciculoventricular pathway. *Dashed lines* indicate onset of QRS complexes.

Atrial Pacing at Various Rates

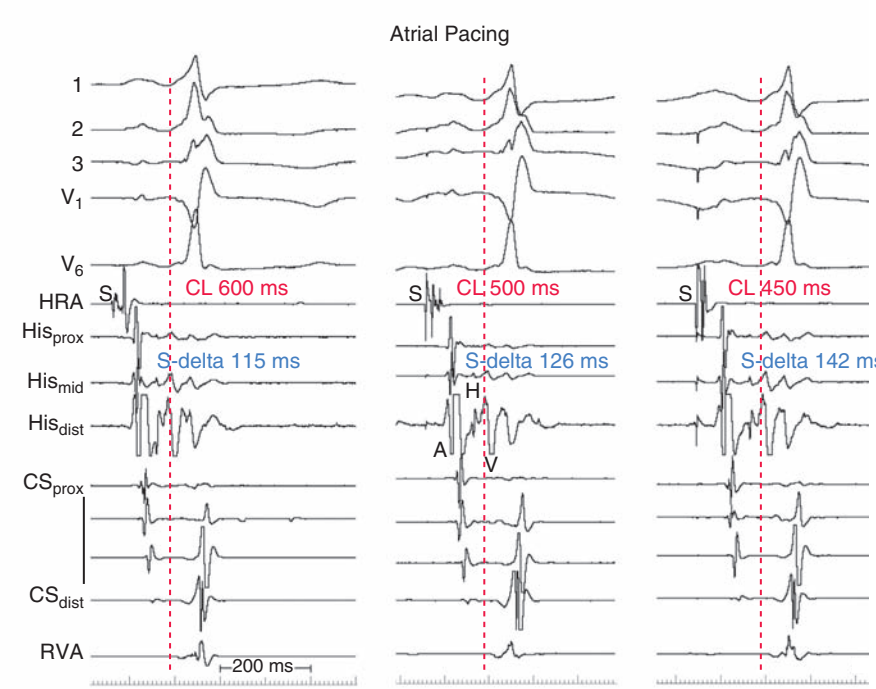

Figure 9-7

In Fig. 9-7 a single complex of atrial pacing at different cycle lengths is shown. It is evident that with progressive shortening of the atrial-paced cycle length, an increase in the S-delta interval occurs. This is because of increase in the AH interval, whereas the HV interval remains fixed at 22 ms and the degree of preexcitation remains unchanged. With standard atrioventricular bypass tracts, there is little if any change in the stimulus-delta interval with faster atrial pacing; because the AH interval lengthens under these conditions, but bypass tract conduction remains rather fixed, a greater proportion of ventricular activation is controlled by bypass tract conduction leading to greater degrees of preexcitation and shortening of the HV interval. The findings in this figure are again most consistent with a fasciculoventricular pathway—one that connects the His bundle with ventricular muscle. With these pathways, the amount of preexcitation does not vary regardless of rate of stimulation or prematurity, and unless there is block in the pathway, whenever the His is activated anterogradely, a preexcited complex ensues.

Junctional Escape Complex

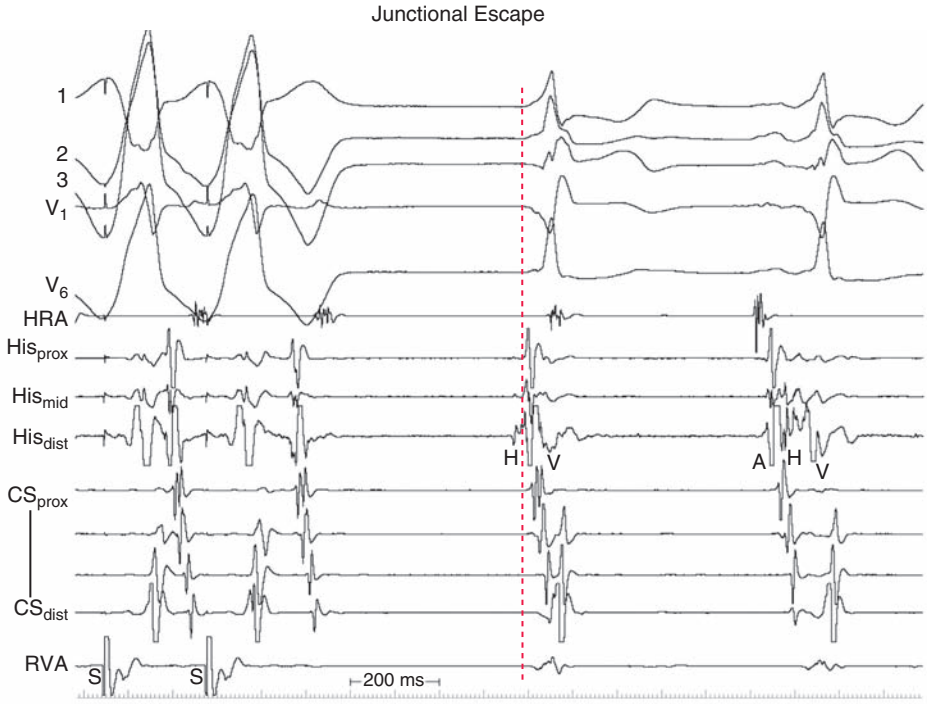

Figure 9-8

One of the strongest lines of evidence for the existence of a fasciculoventricular pathway is shown in Fig. 9-8, with a junctional (His bundle) escape complex after a burst of rapid ventricular pacing. (This technique, when retrograde conduction is present, can suppress the sinus node such that a junctional escape complex may occur.) The junctional escape complex has a pattern of preexcitation identical to that of complexes conducted from the atrium, indicating that the pathway connection is between His bundle and ventricle. With standard atrioventricular bypass tracts, a junctional escape complex will not be preexcited, because preexcited complexes in such cases result from conduction from the atrium to the ventricle over a pathway outside the normal conduction system.

Final ECG

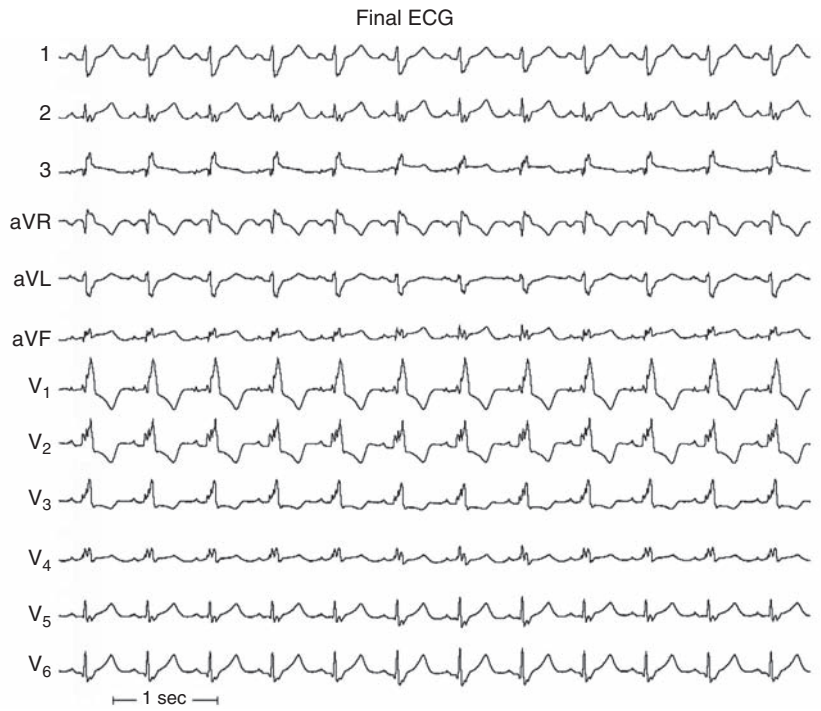

Figure 9-9

Catheter manipulation around the upper septum resulted in "bumping" of the pathway (Fig. 9-9), leading to loss of preexcitation. After the fasciculoventricular pathway was thus traumatized, the QRS complex showed RBBB as anticipated.

The cause of preexcitation in this case was thus a fasciculoventricular pathway; because these do not integrally participate in arrhythmias, this was not targeted for ablation. The patient had inducible typical right atrial cavotricuspid isthmus-dependent atrial flutter at 250 ms cycle length, consistent with the prior findings. Successful ablation was performed for this arrhythmia. At the end of the procedure, after catheter trauma, fasciculoventricular pathway conduction was absent. However, it returned the following day. The patient has done well in follow-up without recurrent arrhythmias.

Summary

- Fasciculoventricular pathways have unique properties:
  - A moderate degree of preexcitation is present
  - Preexcitation does not vary over a range of paced rates
  - The HV interval likewise remains constant
  - Junctional complexes are preexcited
  - These pathways are not integral participants in arrhythmias
- Catheter ablation of bypass tracts is not always necessary, for example:
  - Pathways that do not conduct rapidly enough under any conditions to result in patient risk
  - Pathways with intermittent conduction
  - Pathways that do not participate in arrhythmias (ie, fasciculoventricular pathways)
- This patient had another cause of palpitations unrelated to the bypass tract and consistent with prior data; simple ablation of the bypass tract in this case not only would not have yielded a successful outcome, but could also have risked damage to the normal conduction system

10 Focal Right Atrial Tachycardia

Case Presentation

An 18-year-old woman who was 36 weeks pregnant with her first child presented with dyspnea; she was found to have heart failure (HF), with heart rate 130–170/min, which was believed to be compensatory sinus tachycardia. Echocardiogram showed left ventricular dilation (5.2 cm in diastole), fractional shortening of 0.13, ejection fraction 30%, mild mitral regurgitation, and 4-chamber dilation (or upper-normal size for stage of pregnancy). She was started on standard HF medications (no ACE inhibitor because of pregnancy).

ECG of Tachycardia

What Is the Differential Diagnosis? [Fig. 10-1]

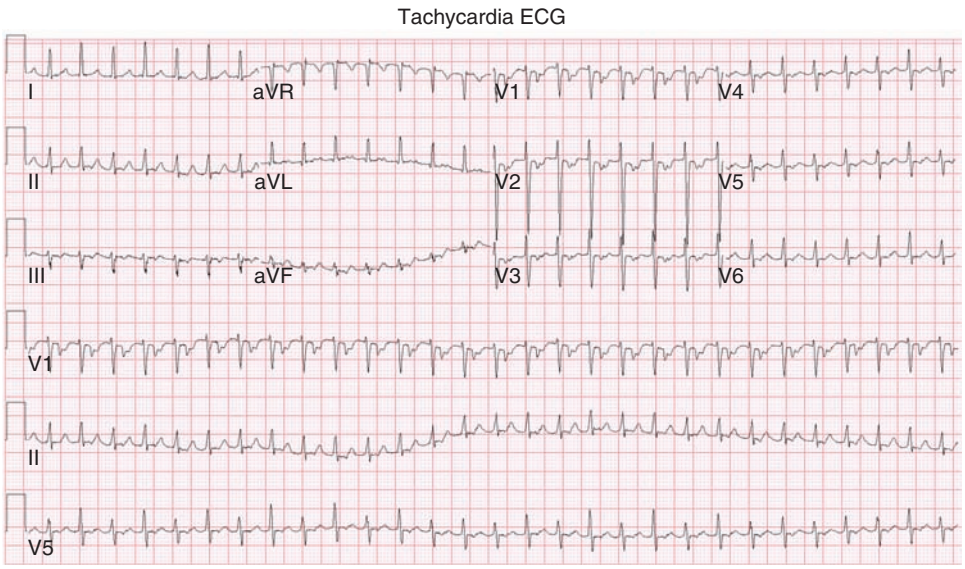

Figure 10-1

The baseline ECG in Fig. 10-1 shows regular supraventricular tachycardia (SVT) about 145/min. The P waves (best seen in lead V1) are very unusual and the PR interval is slightly long for this heart rate, if it were sinus tachycardia. The differential diagnosis includes atrial tachycardia or accessory pathway tachycardia using a right-sided bypass tract for retrograde conduction (from the P-wave vector in the inferior leads and V1). She was given an injection of adenosine that yielded transient 2:1 atrioventricular (AV) block, with continuation of the rapid atrial rhythm. Her child was delivered (cesarean section); tachycardia continued thereafter. She underwent direct-current cardioversion, but reverted to SVT nearly immediately. She was then scheduled for electrophysiology (EP) study and ablation. The response to adenosine excludes orthodromic SVT, in which a 1:1 AV relationship must be maintained, and because the P-wave vector is not consistent with exit from the AV nodal region, AV nodal reentry is excluded; thus, an atrial tachycardia is present.

Subsequent ECG

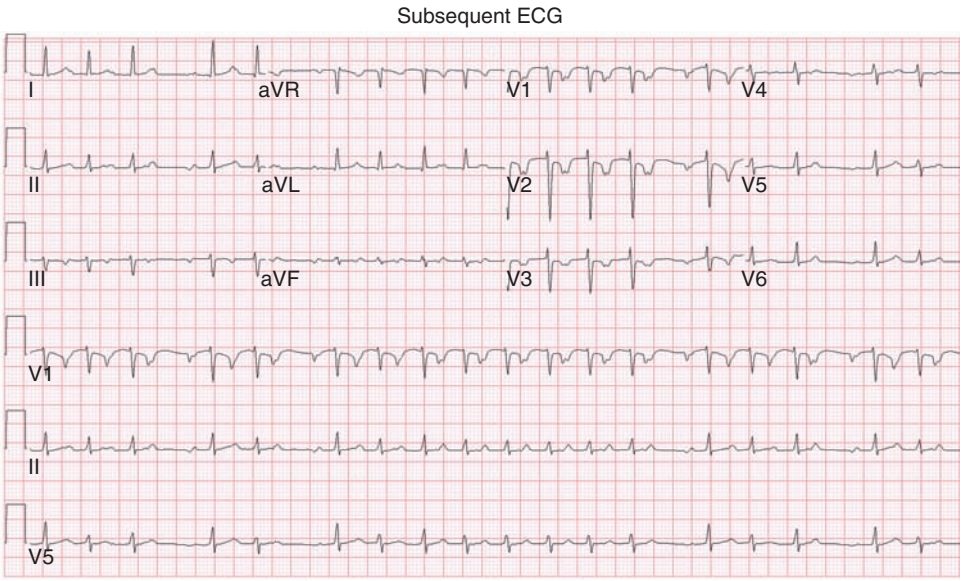

Figure 10-2

An ECG taken after administration of a beta blocker (Fig. 10-2) shows a slightly slower atrial rate along with periods of AV Wenckebach block. This again is indicative of atrial tachycardia and affords a better look at the P-wave morphology (positive in leads 1 and aVL, initially negative in inferior leads and V1–3).

Baseline ECGs and Intracardiac Recordings in SVT

Tachycardia ECGs [Fig. 10-3]

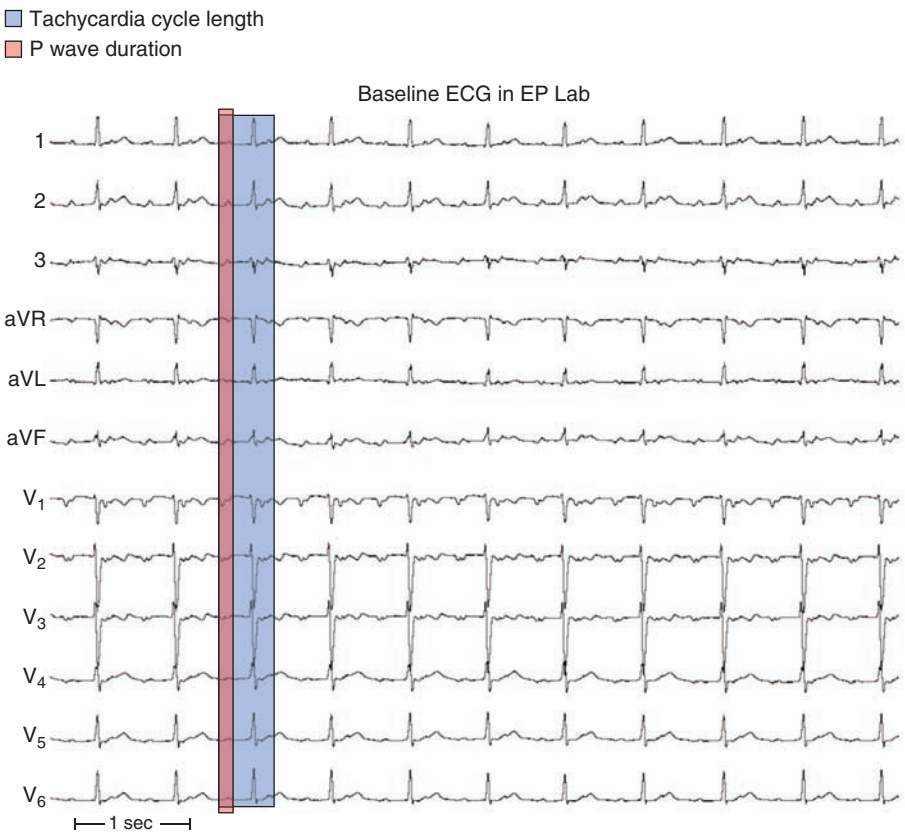

Figure 10-3

The patient was brought to the electrophysiology laboratory for catheter ablation of an atrial tachycardia. The question now is what type of atrial tachycardia: focal or macroreentrant? In most young people with a structurally normal heart, a focal process is present. Macroreentry generally requires some degree of scarring, which is not present in a structurally normal heart. However, because she has HF with early chamber dilatation, perhaps she has scarring in the atrium leading to macroreentry (it is also possible that the arrhythmia has caused a tachycardia-related cardiomyopathy). Because the ablation target is determined by the tachycardia mechanism, it is important to separate focal from macroreentrant causes. In Fig. 10-3, the P-wave duration is shown in *red* and the tachycardia cycle length in *blue* (2:1 AV conduction is present). Generally, the smaller the proportion of the tachycardia cycle length that is occupied by the P wave, the more likely that a focal process is present. In the example here, a focal process seems more likely.

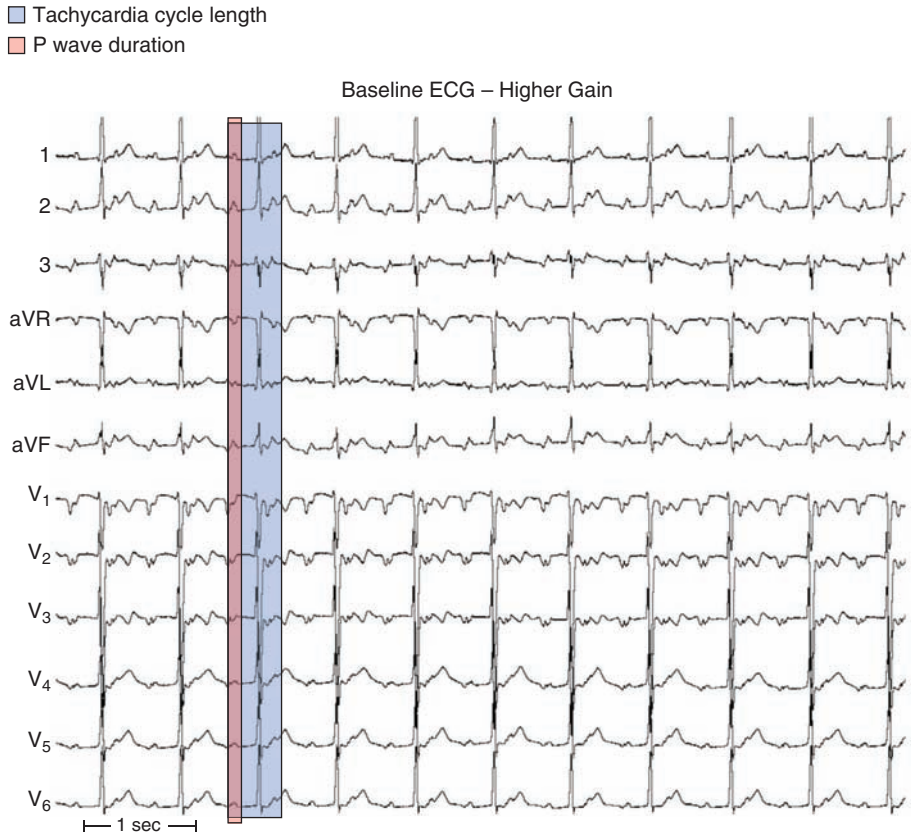

Figure 10-4

Sometimes it is helpful to increase the gain on recordings to be able to see more of the duration of the P wave (Fig. 10-4). In this case the conclusion is the same as before.

Intracardiac Recordings [Fig. 10-5]

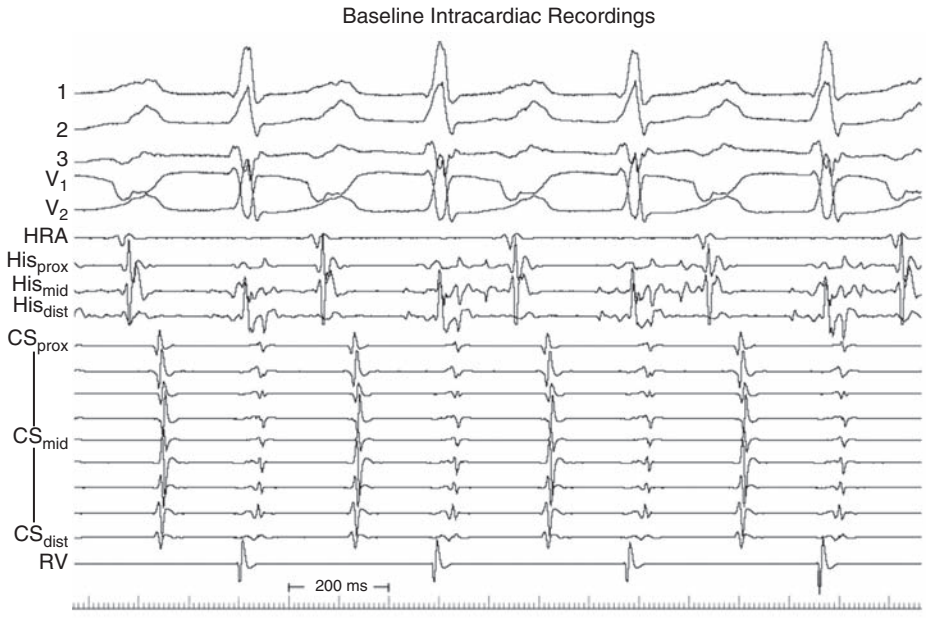

Figure 10-5

Intracardiac recordings during tachycardia are shown in Fig. 10-5. Of the recordings shown, earliest activation appears to occur in the high right atrium (HRA).

TABLE 10-1 Atrial Tachycardias

	Focal			
	Automaticity	**Triggered Activity**	**Microreentry**	**Macroreentry**
Onset	Spontaneous	Induced (burst > PES)	Induced (PES >> burst)	Induced (PES >> burst)
Occurrence	Incessant; bursts	Variable	Sporadic, sustained	Sporadic, sustained
P wave vs TCL	Small fraction	Small fraction	Small fraction	Large portion
Atrial activation	Small fraction	Small fraction	Small fraction	Large portion
Isoproterenol	Facilitates onset; acceleration	Facilitates onset; acceleration	Minimal effect	Minimal effect
Adenosine	Variable effect	Termination	Minimal effect	No affect/ acceleration
Response to single premature extrastimuli	Reset or fusion; flat/ increasing	Reset or fusion; decreasing	Reset or fusion; flat/ increasing	Reset + fusion; flat/ increasing
Overdrive pacing response	Suppression; ↑RC with ↓PCL	Acceleration; ↓RC with ↓PCL	Entrainment; No Δ RC w/↓PCL	Entrainment; No Δ RC w/↓PCL
Ablation target	Late diastolic; unipolar QS	Late diastolic; unipolar QS	Prolonged diastolic	Middiastolic
Response to RF	Accelerate/stop	Accelerate/stop	Slow/stop	Slow/stop

PES, programmed electrical stimulation; TCL, tachycardia cycle length; RC, return cycle of tachycardia; PCL, paced cycle length; QS, completely negative wave in unipolar recording.

Table 10-1 shows differences between three categories of tachycardias with apparent focal propagation from what seems to be a point source (automatic, triggered because of delayed after depolarizations, and microreentry) vs macroreentry.

Overdrive Coronary Sinus Pacing in SVT

Midcoronary Sinus Pacing [Fig. 10-6]

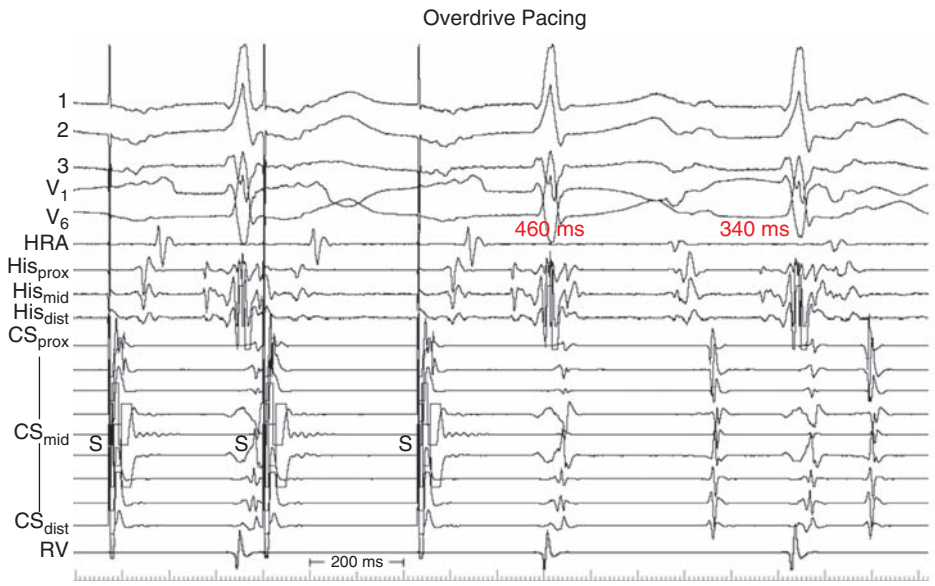

Figure 10-6

The result of overdrive spacing from the midcoronary sinus is shown here, after which the tachycardia resumes. This information, by itself, is not very helpful because both focal tachycardias and macroreentry will have this response. However, the fact that the interval from the last paced complex to the first beat of tachycardia (460 ms) is substantially longer than tachycardia cycle length (340 ms) would be very unusual for macroreentry, in which

the interval consists of propagation time from the pacing site to the circuit, around the circuit once, and back to the pacing site (Fig. 10-6). In most cases of macroreentry, this should ordinarily not be >100 ms or so longer than tachycardia cycle length.

Proximal Coronary Sinus Pacing [Fig. 10-7]

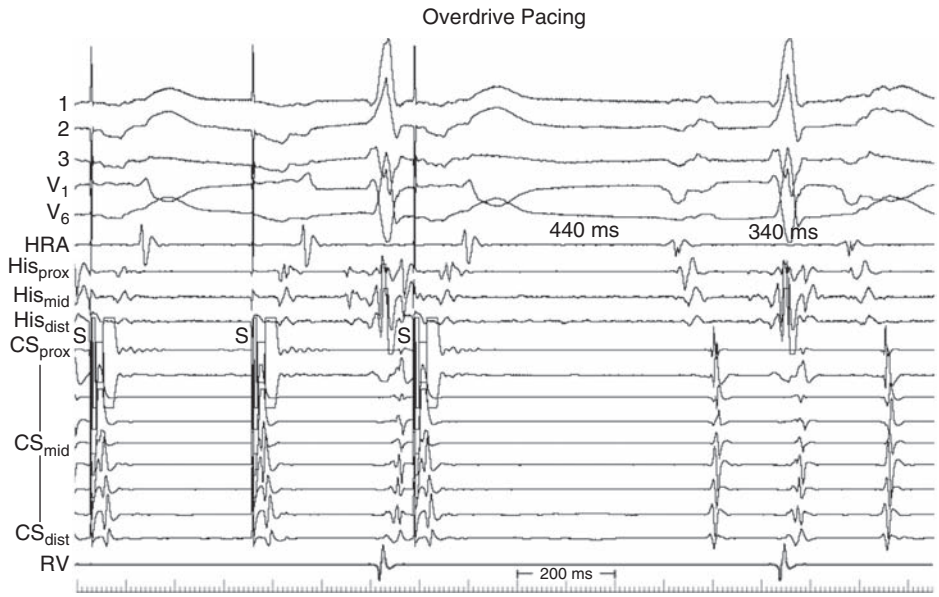

Figure 10-7

Pacing from the proximal coronary sinus yields a slightly shorter interval until the tachycardia resumes, suggesting that this spacing site is slightly closer to the exit from what now appears to be a focus (Fig. 10-7). Ideally, overdrive pacing from several sites could be used looking for fusion (indicating macroreentry), or its absence (suggesting a focal process); however, because the tachycardia is incessant, knowing what pure pacing looks like for comparison to pacing during tachycardia is not possible, making this technique less helpful at this time. Pacing from right atrium and distal coronary sinus yielded similar results. All the evidence taken together suggests a focal process.

Activation Mapping

Various Sites

Activation Mapping [Fig. 10-8]

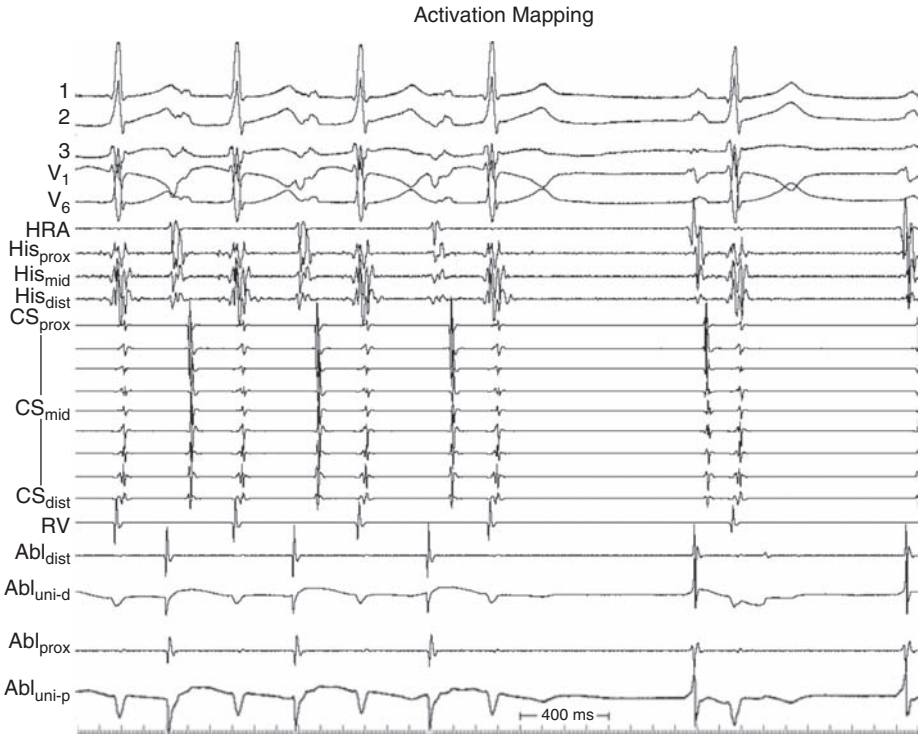

Figure 10-8

Now that a focal process has been identified as the likely cause of the tachycardia, activation mapping can begin. During the process of mapping, the tachycardia suddenly terminated when moving the catheter along the lateral tricuspid annulus (Fig. 10-8). This so-called "bump-mapping" has important implications: it signifies that (1) a critical site for continuation of the tachycardia has been "bumped" by the catheter (thus, where the catheter was at the time of this encounter is important); (2) the amount of tissue necessary for continuation of the tachycardia is quite small, because the effect of trauma with the catheter tip is spatially quite limited; and, finally, (3) the source is on the endocardial surface, because mechanical effects of the catheter on the endocardium would not be expected to affect deep myocardial or epicardial sources. Of note, this phenomenon does not distinguish between a focal process and macroreentry because tachycardias of either type may be terminated by catheter contact.

Activation Mapping [Fig. 10-9]

Figure 10-9

Fortunately, tachycardia resumes in Fig. 10-9, and gradually "warms up" (gradual rate increase after the onset). This is most consistent with a focal, automatic process.

Activation Mapping [Fig. 10-10]

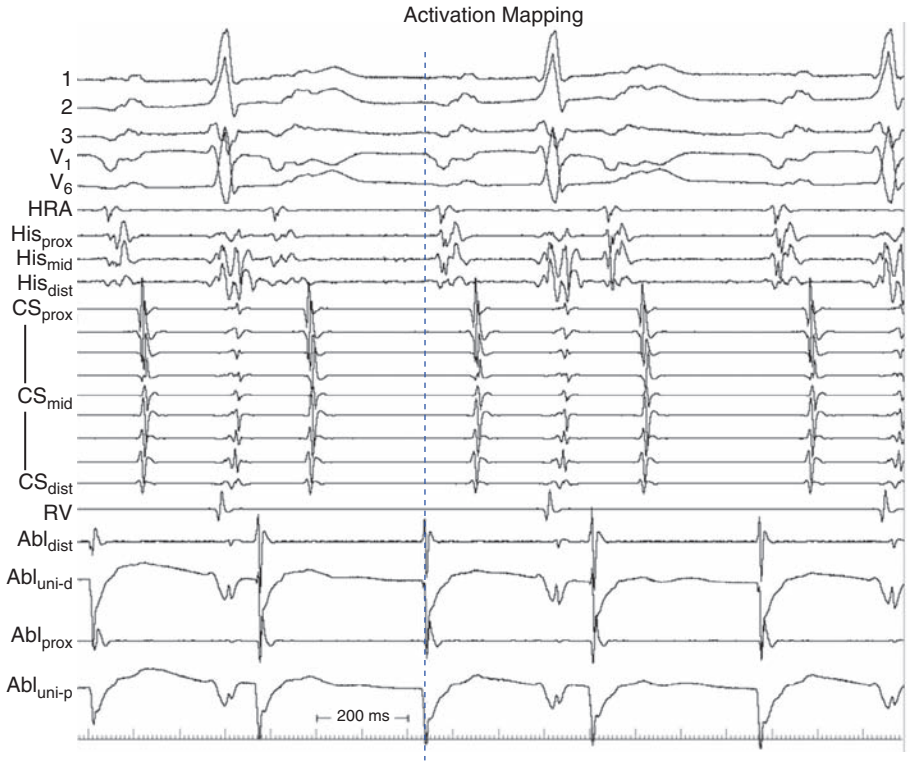

Figure 10-10

A site on the lateral tricuspid annulus is sampled during mapping (Fig. 10-10). The P-wave onset is designated by a *dashed line*; the ablation/mapping electrograms occur slightly (about 5 ms) before the P-wave onset; the distal bipolar electrode and unipolar signal have similar timing, and the unipolar has a "QS" configuration. Although the electrogram parameters are encouraging, the timing is not; ordinarily, propagation from a focus takes 20–40 ms before the onset of the P wave occurs, and so additional mapping is necessary.

Activation Mapping [Fig. 10-11]

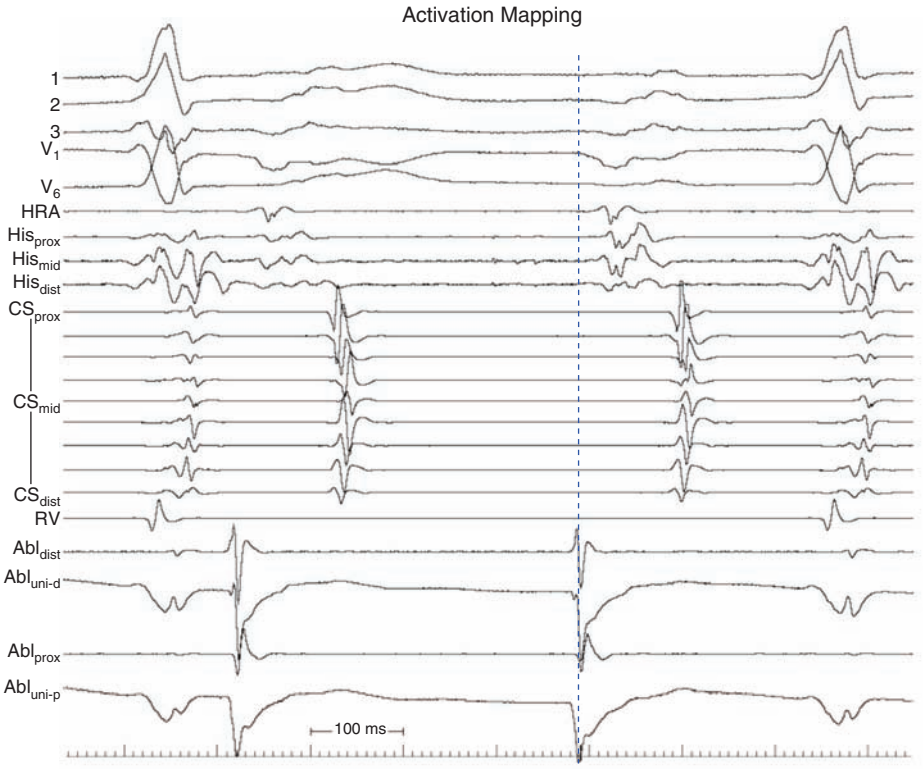

Figure 10-11

At a faster sweep speed (Fig. 10-11), it is clear that this site is not very early before the P-wave onset.

Electroanatomic Map

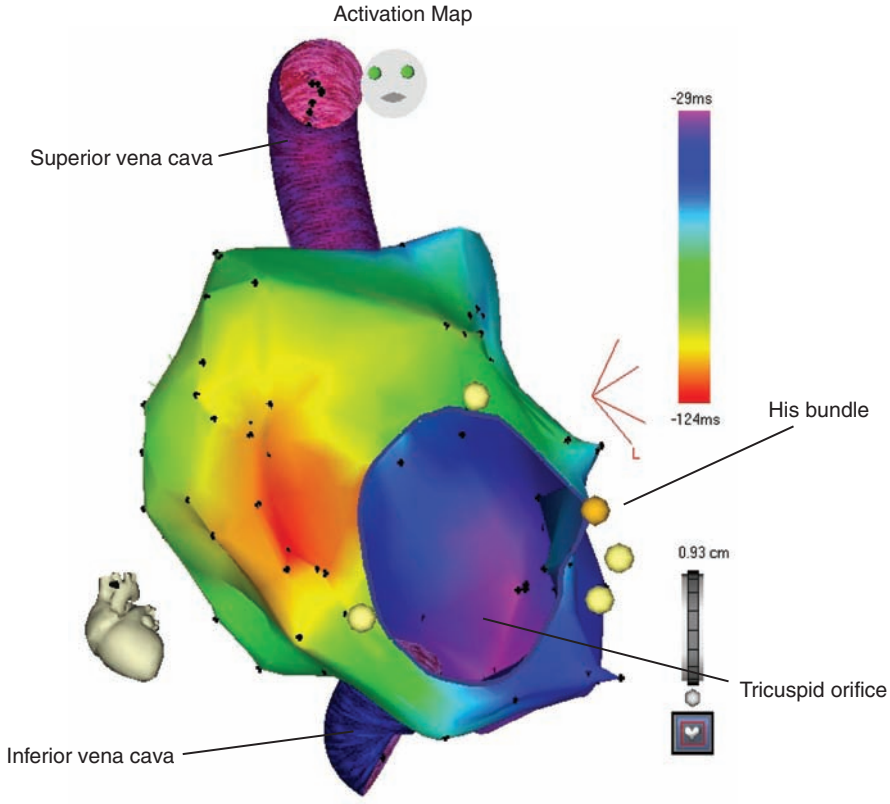

Figure 10-12

An electroanatomic map of right atrial activation during the tachycardia is shown in Fig. 10-12, indicating focal propagation from a site on the lateral tricuspid annulus (red area, surrounded by orange, yellow, etc.).

Additional Sites Sampled and Pace Mapping

Activation Mapping [Fig. 10-13]

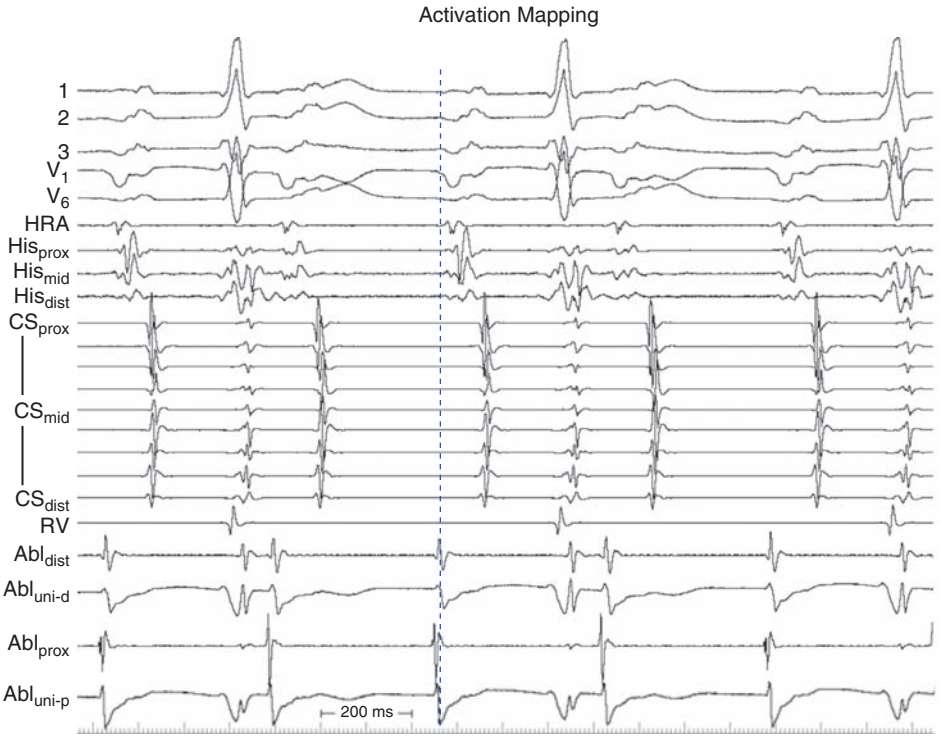

Figure 10-13

Additional mapping is performed; at this site (Fig. 10-13), the proximal bipolar electrogram has a timing before the distal, and is thus not a good site for ablation.

Pace Mapping [Fig. 10-14]

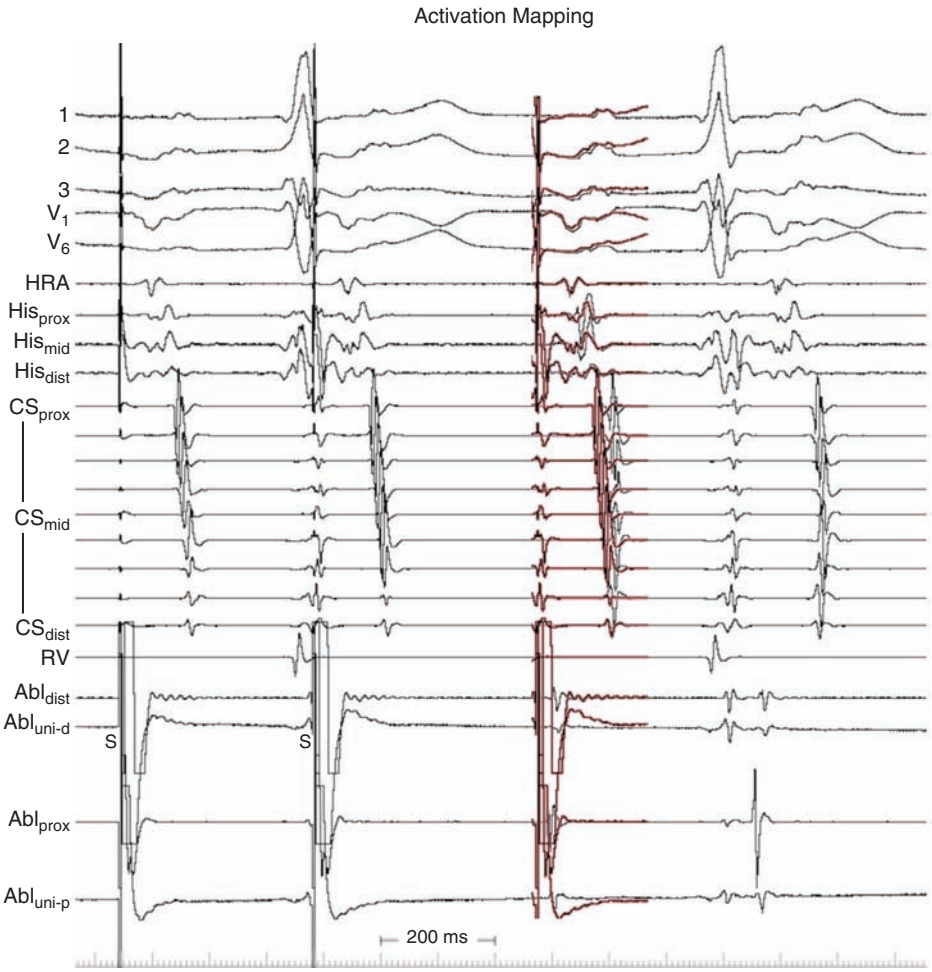

Figure 10-14

Pacing at this site (Fig. 10-14) yields a poor match with tachycardia (paced activation sequence in *red* superimposed on first tachycardia cycle after pacing). When the pacing electrode is at the actual site of impulse formation in a focal tachycardia, pacing should exactly match the activation sequence of the tachycardia.

Activation Mapping [Fig. 10-15]

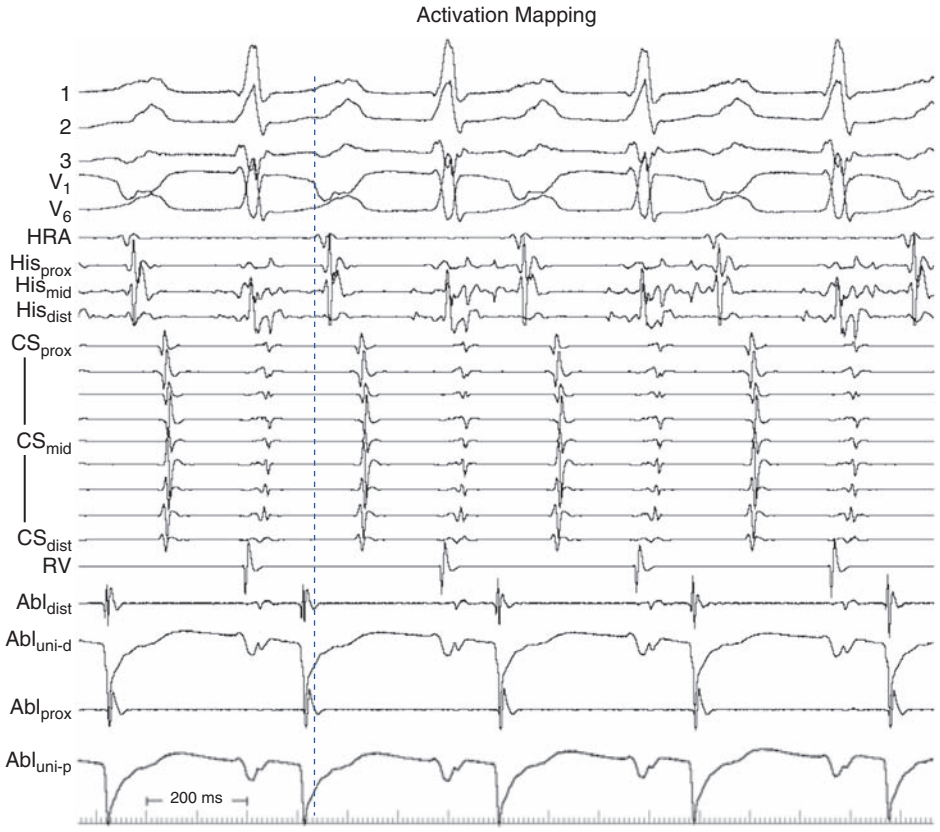

Figure 10-15

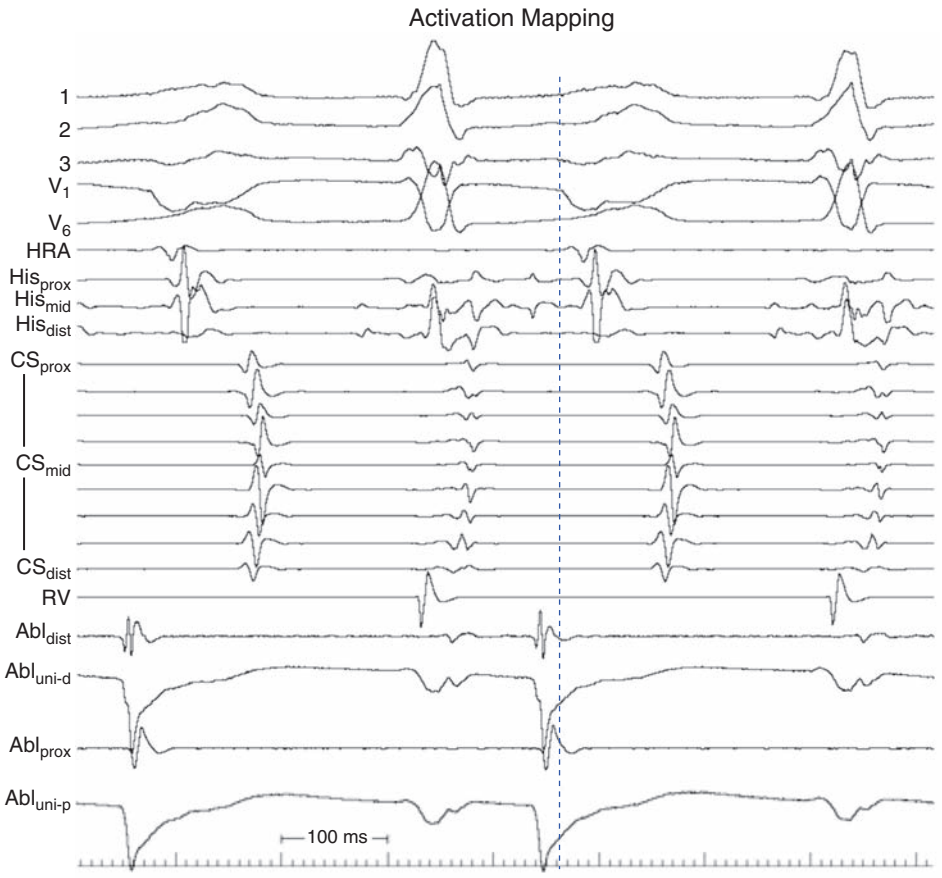
Another site is sampled; in Fig. 10-15, local activation in both the bipolar and the unipolar recordings substantially precedes P-wave onset (*dashed line*, inferred from its timing relationship to the HRA recording, because tachycardia now has a 1:1 AV relationship and the onset of the P wave is not as clear). The site is now 40 ms before P-wave onset, with unipolar–bipolar "agreement" and a "QS" unipolar configuration.



Activation Mapping [Fig. 10-16]

Figure 10-16

In Fig. 10-16, the same site is shown at a faster sweep speed, showing the site is 40 ms before P-wave onset.

Pace Mapping [Fig. 10-17]

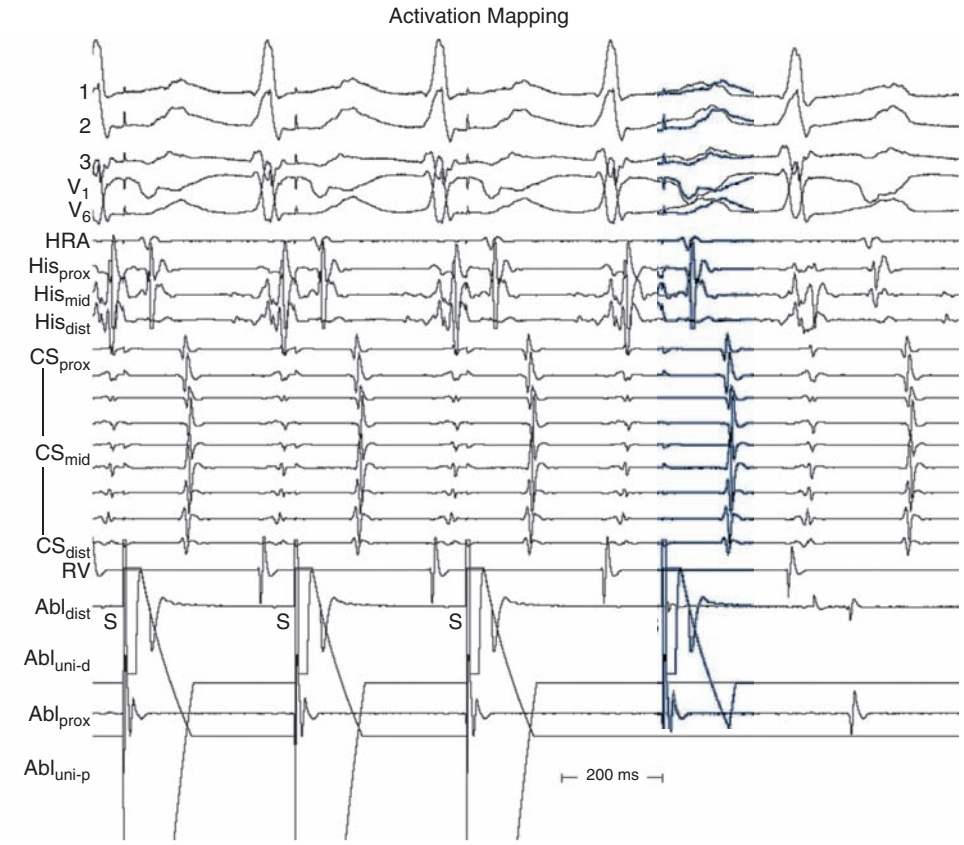


Figure 10-17

Pacing at this site (Fig. 10-17) yields a perfect match with tachycardia (paced complex in blue superimposed on first tachycardia complex after pacing). This corroborates the early local activation time recorded at this site.

Ablation

Figure 10-18

Radiofrequency energy application at this site (Fig. 10-18, starting at the *blue arrow*) results in a rapid acceleration of tachycardia followed by abrupt termination to sinus rhythm.

ECG Postablation

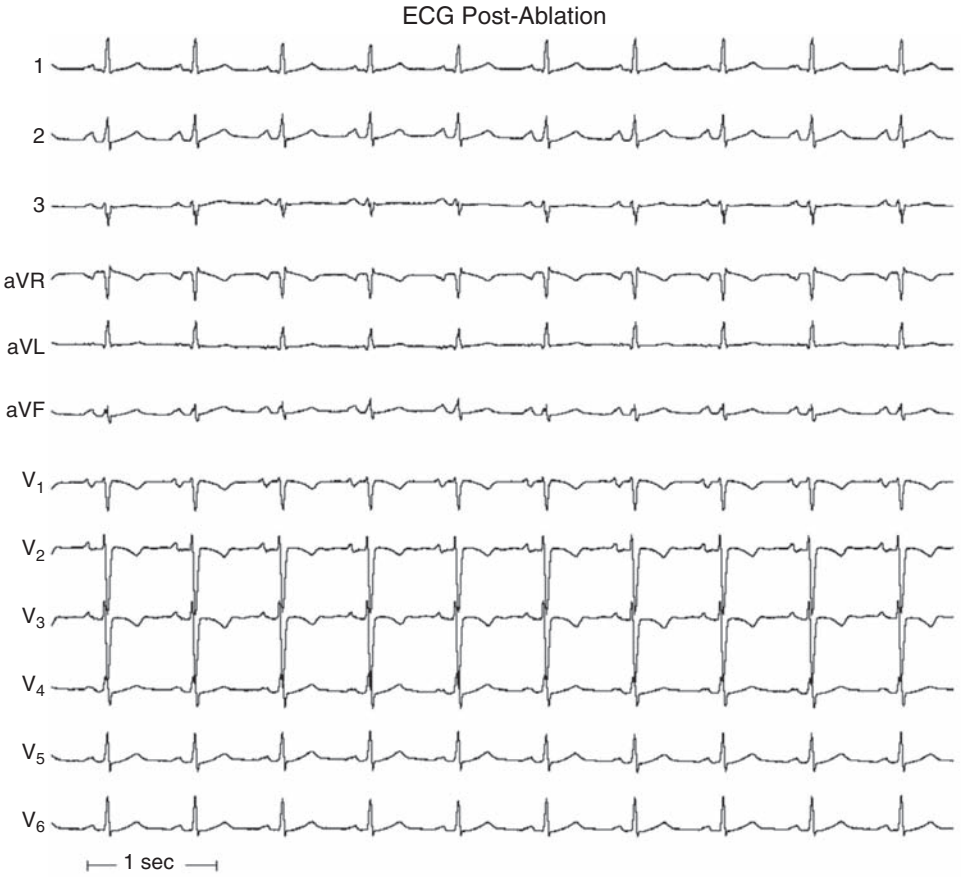

Figure 10-19

Sinus rhythm persisted through the waiting period. The P wave shown in Fig. 10-19 is not particularly abnormal despite the prolonged high rate and mild HF.

Atrial Activation Sequence with Various Sites of Coronary Sinus Pacing vs SVT

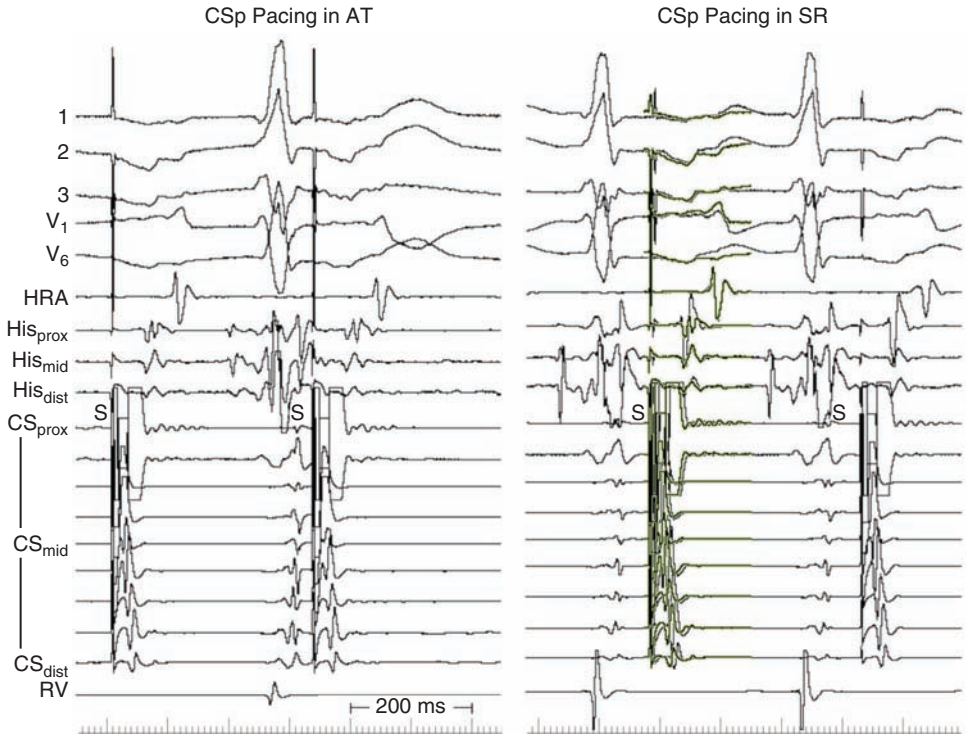

Figure 10-20

After restoration of sinus rhythm, pacing from different sites can be performed to determine what "pure" pacing from these sites looks like, compared with pacing during tachycardia. If there is a difference between these, fusion is present and macroreentry can be diagnosed. If pacing during tachycardia and pure pacing have identical activation sequences, a focal process is more likely. In Fig. 10-20, pacing from the proximal CS (CSp) during SVT at left is compared with pure pacing during sinus rhythm at right. A complex of pacing during SVT *(green)* is superimposed on a pure paced complex; these are identical.

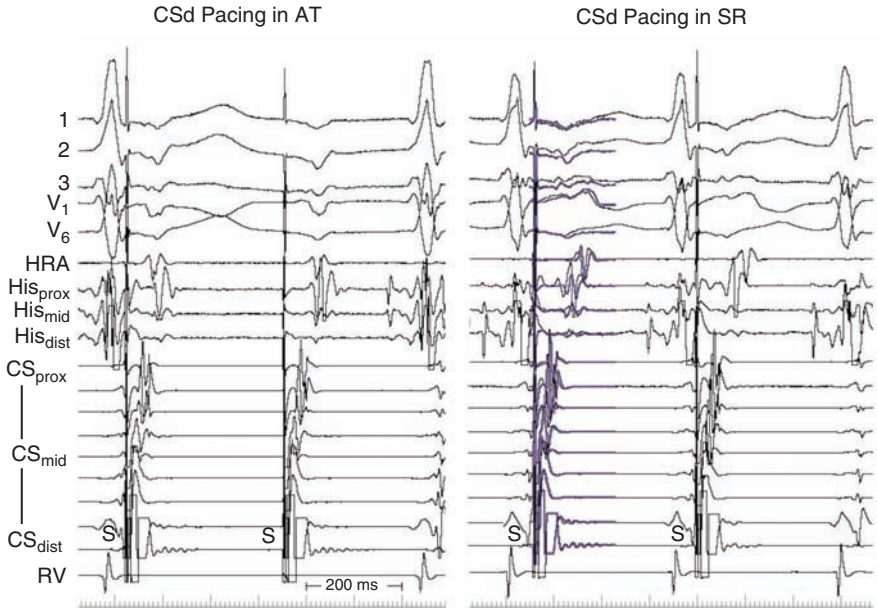

Figure 10-21

Similarly, pacing from the distal CS electrodes is compared when performed during tachycardia vs sinus rhythm. Again, in Fig. 10-21, pacing during tachycardia *(purple)* is superimposed on pure pacing, showing no difference.

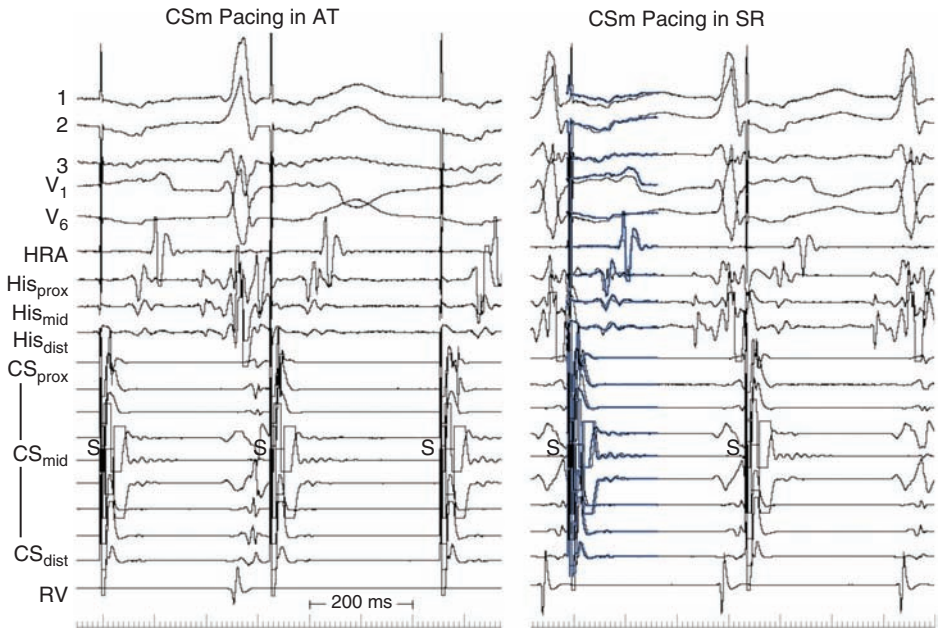

Figure 10-22

Pacing from the middle CS electrodes (Fig. 10-22) again shows no difference in atrial activation whether during tachycardia or sinus rhythm. Again, pacing during tachycardia *(blue)* is superimposed on pure pacing, showing no difference. Had this lack of evidence of fusion despite pacing at several sites been available earlier in the study, it would have helped exclude macroreentry.

Ventricular Pacing During Sinus Rhythm

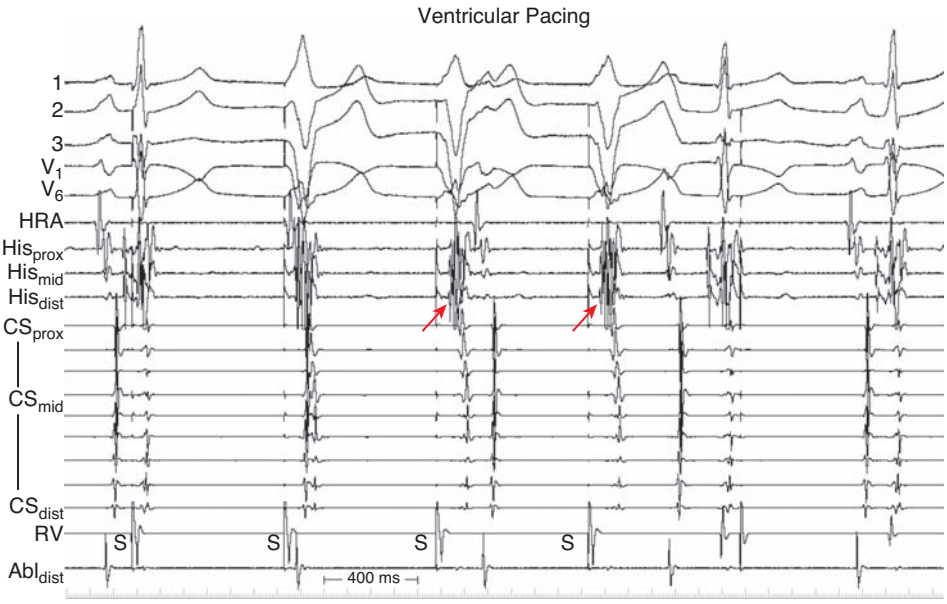

Figure 10-23

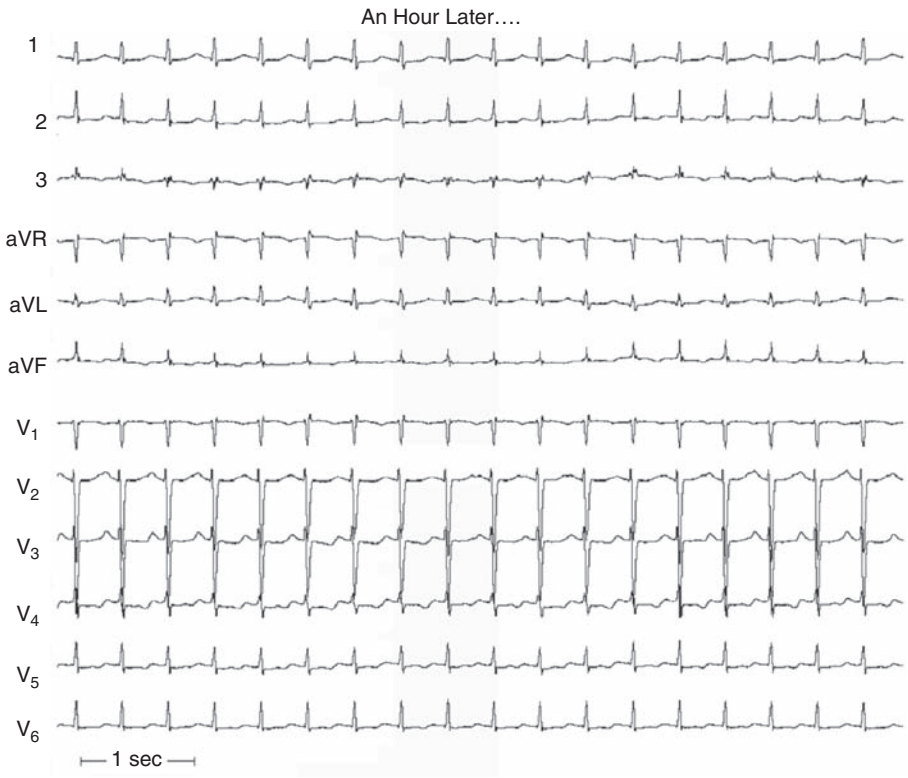
In Fig. 10-23, ventricular pacing immediately after ablation shows no retrograde conduction, with block in the AV node (retrograde His seen on third and fourth complexes [*arrow*]).

Tachycardia 1 h After Ablation



Tachycardia [Fig. 10-24]

Figure 10-24

Isoproterenol was administered during the waiting period to try to reinitiate atrial tachycardia, which did not occur; however, this arrhythmia was noted in Fig. 10-24.

Atrial Pacing Induces SVT

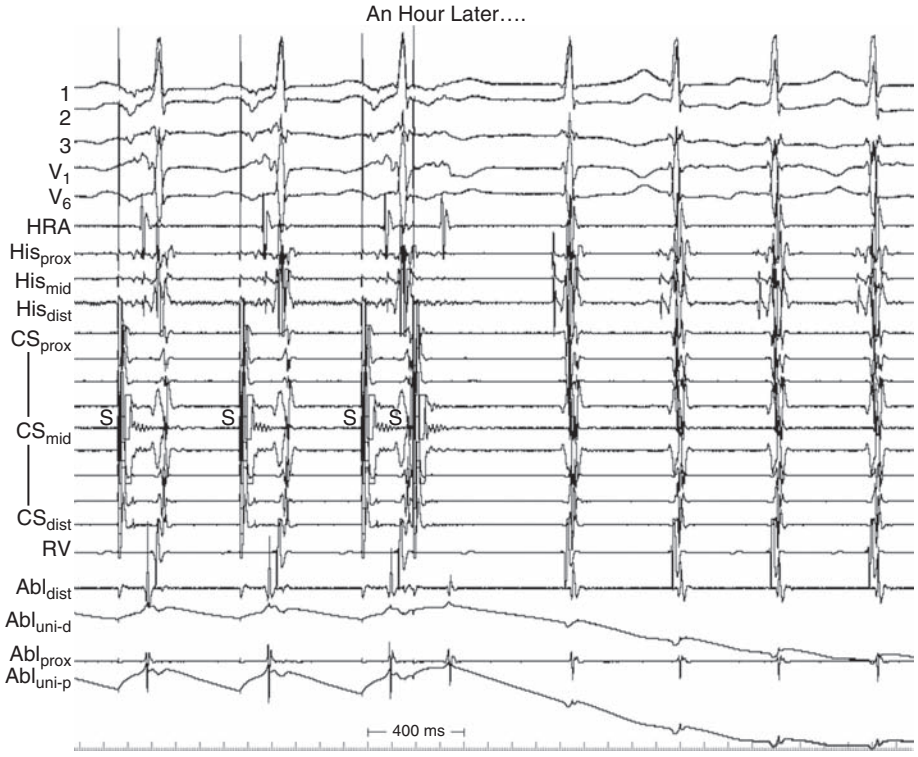


Figure 10-25

Atrial extrastimulus testing, to try to reinitiate atrial tachycardia, instead elicited the arrhythmia seen in Fig. 10-25. The atrial activation is concentric now and is coincident with ventricular activation, and SVT started after a long AH interval. All of these features are consistent with AV nodal reentry as a second tachycardia diagnosis.

Ventricular Extrastimuli and Overdrive Pacing in SVT (Figs. 10.26 and 10.27)

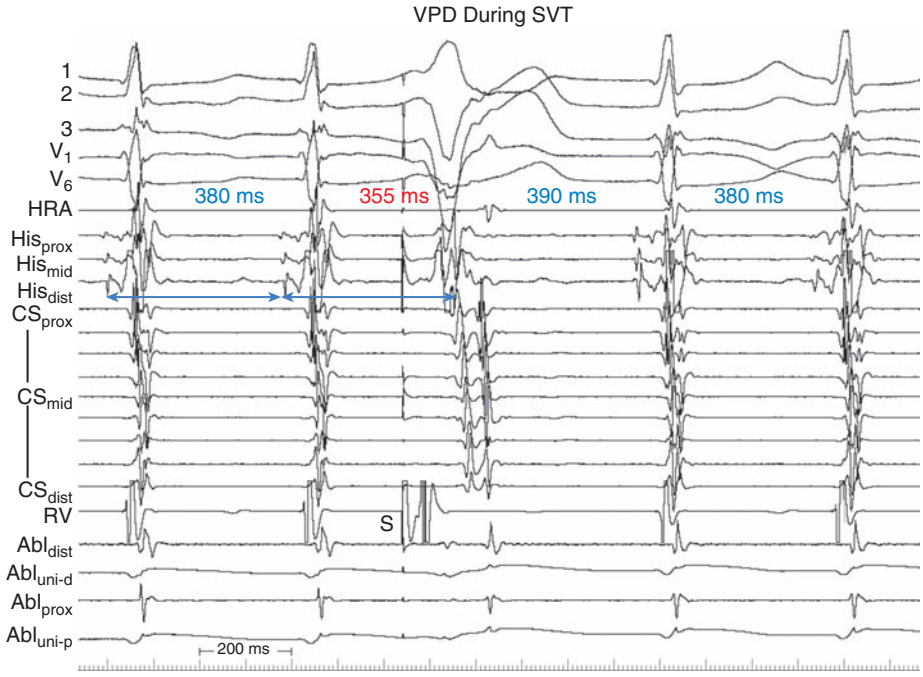

Figure 10-26

A ventricular extrastimulus (S) introduced during tachycardia advances the timing of atrial activation; however, the extrastimulus occurs at a time when the His bundle is not refractory (Fig. 10-26; *arrows* indicate where next expected His would occur). Thus retrograde conduction could easily have gone through the His bundle and AV node to preexcite the atrium. No inference can be made as to whether a bypass tract is present from this (though almost surely not, because atrial activation occurs within the QRS complex).

Ventricular Overdrive Pacing in SVT

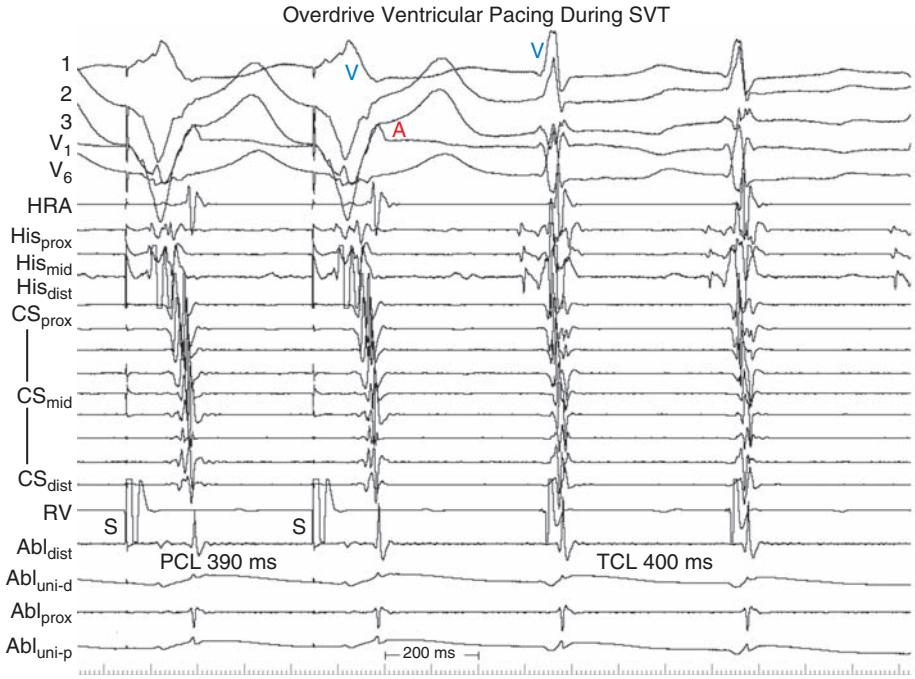

Figure 10-27

A "V-A-V" response seen with ventricular overdrive pacing during SVT excludes atrial tachycardia with a long PR interval and, with all the other data taken together, largely makes a diagnosis of AV nodal reentry (Fig. 10-27). Although this arrhythmia had not been documented clinically, it seemed prudent to undertake ablation at this setting because it was sustained and rather rapid.

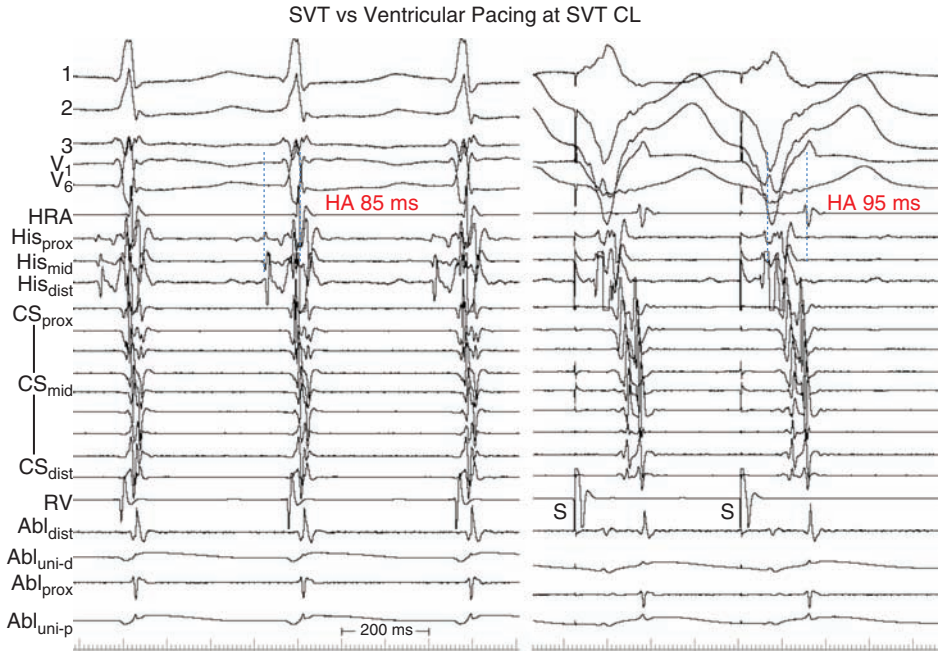

Figure 10-28

Additional evidence for AV nodal reentry, and against atrial or junctional tachycardias, is the HA interval in SVT vs ventricular pacing at the SVT cycle length. In Fig. 10-28, the HA in SVT (from onset of proximal His potential to HRA atrial recording, *dashed lines*) is 85 ms, slightly less than the HA during ventricular pacing at SVT cycle length (measured from end of proximal His deflection to same HRA atrial recording, *dashed lines*). If this were a junctional/His bundle tachycardia, these intervals should be the same; if atrial tachycardia, there is no reason that they should be similar because retrograde conduction with pacing and AH interval during atrial tachycardia are completely independent occurrences.

Catheter Manipulation at Tricuspid Annulus

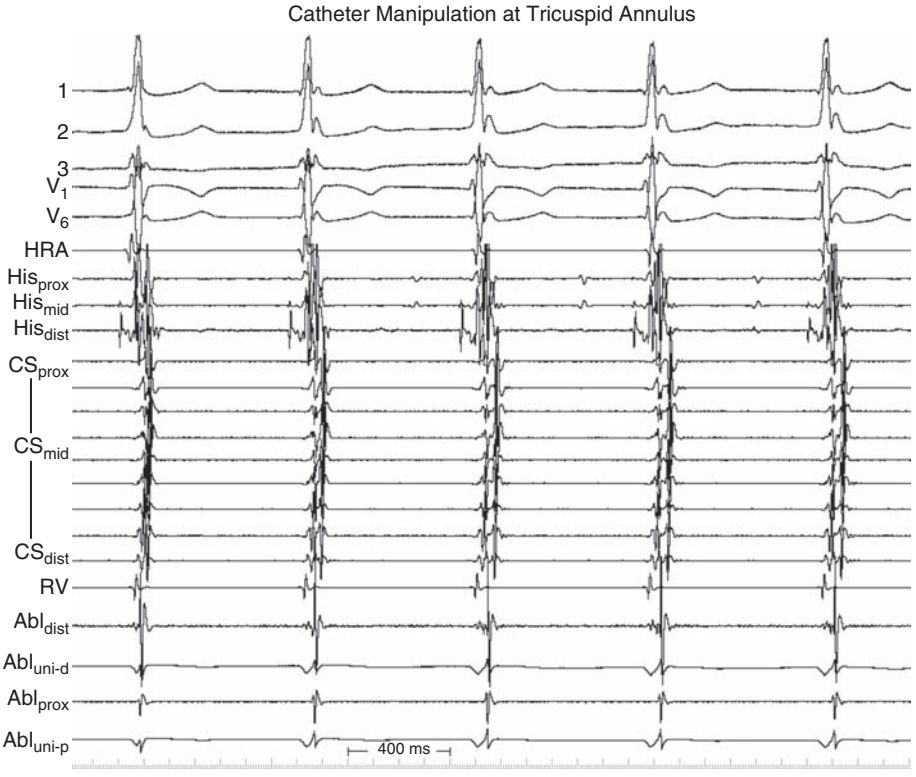

Figure 10-29

While positioning the ablation catheter for AV nodal slow pathway ablation, the rhythm shown in Fig. 10-29 was recorded. This is irritative junctional rhythm from the catheter rubbing on the slow pathway region, indicative of a good site for ablation. Note that, although this appears to be junctional with retrograde conduction, the P waves in the surface ECG are positive, indicating that this is sinus rhythm at almost the same rate.

Successful catheter ablation of the AV nodal slow pathway was accomplished, resulting in accelerated junctional rhythm; inducible AV node reentry was eliminated and atrial tachycardia likewise did not occur, either in the baseline state or after isoproterenol provocation. Normal AV conduction was present at the end of the procedure. After recovery, the patient did well without recurrence of any form of tachycardia and had normalization of left ventricular systolic function 3 months later.

Summary

- Focal AT can cause tachycardia-mediated cardiomyopathy; it is unusual to have the reverse (cardiomyopathy causing AT).
- Features of tachycardia-mediated cardiomyopathy:
  - No symptoms until HF occurs (no palpitations)
  - Ventricular rate 120–140/min (fast enough to cause HF, slow enough to escape detection/not cause palpitations, etc.)
  - HF can be cured when tachycardia is eliminated.
  - HF can recur if rapid rate recurs.
- Lessons:
  - Before ablating, delineate general mechanism: focal vs macroreentry.
  - Focal tachycardia target site features: <40 ms before P wave; QS unipolar
  - Bump mapping: signifies that the target site occupies a small critical area that is very superficial; but because this often occurs with sudden catheter movement, the catheter tip is rarely still at the "bumped" tissue by the time this is noticed.
  - Patients can have more than one type of tachycardia/cause of symptoms.

11 Focal Left Atrial Tachycardia

Case Presentation

A 73-year-old woman with recent onset renal failure complained of palpitations and near syncope for the last few weeks, with increasing frequency during dialysis. ECG showed non-sustained episodes of wide as well as narrow complex tachycardia, CL ~370 ms. She had a history of hypertension; her renal disease was of unclear cause (normal renal function 6 months prior to being on dialysis [via indwelling subclavian catheter]). She is being considered for living related donor transplant. Her last 10 dialysis sessions were stopped prematurely due to tachycardia episodes. Physical examination findings were normal aside from mild hypertension and the dialysis catheter. Her resting ECG showed a possible old anterior scar. An echocardiogram showed left ventricular hypertrophy, stage 2 diastolic dysfunction and mitral annular calcification. She was referred for electrophysiology (EP) study and possible ablation of narrow and wide QRS tachycardias.

Baseline ECG and Intracardiac Recordings

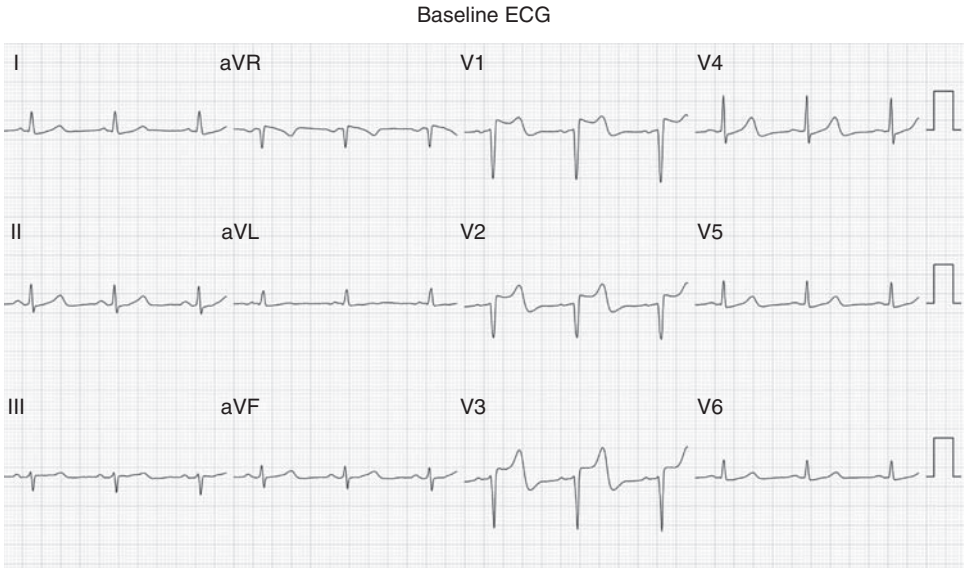

Figure 11-1

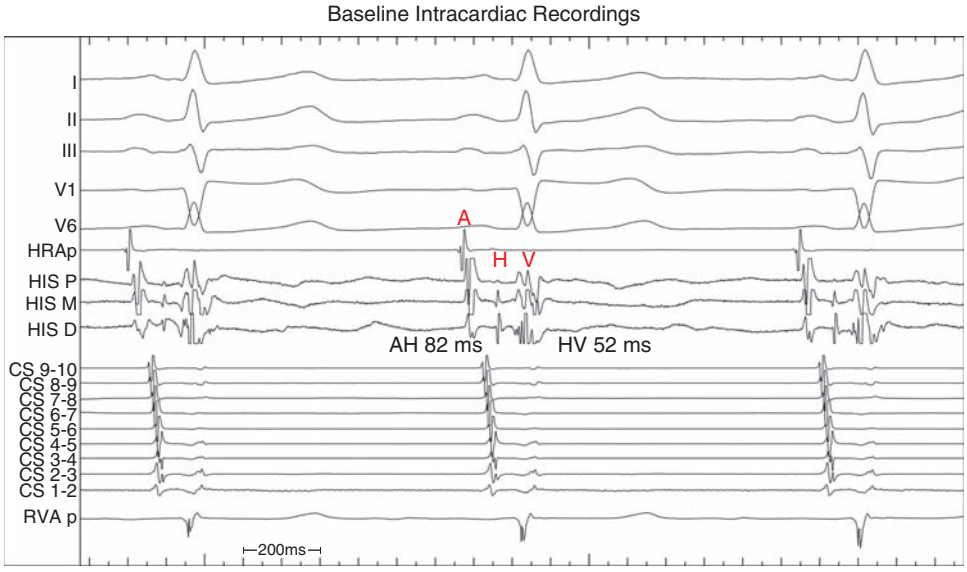

Figure 11-2

In Fig. 11-1 and Fig. 11-2, all intervals are normal. The ST elevation in V1–V3 in Fig. 11-1 is a recording artifact; R-wave progression is delayed but there is no definite infarct pattern. There are no clues from ECG or standard intracardiac recordings as to the nature of the rhythm disturbances.

Ventricular Pacing

What Is the Differential Diagnosis?
Where Is the Block? [Fig. 11-3]

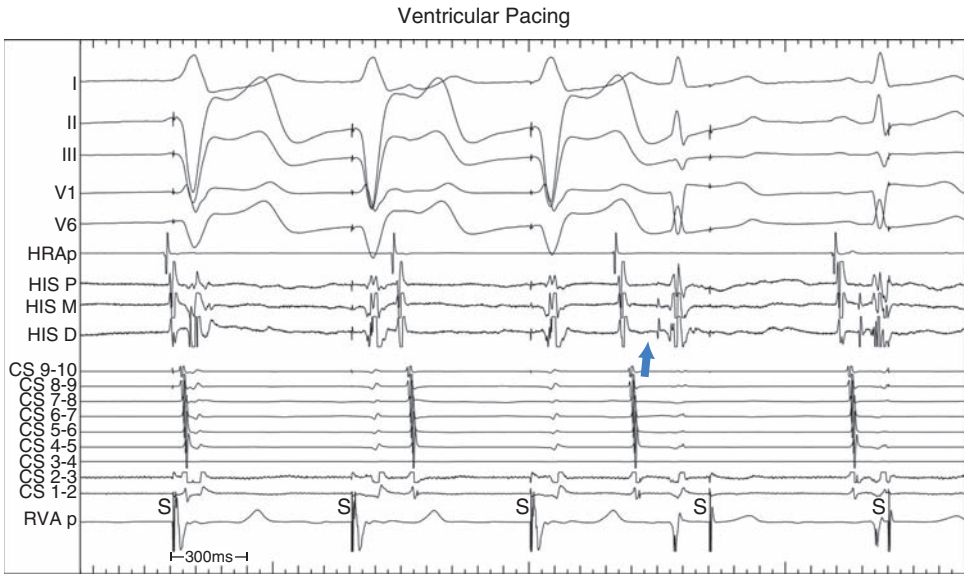

Figure 11-3

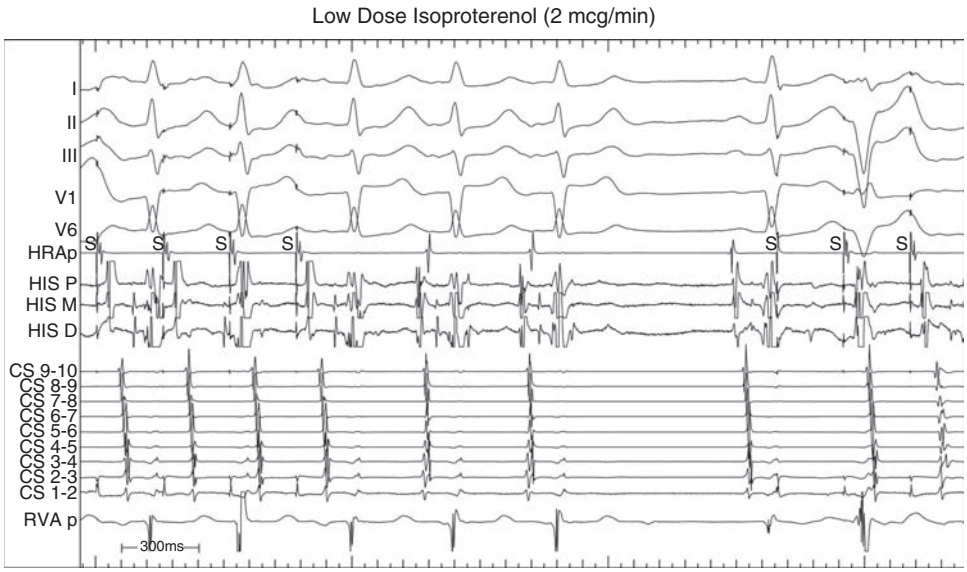
One of the first tests to perform is ventricular pacing to assess retrograde conduction (presence, pattern); in Fig. 11-3, there is no retrograde conduction (sinus complexes continue unaffected by ventricular pacing). This immediately makes orthodromic supraventricular tachycardia (SVT) related to a concealed bypass tract extremely unlikely, and even atrioventricular (AV) nodal reentry usually has retrograde conduction over the fast pathway at rest. In some cases of AV nodal reentry (and rare cases of orthodromic SVT), retrograde conduction may be restored after isoproterenol infusion and SVT can be induced under those conditions. However, the absence of retrograde conduction at this point makes an atrial tachycardia more likely as the cause of the patient's SVT.

The site of retrograde block is identified as the AV node, because the atrio-His interval following a paced complex *(arrow)* is longer than the resting AH (complex at right) because of concealed conduction into the AV node.

What Next?

After some additional testing, we now know that the AH (82 ms) and HV (52 ms) intervals are normal; the AV Wenckebach cycle length is 430 ms; there is no VA conduction; anterograde dual-AV nodal pathways are present, without echoes or inducible tachycardia; and no sustained arrhythmias can be initiated with atrial or ventricular stimulation (bursts, extrastimuli).

Atrial Pacing on Low-Dose Isoproterenol



What Is the Differential Diagnosis? [Fig. 11-4]

Figure 11-4

In the absence of inducible arrhythmias in the baseline state, isoproterenol infusion is begun. In Fig. 11-4, atrial pacing induces two cycles of tachycardia. This is described as a "long RP" rhythm, the differential diagnosis for which is atrial tachycardia, atypical AV nodal reentry (anterograde fast, retrograde slow pathways), and orthodromic reentry related to a slowly conducting bypass tract. The mode of initiation would be quite unusual for AV nodal reentry, because conduction would have to block in the slow pathway with the last atrial stimulus, conduct over the fast pathway, and yet go back up the slow pathway to form the first beat of tachycardia. The other two possibilities (atrial tachycardia or orthodromic reentry) remain.

Higher Dose Isoproterenol

Spontaneous SVT Onset

What Is the Differential Diagnosis [Fig. 11-5]? What Do You Need to Do to Figure It Out?

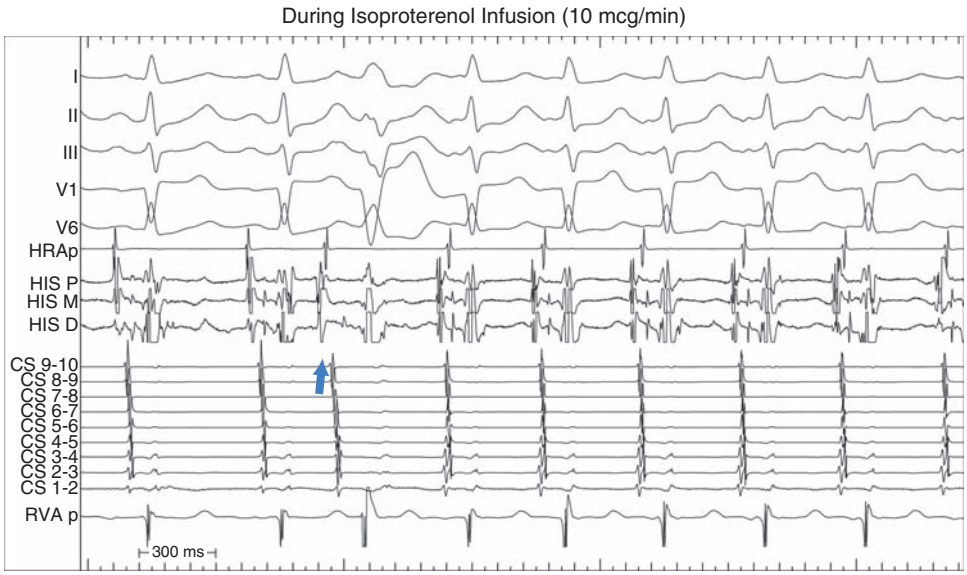


Figure 11-5

With an increase in the dose of isoproterenol, tachycardia occurs spontaneously. A spontaneous atrial premature complex (*arrow*, Fig. 11-5) appears to be conducted with left bundle branch block (LBBB) aberration, after which sustained narrow QRS tachycardia ensues. The atrial activation sequence is the same as in the two cycles of the rhythm seen in the previous figure on a lower dose isoproterenol, and is "concentric." This is consistent with a typical fast pathway exit (less so with slow pathway exit), a septal bypass tract, or a septal (or slightly left-sided) atrial tachycardia. Further testing is needed to distinguish among these possible diagnoses.

ECG and Intracardiac Recordings in SVT

What Is the Differential Diagnosis [Fig. 11-6]?

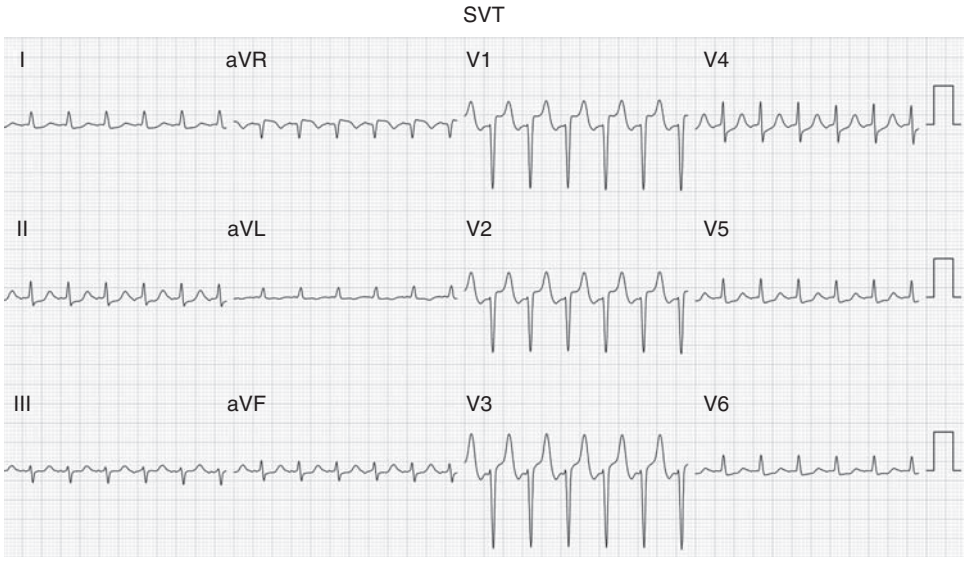

Figure 11-6

A 12-lead ECG of sustained tachycardia is shown in Fig. 11-6. The location and configuration of the P wave is less evident here than on the intracardiac recordings.

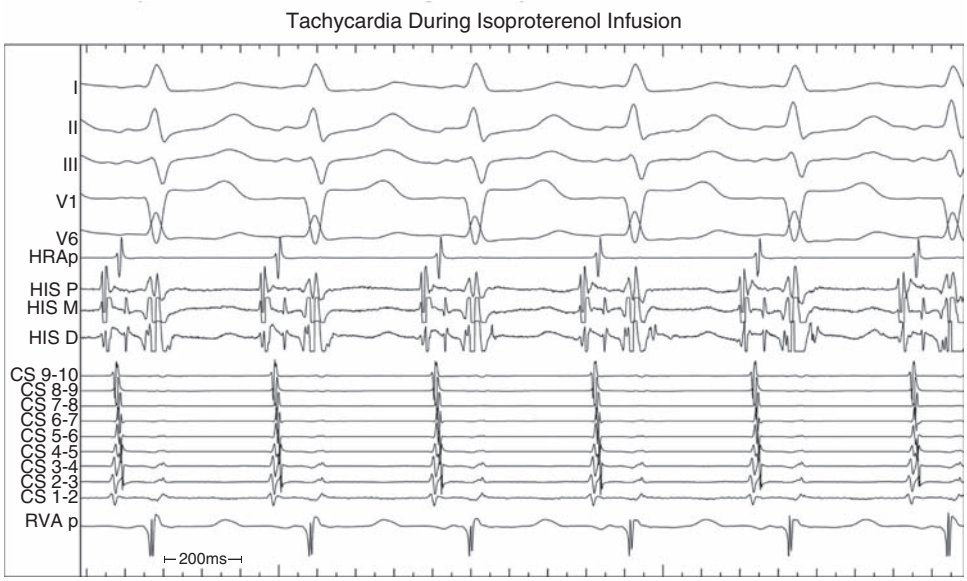

Figure 11-7

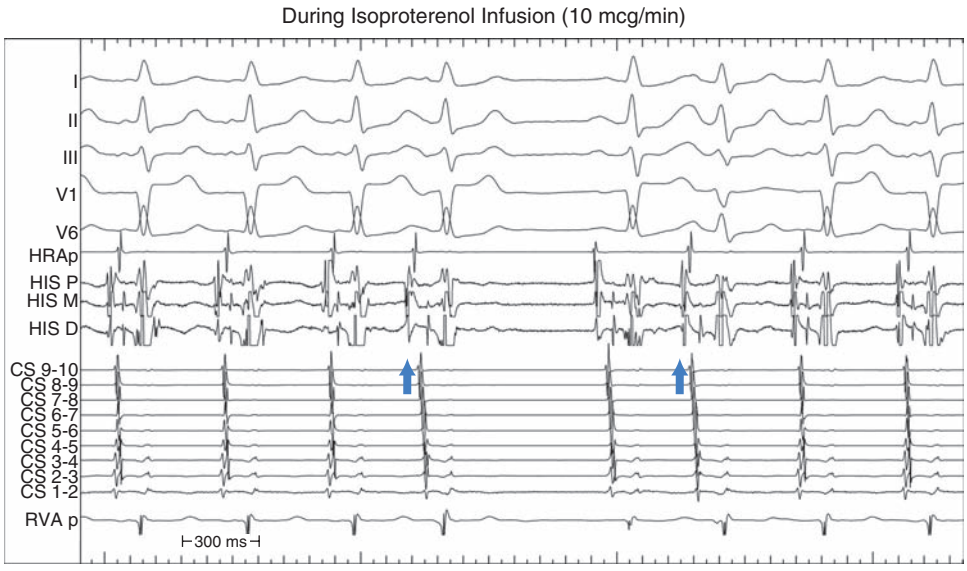
Intracardiac recordings of tachycardia are again shown (Fig. 11-7) at a more rapid sweep speed. It is clear that earliest activation among the atrial recordings is at the region of the His bundle.

SVT Termination



What Is the Differential Diagnosis? [Fig. 11-8]

Figure 11-8

In Fig. 11-8, tachycardia suddenly terminates after an atrial premature complex *(arrow)*. A sinus complex follows and then another atrial premature complex *(second arrow)*, and then tachycardia resumes. The fact that sustained tachycardia is terminated as well as initiated by atrial premature complexes that appear to be different from the ongoing tachycardia is suggestive of a reentrant, rather than focal, atrial tachycardia. However, none of the other tachycardia diagnoses have been definitively eliminated as yet.

Ventricular Pacing During Sinus Rhythm

What All Does This Tell? [Fig. 11-9]

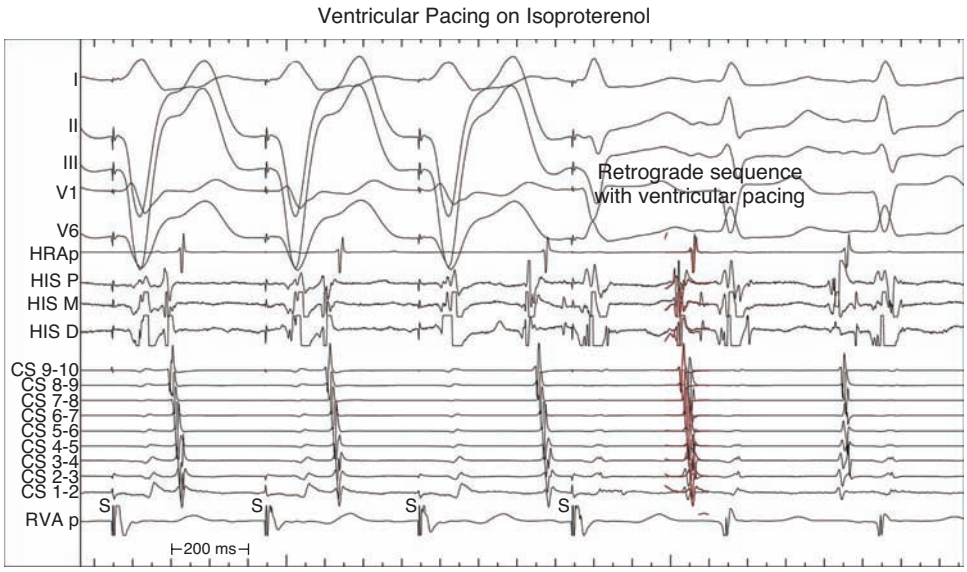


Figure 11-9

Ventricular pacing is now performed during sinus rhythm while on the isoproterenol infusion. As is often the case, retrograde conduction is restored with isoproterenol where it had been absent in the baseline state. On the first two complexes shown in Fig. 11-9, retrograde conduction is concentric with a short retrograde conduction time; on the third complex, a longer retrograde conduction time is seen followed by a His potential and narrow QRS complex despite another stimulus artifact occurring. This is indicative of retrograde dual-AV nodal physiology (retrograde slow pathway, anterograde fast pathway), one of the potential mechanisms of the patient's tachycardia (which starts immediately thereafter). However, the atrial activation sequence of the retrogradely conducted complexes (superimposed in red on an SVT complex) is a little different from that of tachycardia, indicating that the tachycardia diagnosis is probably not, in fact, AV nodal reentry. A slowly conducting bypass tract mediating orthodromic reentry also seems very unlikely because the atrial activation sequence during ventricular pacing is different from tachycardia, but has not been definitively excluded at this point

Wide-QRS Complex Tachycardia ECG and Intracardiac Recordings

What Is the Differential Diagnosis? [Fig. 11-10]

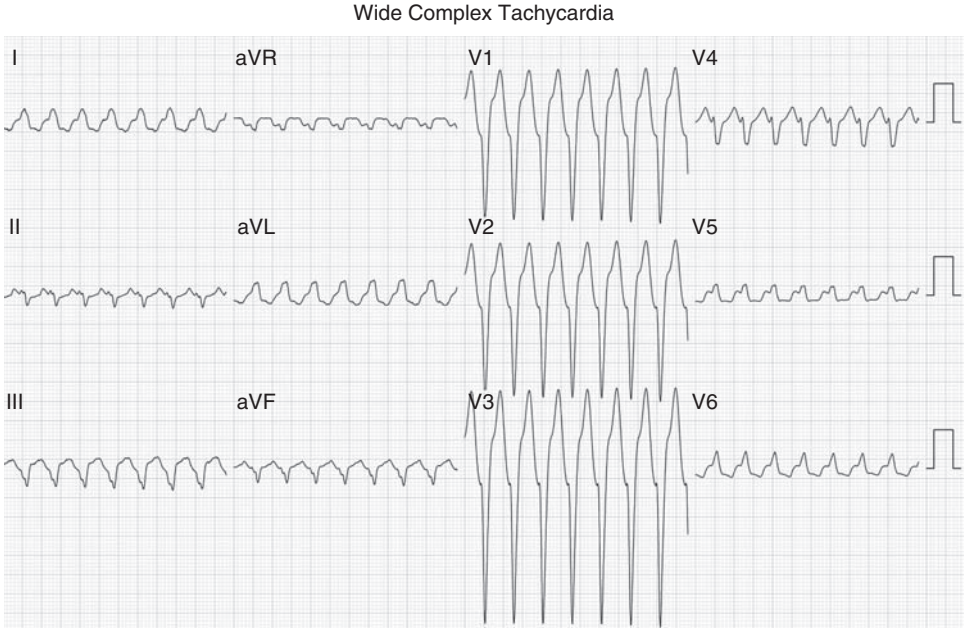

Figure 11-10

A few minutes later, while still on isoproterenol, a wide complex tachycardia occurs (Fig. 11-10). Recall that the patient had both narrow and wide complex tachycardias with similar rates. The tachycardia shown has a rate nearly identical to that of the narrow complex tachycardia encountered minutes earlier, and has a left branch block configuration consistent with SVT with aberration.

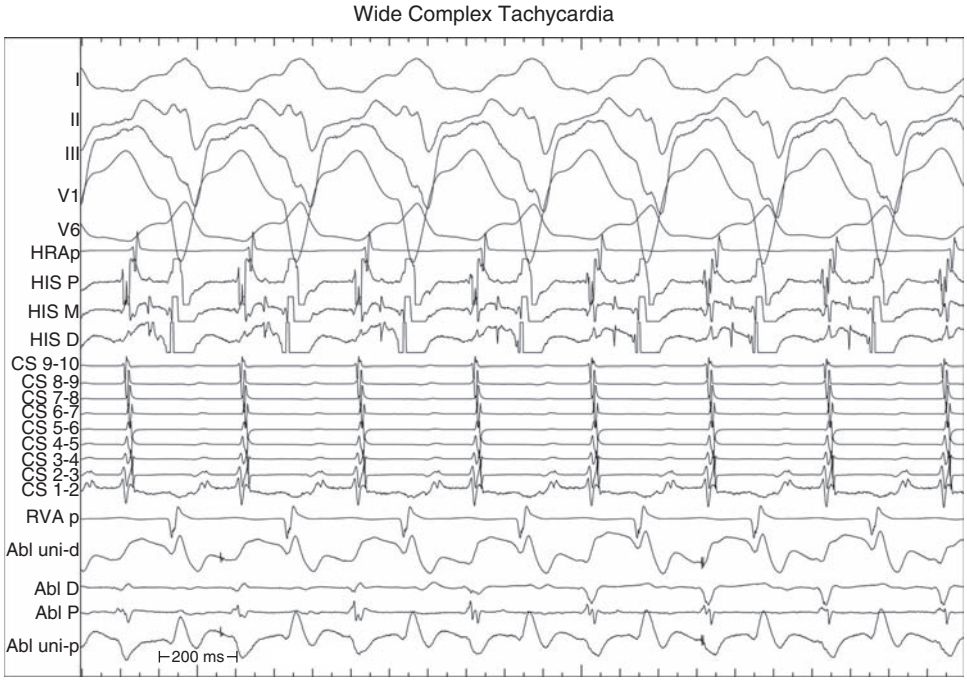

Figure 11-11

Intracardiac recordings from around the same time (Fig. 11-11) show a 1:1 atrioventricular relationship, with an atrial activation sequence identical to that of the narrow complex tachycardia. In addition, a His potential precedes every QRS complex, indicating that the rhythm is supraventricular with aberration.

The coronary sinus catheter has been advanced somewhat, accounting for its change in activation sequence and timing relative to the His bundle atrial activation.

Wide-to-Narrow QRS Tachycardia Transition

Why Did the QRS Narrow? [Fig. 11-12]

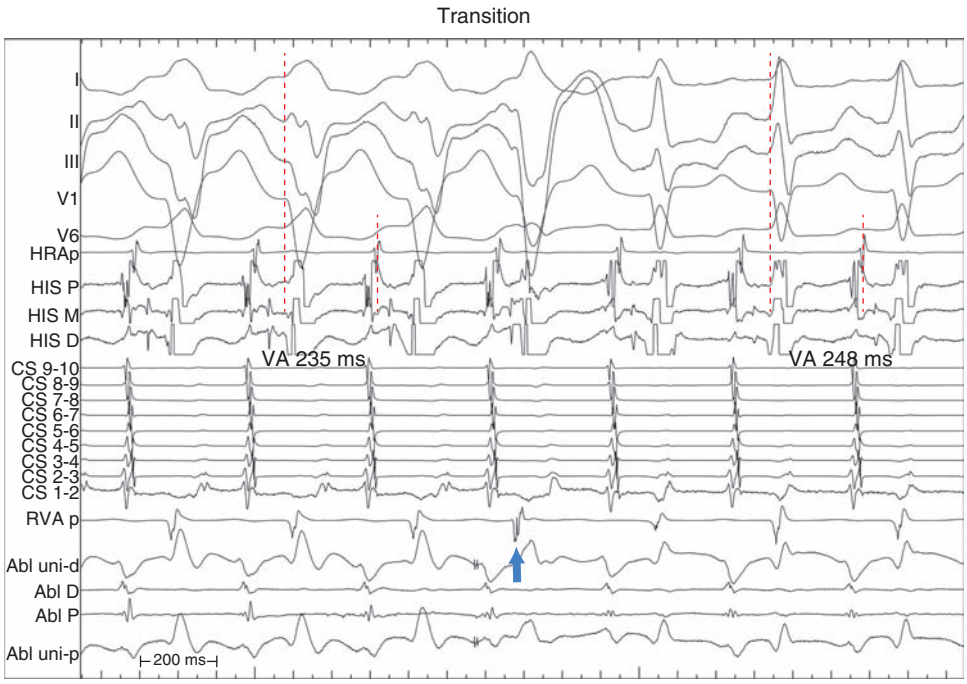

Figure 11-12

Spontaneous transition from wide to narrow QRS complex is seen in Fig. 11-12. An important measurement to make in this situation is the VA interval (onset of QRS to an atrial electrogram *[dashed lines]*). With orthodromic reentry related to a left-sided bypass tract, the VA interval with LBBB will exceed that during narrow QRS tachycardia by >35 ms. In this example, there is no difference in the VA intervals, excluding participation of a left free wall bypass tract.

The QRS complex narrowed because of a spontaneous premature ventricular complex from the right ventricle *(arrow)* that likely prematurely activated the LBBB, allowing it more time to recover for the subsequent complex, that could then conduct normally.

Ventricular Pacing in SVT to Delineate P-Wave Onset

What's Up with This? [Fig. 11-13]

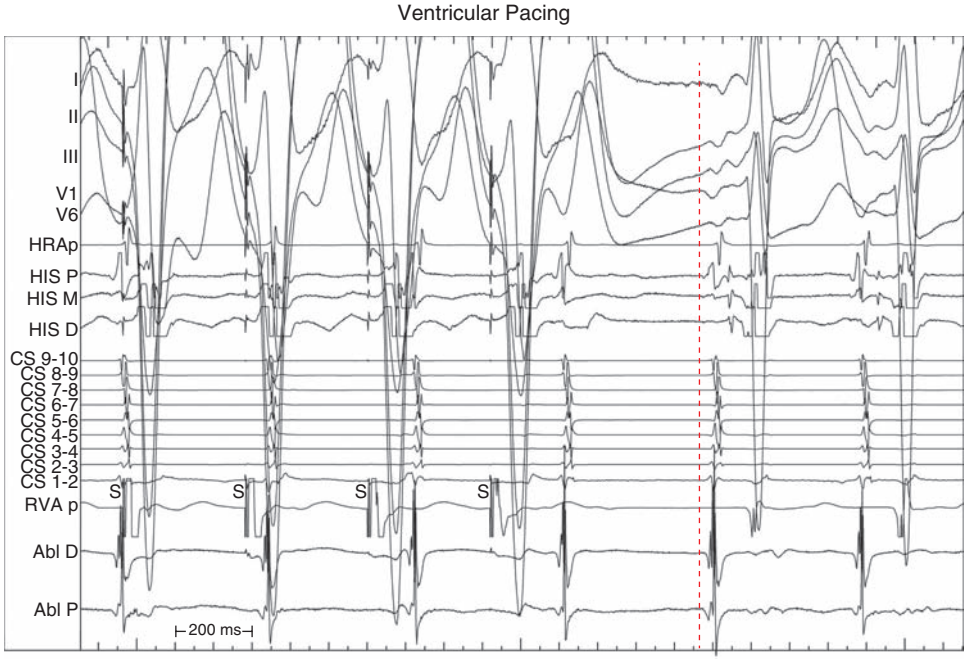

Figure 11-13

In Fig. 11-13, ventricular pacing is performed during tachycardia; surface ECG leads have increased gain to demonstrate P-wave onset for mapping purposes *(dashed red line)*. Of note, atrial activation continues throughout the figure unaffected by ventricular pacing; this excludes orthodromic reentry, in which atrial activation depends on prior ventricular activation. Because this and AV nodal reentry have now been excluded, the diagnosis is atrial tachycardia. Now that the P wave onset has been clarified, it can be indexed to another more readily seen recording (such as HRA, 50 ms after P wave onset) to compare the timing of mapping sites, without having to guess where the P wave starts or repeat ventricular pacing to discern it.

Right Atrial and then Coronary Sinus Pacing During Tachycardia

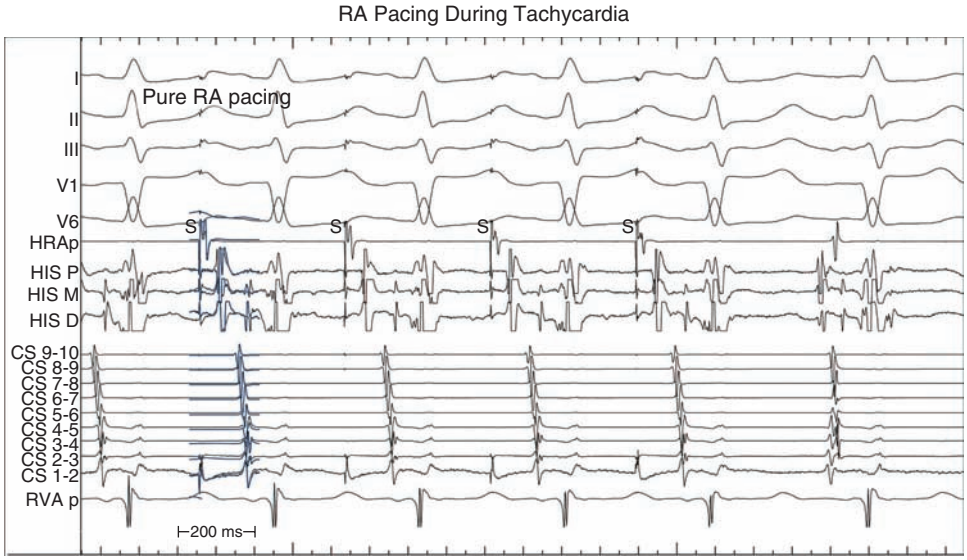

Figure 11-14

Now that a diagnosis of atrial tachycardia has been established, it remains to be determined whether this is because of macroreentry or a focal process. The modes of initiation and termination seen in previous figures are consistent with either. In the example shown in Fig. 11-14, a complex of "pure" right atrial pacing *(blue)* obtained during sinus rhythm is superimposed on a complex of pacing from the same site during tachycardia (a tachycardia beat resumes at right). It is clear that the activation sequence is the same whether pacing during sinus rhythm or tachycardia, indicating absence of fusion. Mere absence of fusion when pacing from one site does not establish a diagnosis of a focal process (however, if macroreentry is present, it is often possible to demonstrate fusion when pacing from a single site).

What Do the Results of Pacing During Tachycardia Tell Us? [Fig. 11-15]

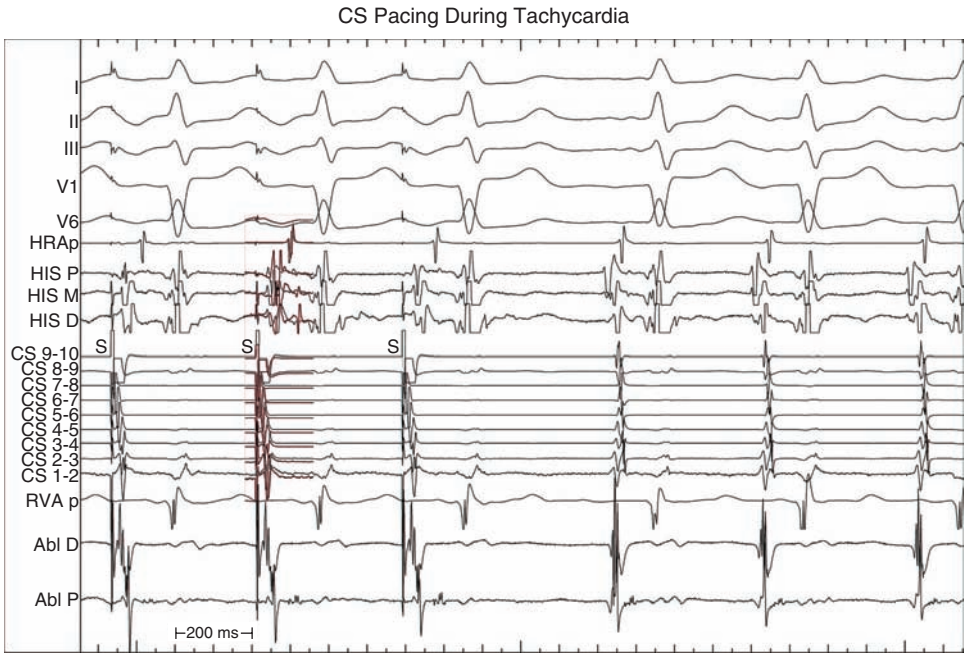

Figure 11-15

In Fig. 11-15, pacing from the proximal coronary sinus (CS) is shown during tachycardia (that resumes at right) as well as a single complex of "pure" CS pacing during sinus rhythm superimposed *(red)*. Again, there is no difference between these, and thus no fusion. Similar results were obtained when pacing from the distal CS (not shown). Thus absence of fusion when pacing from multiple sites, and ideally at multiple cycle lengths, makes a focal process far more likely. This was the diagnosis in this case.

Activation and Pace Mapping in Right Atrium

Is This a Good Site?

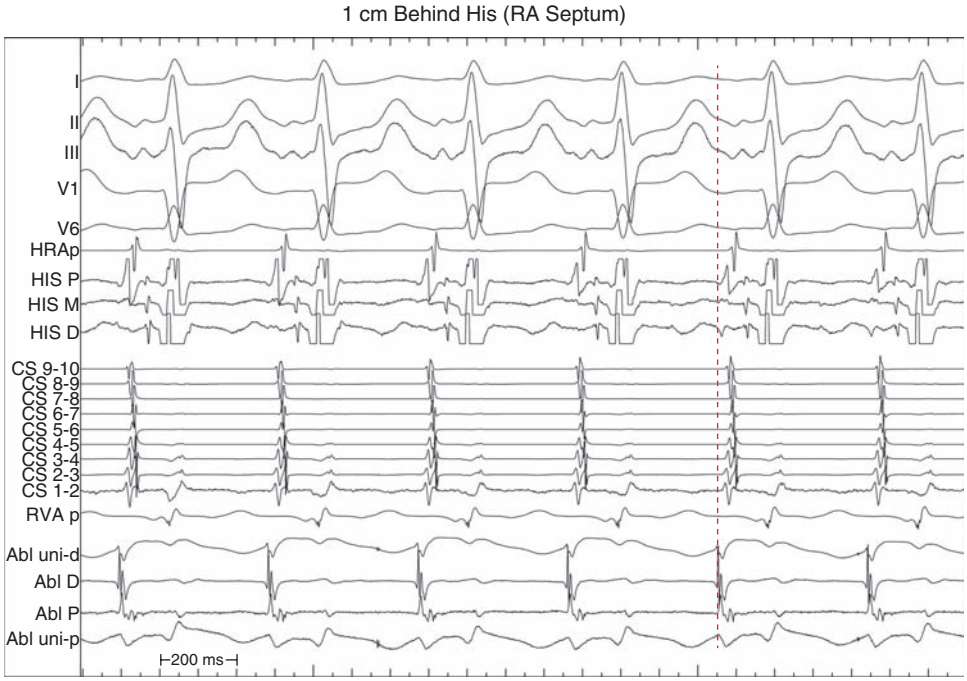

Figure 11-16

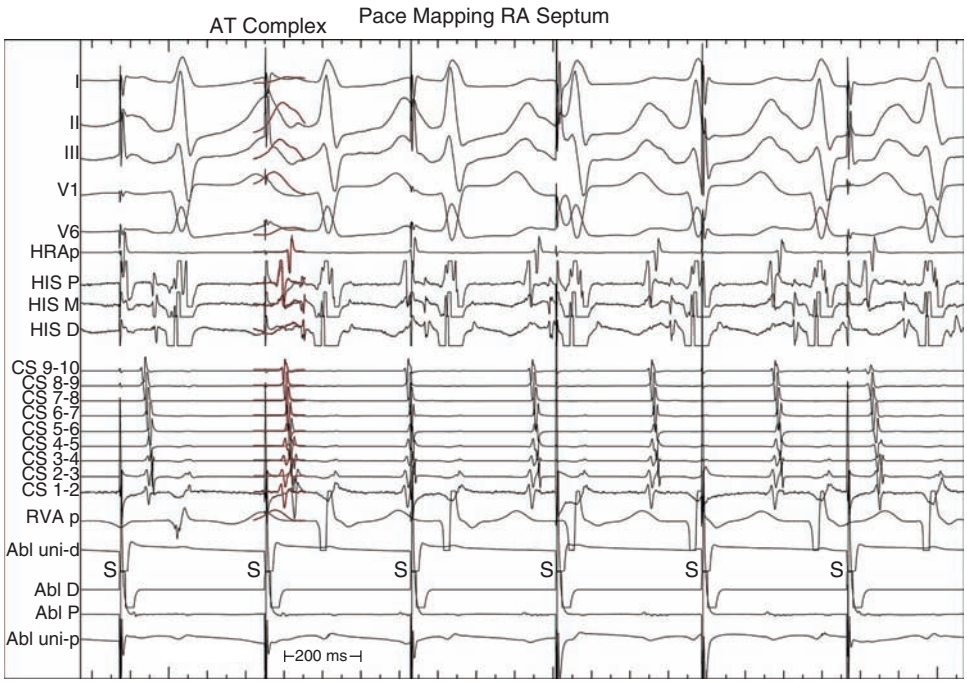
Now that a focal atrial tachycardia has been diagnosed, an electrogram that is 30–40 ms before the P-wave onset may be sought for ablation. Mapping on the right side of the interatrial septum (Fig. 11-16), near the His bundle location, discloses a site about 5 ms before P-wave onset (*dashed red line*, 50 ms before HRA recording as demonstrated in figure). The

unipolar recording has a small initial R wave; this, as well as the unimpressive timing of the atrial electrogram, excludes this as a good site for ablation.



Well?

Figure 11-17

Further evidence that this is not a good site for ablation is the fact that pacing from that site yields a very different atrial activation sequence compared with that during tachycardia (Fig. 11-17, in *red*). Pacing from the site of impulse formation of a focal tachycardia should exactly replicate the atrial activation sequence during tachycardia.

Electroanatomic Mapping of Right Atrium

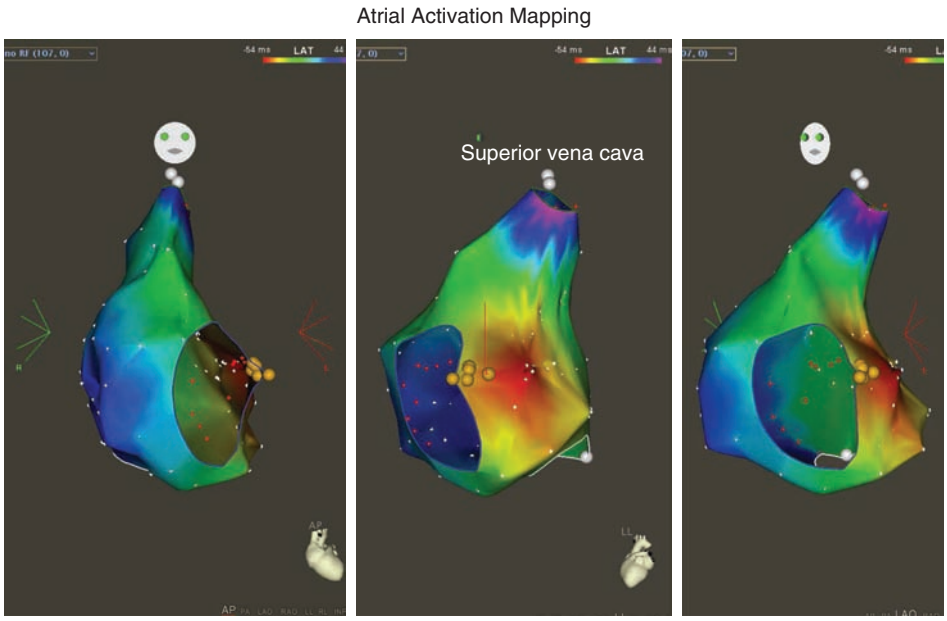


Figure 11-18

What Next?

Electroanatomic activation mapping of the right atrium during tachycardia (Fig. 11-18) shows a pattern of centrifugal spread from a focus just behind the His bundle location *(orange dots)*. At this time in the procedure, we have diagnosed narrow and wide QRS tachycardia that appear to have the same cause (focal atrial tachycardia); the tachycardia has earliest activation at or just behind the His bundle recording site, but is not very early (5 ms before P-wave onset); the earliest site covers a rather broad area; and the pace-match from there is poor. Isoproterenol is still required to sustain tachycardia for mapping but the patient's blood pressure is 200/120 mm Hg.

Activation and Pace Mapping Left Atrial Site

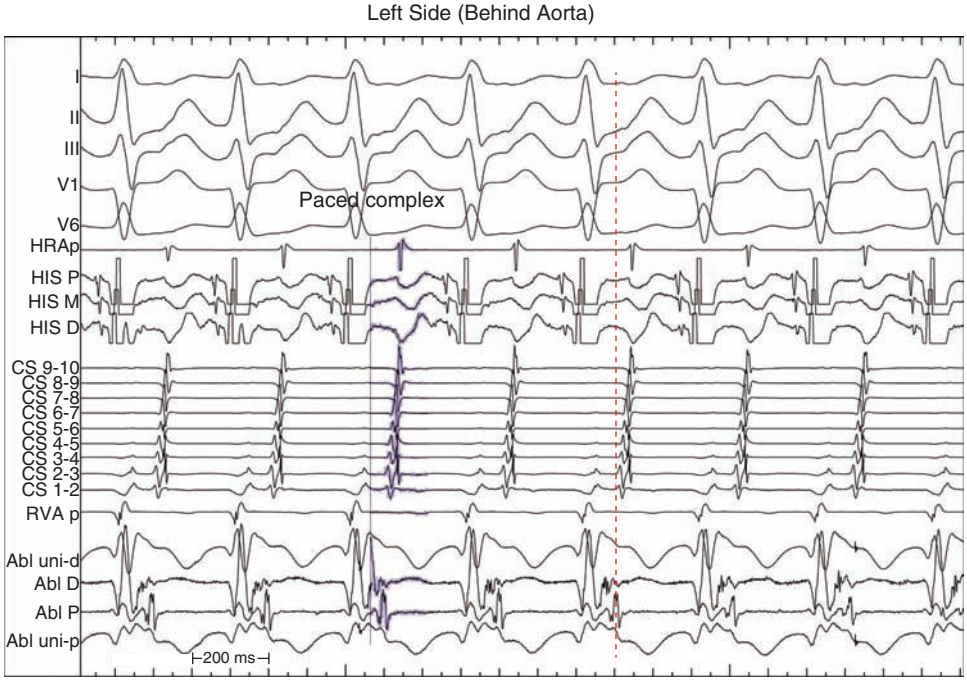

Figure 11-19

Despite the focal activation pattern on the electroanatomic map, no right atrial site showed reasonable activation times; in such cases, the left side of the septum, right superior pulmonary vein, and aortomitral continuity/mitral annulus should be evaluated before ablating behind the His bundle. After transseptal catheterization, mapping of these structures was accomplished; the site shown in Fig. 11-19 is on the mitral annulus at its junction with the aortic root (large ventricular, small and fractionated atrial electrogram). A single complex of pacing from this site is shown *(purple)* superimposed on tachycardia, yielding a perfect match. The unipolar recording is not as helpful in this situation because a large ventricular electrogram obscures the smaller atrial signal. The electrogram at this site is fragmented and considerably before the P wave onset (*dashed red line*, known from relation to HRA recording as in Fig. 11-13).

Radiofrequency Application at Left Atrial Site

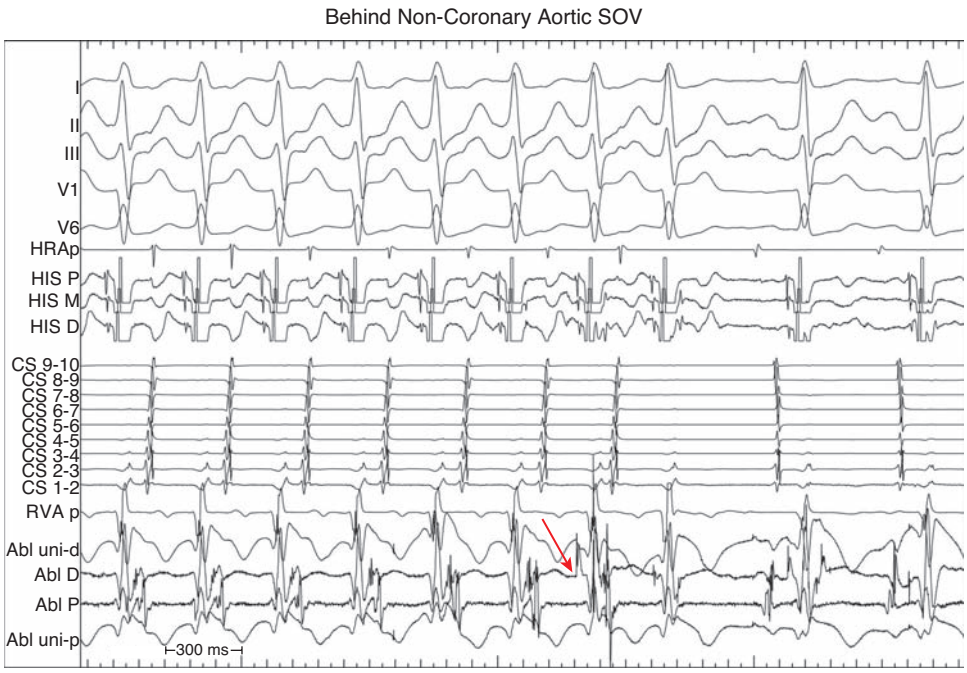

Figure 11-20

Radiofrequency (RF) energy is delivered at the site shown in Fig. 11-20 at the time indicated; tachycardia terminates immediately to sinus rhythm. Additional RF applications were made in this region.

Comparison of Best Right and Left Atrial Sites

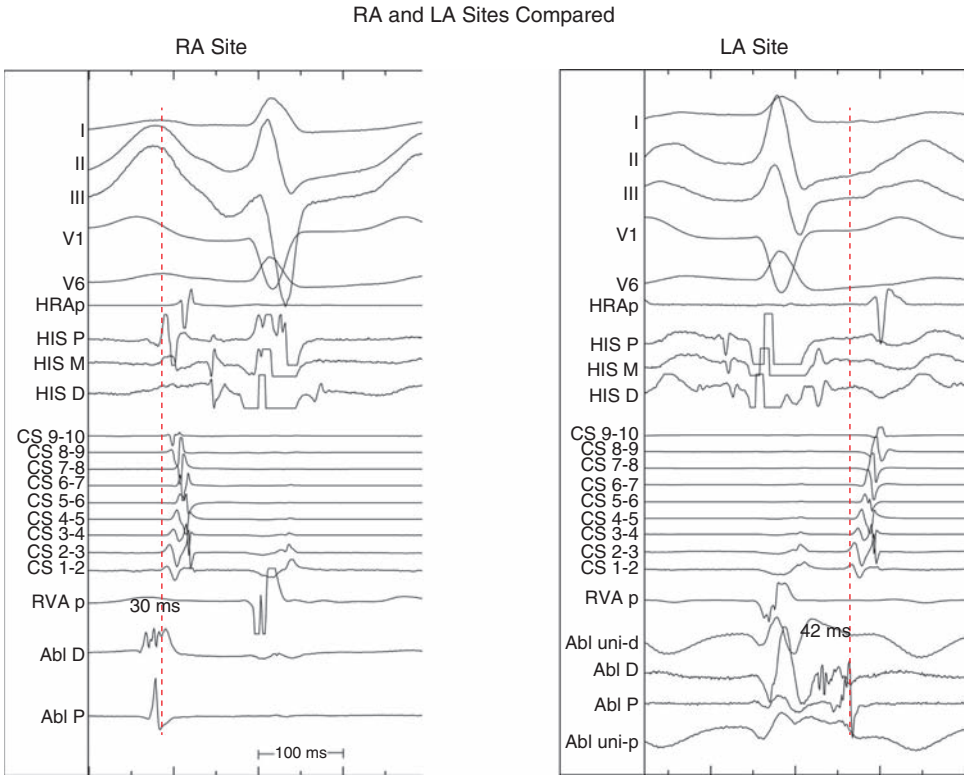

Figure 11-21

A comparison of mapping sites at rapid sweep speed is shown in Fig. 11-21. The best right atrial site is shown at left, preceding the P-wave onset (*dashed red line*, indexed from the timing of the CS atrial recordings) by 30 ms. In contrast, the successful ablation site on the mitral annulus occurs 42 ms before P-wave onset.

Electroanatomic Map of Left Atrium

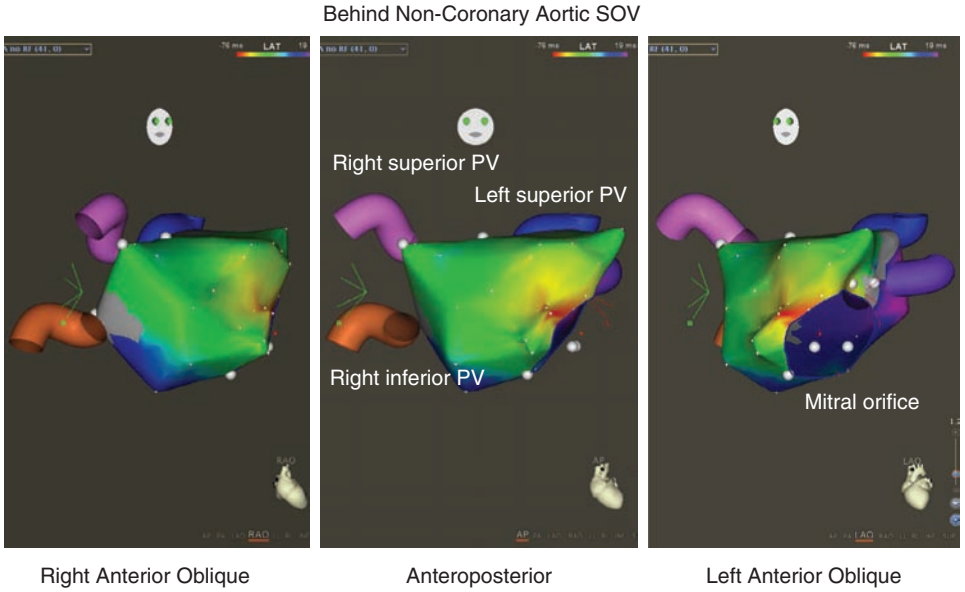

Figure 11-22

Electroanatomic activation map during tachycardia of the left atrium is shown in Fig. 11-22, with a focal propagation pattern from a site *(red spot)* on the anterior medial mitral annulus.

Fluoroscopic Views of Best Right and Left Atrial Sites

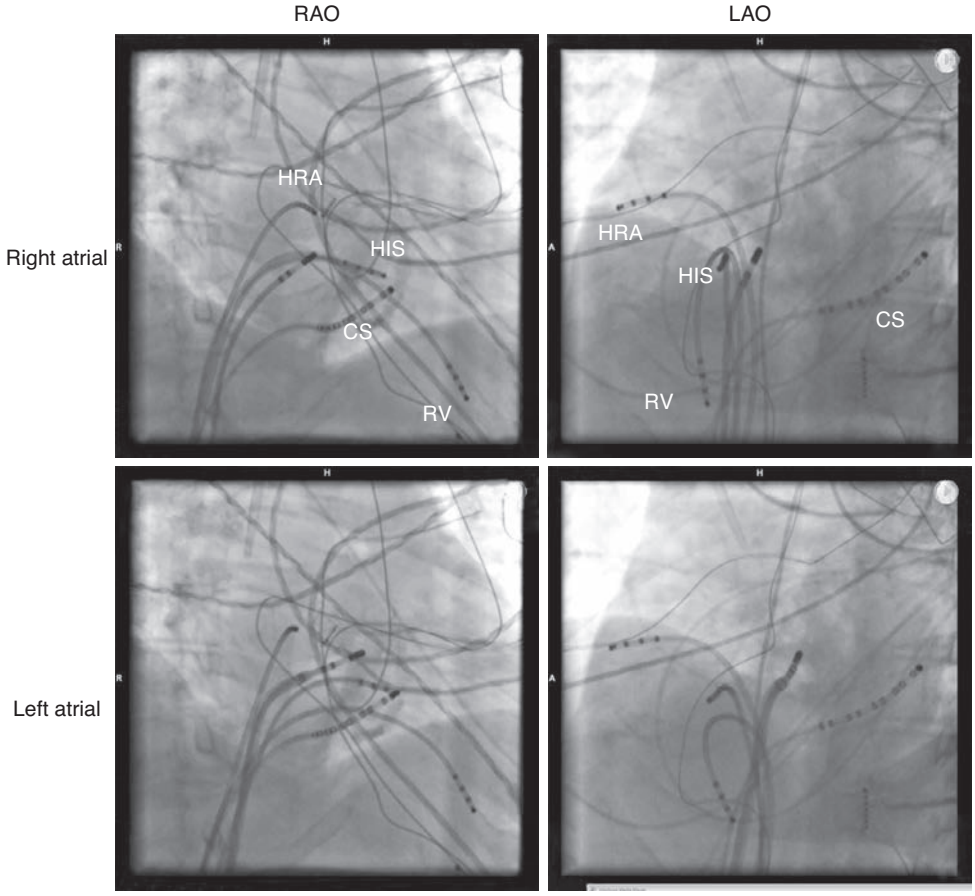

Figure 11-23

Fig. 11-23 displays comparative fluoroscopic views of catheter locations at sites of the earliest right and left atrial activation during SVT (catheter with large electrode at tip). *CS*, coronary sinus; *HRA*, high right atrium; *LAO*, left anterior oblique; *RAO*, right anterior oblique; *RV*, right ventricle.

Cutaway View of Atrioventricular Groove

Figure 11-24

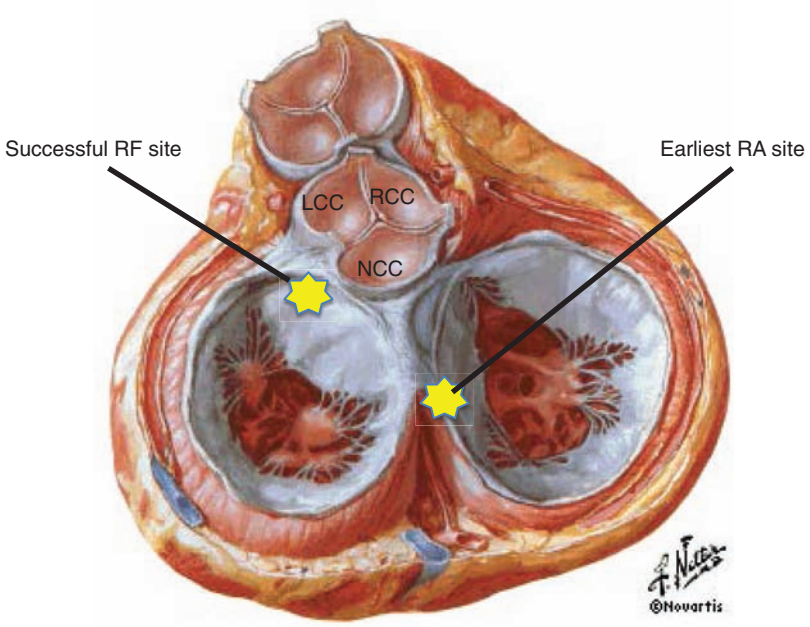

Fig. 11-24 shows atrioventricular valves annuli viewed from above, with both the successful left atrial ablation site and site of the earliest right atrial activation indicated. *LCC*, left coronary cusp; *NCC*, noncoronary cusp; *RCC*, right coronary cusp. (Copyright [2016] Elsevier Inc. All rights reserved. www.netterimages.com.)

Summary

- Atrial tachycardia can strike at any age.
- Know your mechanism (focal vs macroreentry) before mapping (target-site characteristics are determined thereby).
- Focal atrial tachycardia can arise from many places.
- P-wave configuration in SVT provides substantial localization information before and during the procedure.
- "Earliest atrial activation at His" suggests the following:
  - Right superior PV source (His-A after P-wave onset)
  - Left septal source (His-A ~10 ms before P-wave onset)
  - Anterior left atrial source (aortomitral continuity, etc.—His-A ~10 ms before P-wave onset)
  - Para-Hisian source (His-A ~20 ms before P-wave onset)
- Before ablating near the His, check out the left atrium.

12 Typical Atrial Flutter

Case Presentation

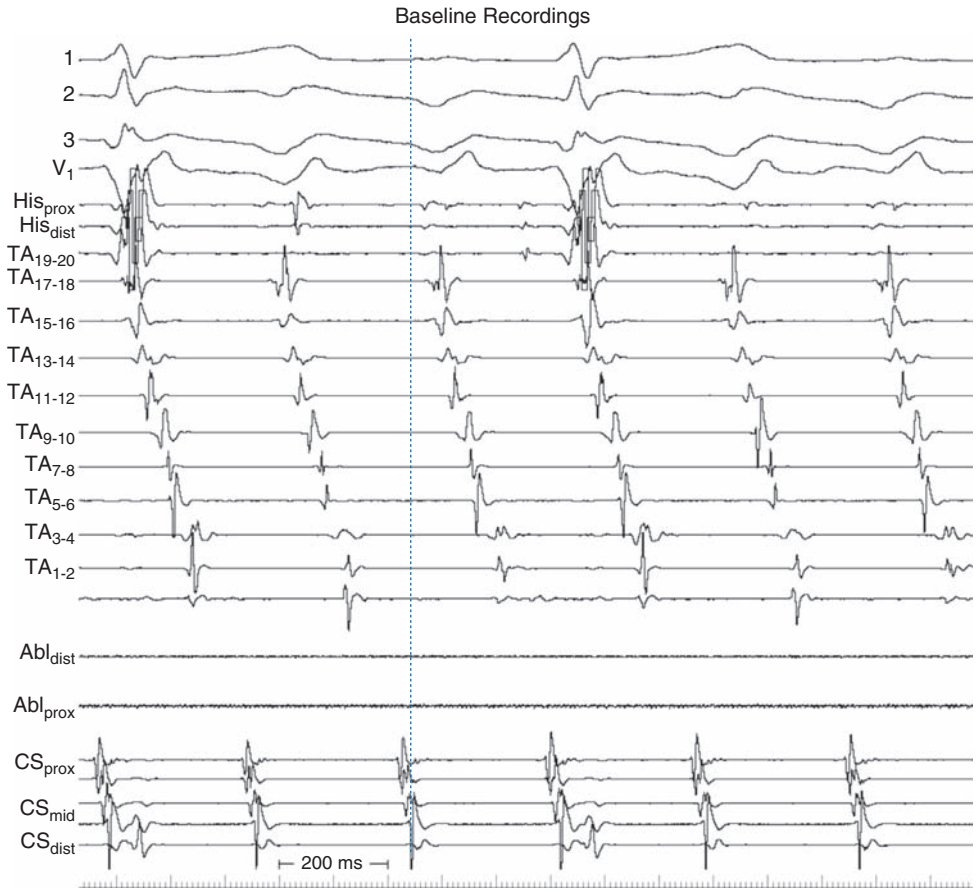
A 58-year-old man with a history of palpitations for several years had a diagnosis of atrial arrhythmias as well as bradycardia, but had no treatment for these. One year before his current presentation, he had an unheralded stroke with aphasia and hemiplegia. He underwent successful thrombolytic therapy with no residual neuorologic impairment. At the time of his stroke, he was diagnosed with atrial flutter and soon after, underwent attempted flutter ablation. At the end of an 8-hour procedure, cavotricuspid isthmus block was achieved but flutter was still present (thought to be either lower loop or intraisthmus reentry). He was chronically anticoagulated; he was also treated with propafenone, but without success. He began having palpitations and was referred for another ablation attempt. Left ventricular function was normal on echocardiography.

Baseline ECG and Intracardiac Recordings

Catheter Choices?
[Fig. 12-1]
Strategy?

Figure 12-1

The baseline ECG in Fig. 12-1 appears to be consistent with typical right atrial cavotricuspid isthmus-dependent flutter, but that was said to have been ablated at the prior procedure. Reasonable choices for catheters are coronary sinus (with some electrodes near the ostium), tricuspid annular catheter ("halo"), and a His bundle catheter, as well as the ablation catheter.



We Begin with the Differential Diagnosis: [Fig. 12-2 and 12-3]

A. Typical CCW flutter
B. Lower loop reentry
C. Intraisthmus reentry
D. Focal AT near CS os
E. AT from left atrium

Figure 12-2

Intracardiac recordings of the baseline rhythm are shown in Fig. 12-2. Again, this appears to be entirely compatible with cavotricuspid isthmus reentry—but there are other possible diagnoses that should be eliminated before choosing an ablation target. A broad differential diagnosis includes typical counterclockwise (CCW) cavotricuspid isthmus flutter; lower loop reentry; intraisthmus reentry; focal atrial tachycardia (AT) near the coronary sinus ostium (CS); or atrial tachycardia from the left atrium.

Diagnostic Maneuvers

CS Distal Pacing

Differential diagnosis:
- typical CCW flutter
- lower loop reentry
- intra-isthmus reentry
- focal AT near CS os
- AT from left atrium

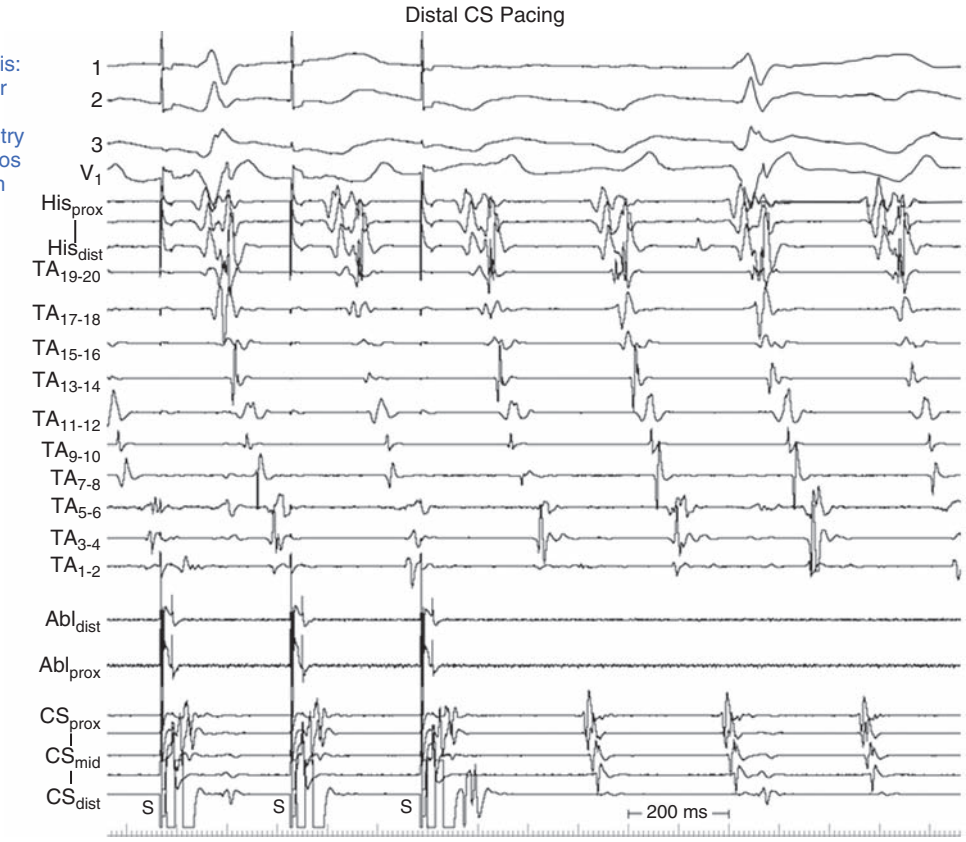


Figure 12-3

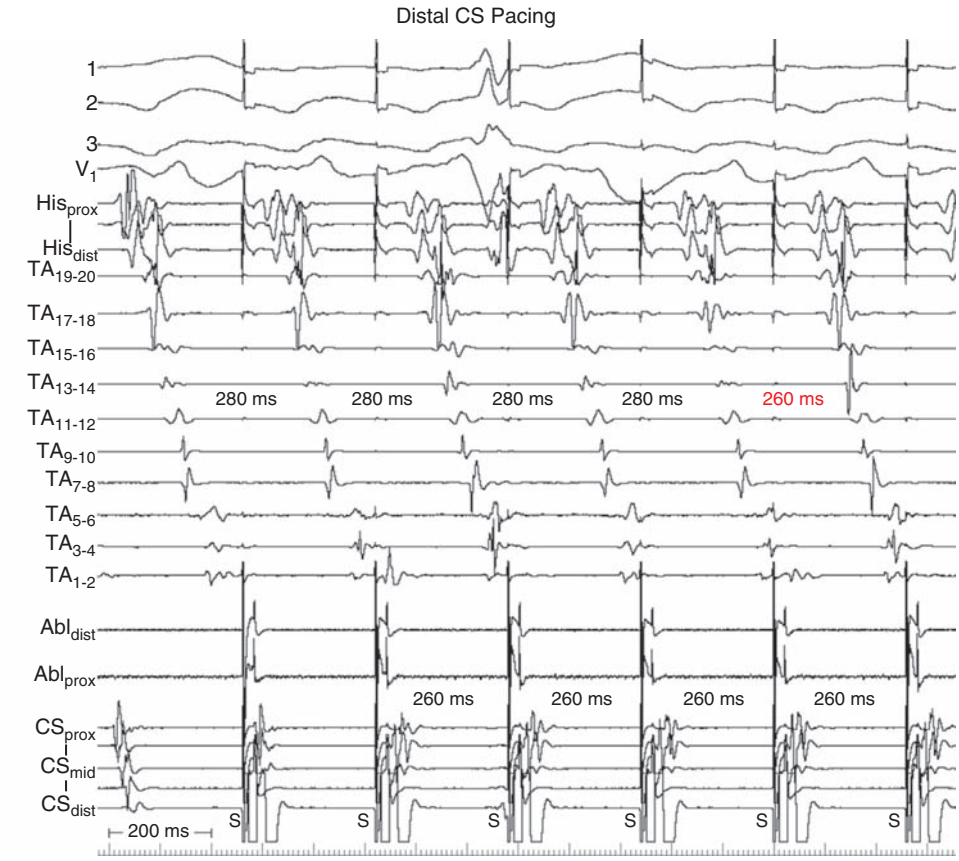
Burst pacing from the distal CS, as shown in Fig. 12-3, is a good way to start trying to distinguish among possible diagnoses; in a patient without prior ablation, pacing from this site during sinus rhythm should have a "chevron" appearance to the halo recordings (earlier at TA 1-2 and TA 19-20, latest at lateral right atrium [TA 11-12]). If such a pattern is seen with pacing from the CS during the tachycardia, it is not likely to be typical flutter. The activation pattern in halo recordings shown here looks the same as during tachycardia—suggesting fusion (some contribution from tachycardia, some from pacing). However, it is important to remember that this inference is valid if the patient has not had prior ablation in the right atrium that could disrupt activation patterns. Because this patient has had a previous ablation attempt, we cannot assume what pacing from the distal CS should look like, and thus cannot conclude that entrainment has been demonstrated. Unfortunately, pacing from the distal CS in this case appears to have little diagnostic value, and our differential diagnosis is unchanged.



We Can Eliminate AT from Left Atrium from the Differential Diagnosis: [Fig. 12-4]

A. Typical CCW flutter
B. Lower loop reentry
C. Intraisthmus reentry
D. Focal AT near CS os

Figure 12-4

Although most attention is focused on what happens at the end of a pacing attempt, there is also information at the onset of pacing (Fig. 12-4). Here, with the onset of distal CS pacing, the proximal CS electrodes are controlled by the second stimulus and are accelerated to the paced cycle length (260 ms). The halo recordings, by contrast, are not accelerated until the fifth stimulus. If this tachycardia arose in the left atrium, as soon as that chamber is controlled, all other recordings that are passive should be controlled as well. Here, because the right atrial recordings continue unchanged for a few cycles after full left atrial control, the arrhythmia must arise in the right atrium. Thus one choice in the differential diagnosis (atrial tachycardia from the left atrium) has been eliminated.

Differential diagnosis:
- typical CCW flutter
- lower loop reentry
- intra-isthmus reentry

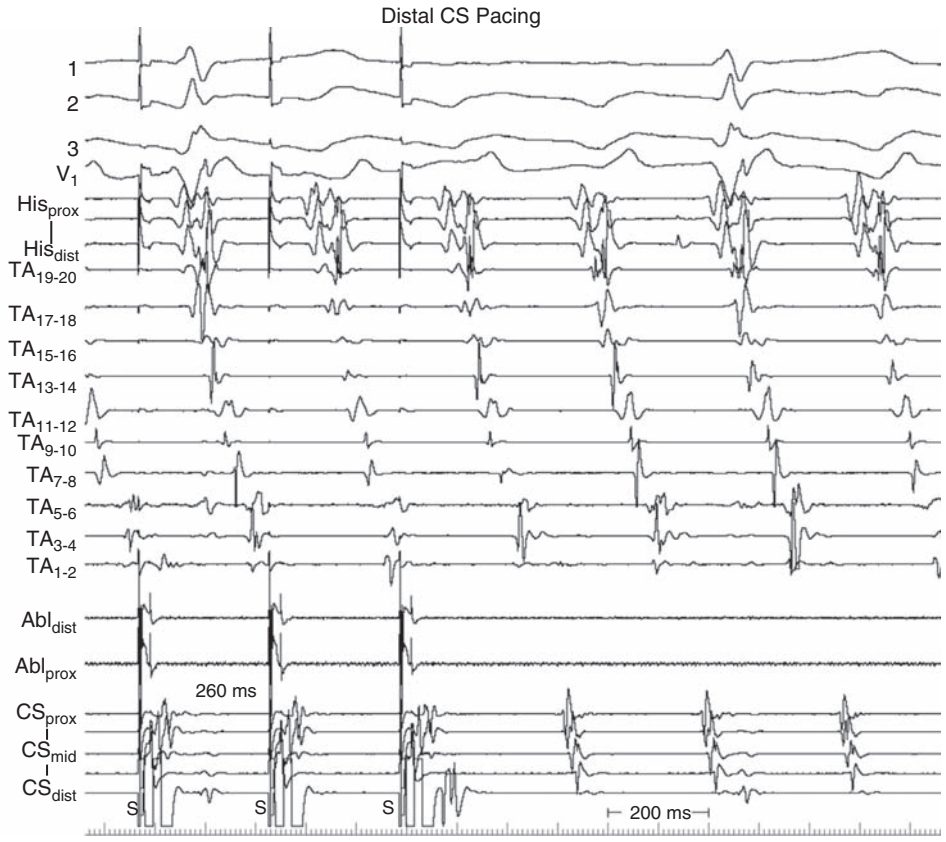


Figure 12-5A

Differential diagnosis:
- typical CCW flutter
- lower loop reentry
- intra-isthmus reentry

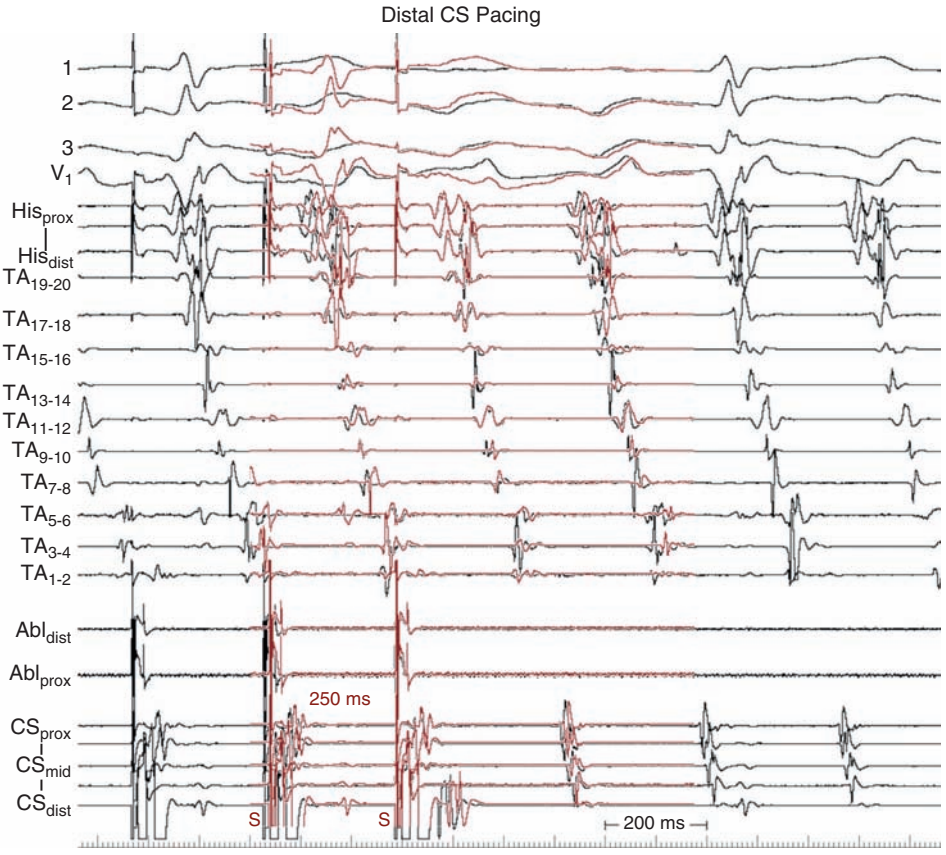

Figure 12-5B

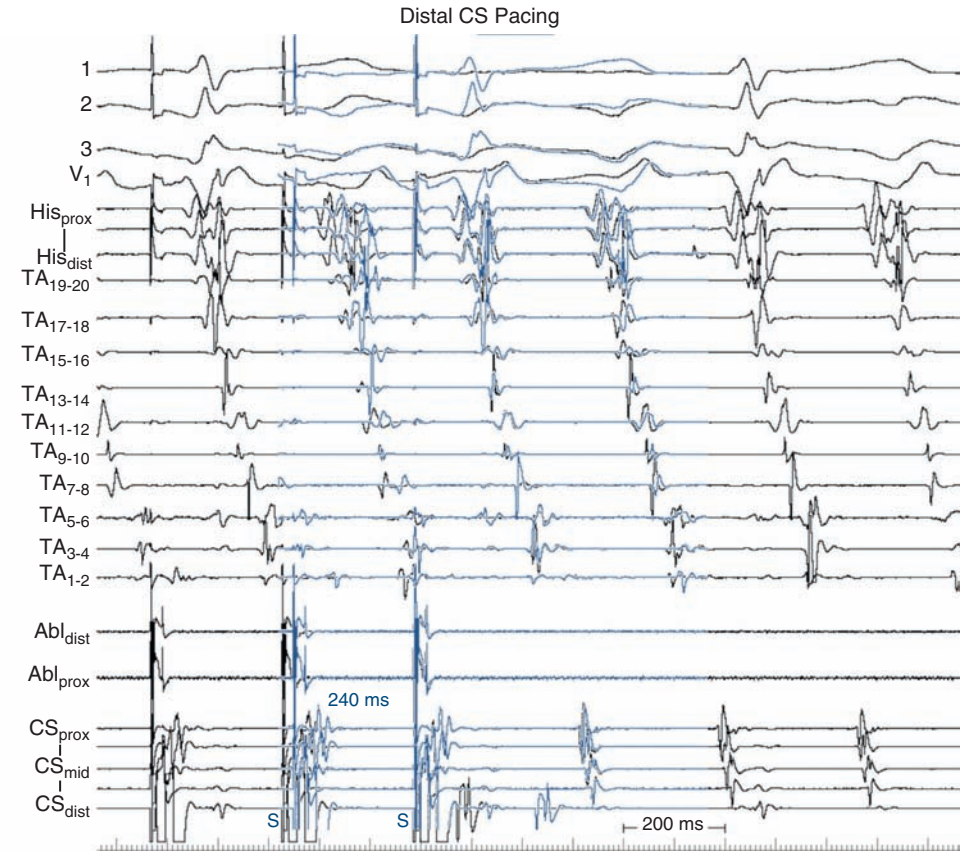

Figure 12-5C

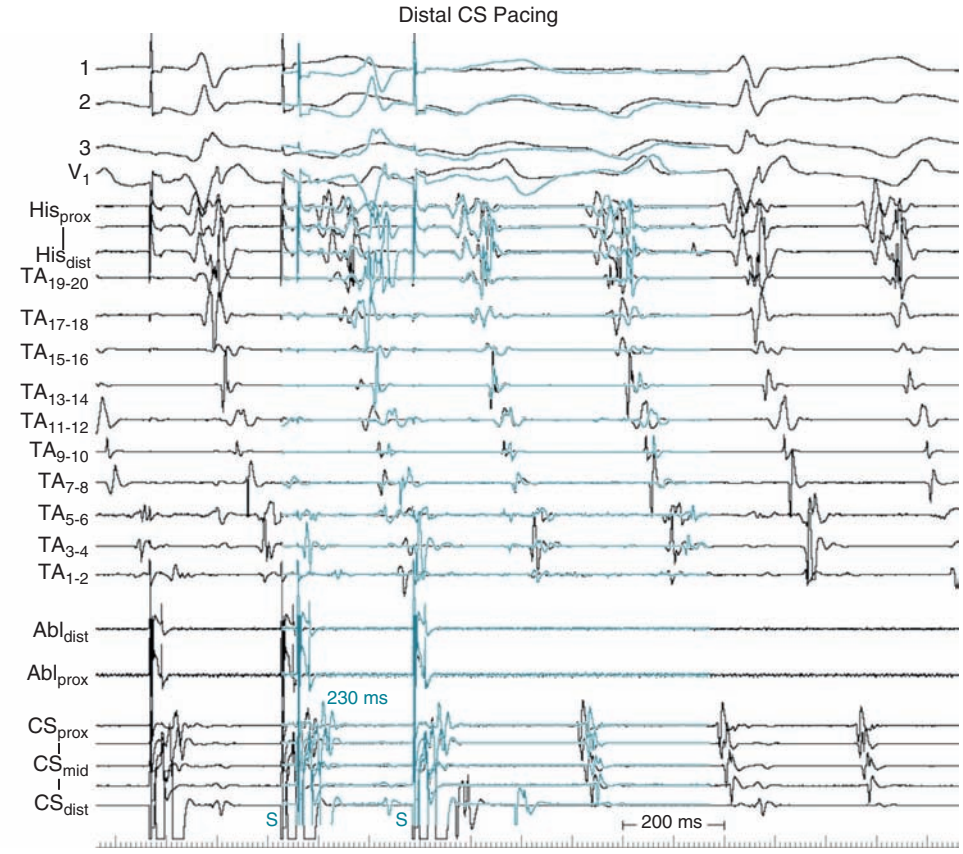

Figure 12-5D

Differential diagnosis:
- typical CCW flutter
- lower loop reentry
- intra-isthmus reentry

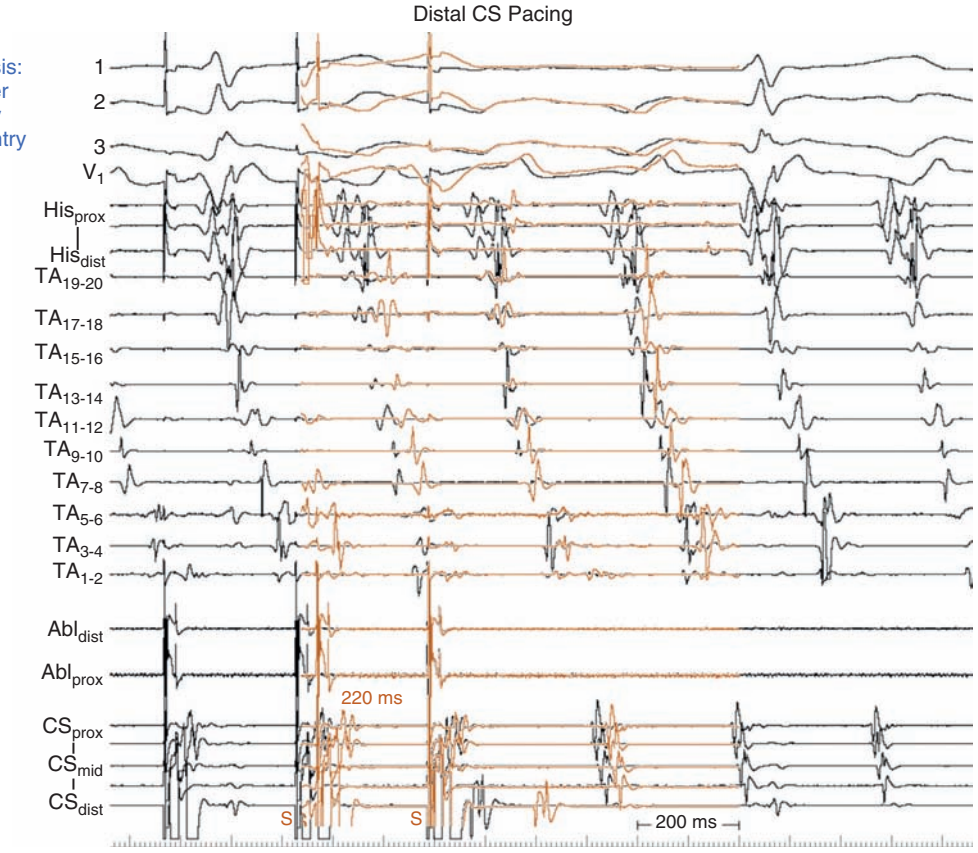

Figure 12-5E

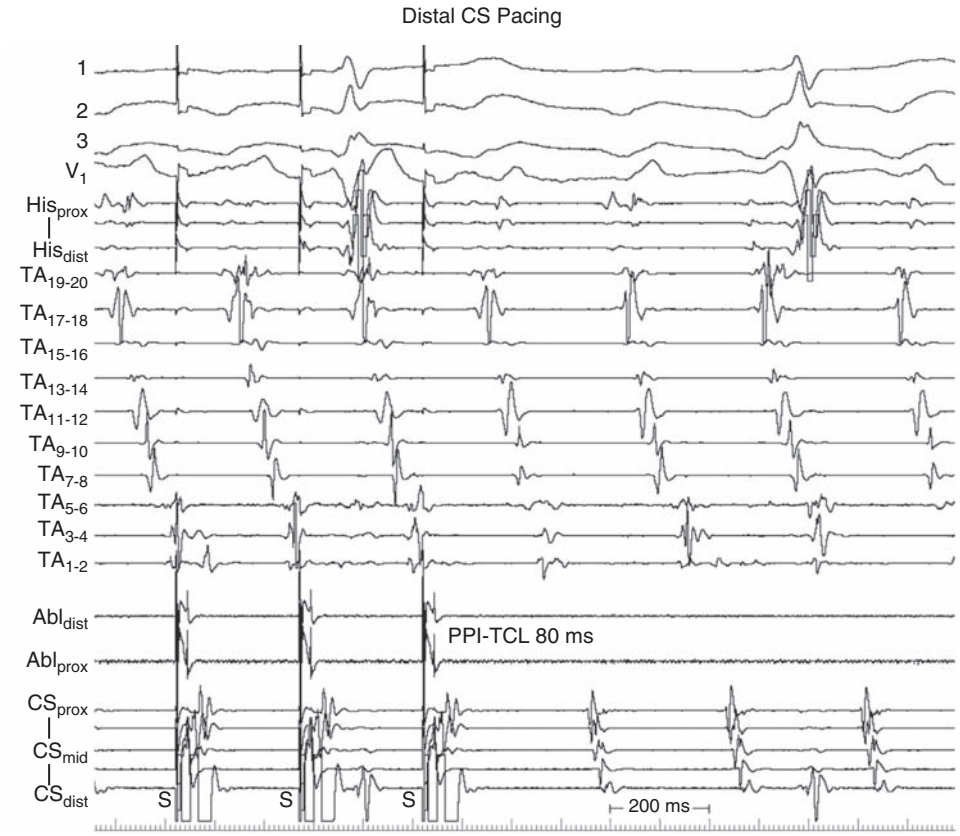
Focal atrial tachycardias often exhibit overdrive suppression; that is, with faster paced rates during tachycardia, the first tachycardia complex after pacing stops will occur after progressively longer delays. In Fig. 12-5 A-E, overdrive pacing at increasingly faster rates (shorter cycle lengths as indicated in different color overlays on Fig. 12-5 B-E) shows no appreciable overdrive suppression. This response is most consistent with a circuit having a fixed path length. Thus a focal tachycardia near the CS ostium (or anywhere else) appears unlikely. Another possible diagnosis has been eliminated.



We Can Eliminate Focal AT Near CS os from Our Differential Diagnosis: [Fig. 12-5E and 12-10B]

A. Typical CCW flutter
B. Lower loop reentry
C. Intraisthmus reentry

Figure 12-6

In Fig. 12-6, pacing is again performed from the distal CS, to evaluate relative distance from the pacing site to a suspected circuit. The post-pacing interval (PPI) minus tachycardia cycle length (TCL) difference, 80 ms, suggests a significant distance from the distal CS pacing location to the circuit.

CS Proximal Pacing

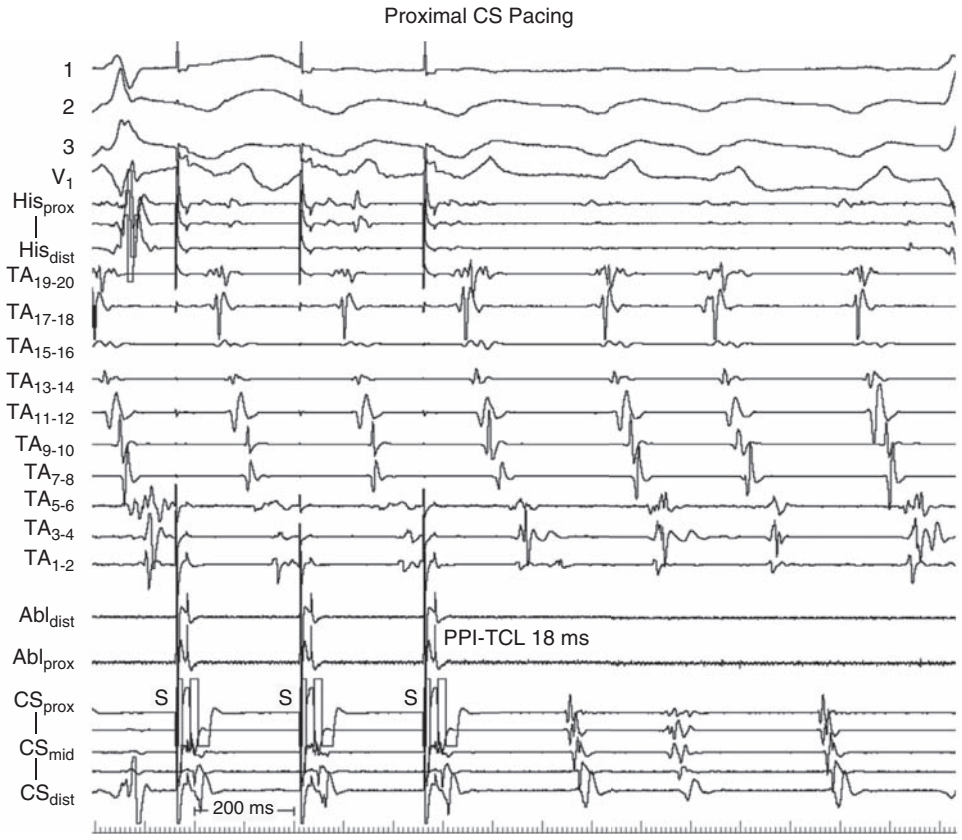


Figure 12-7

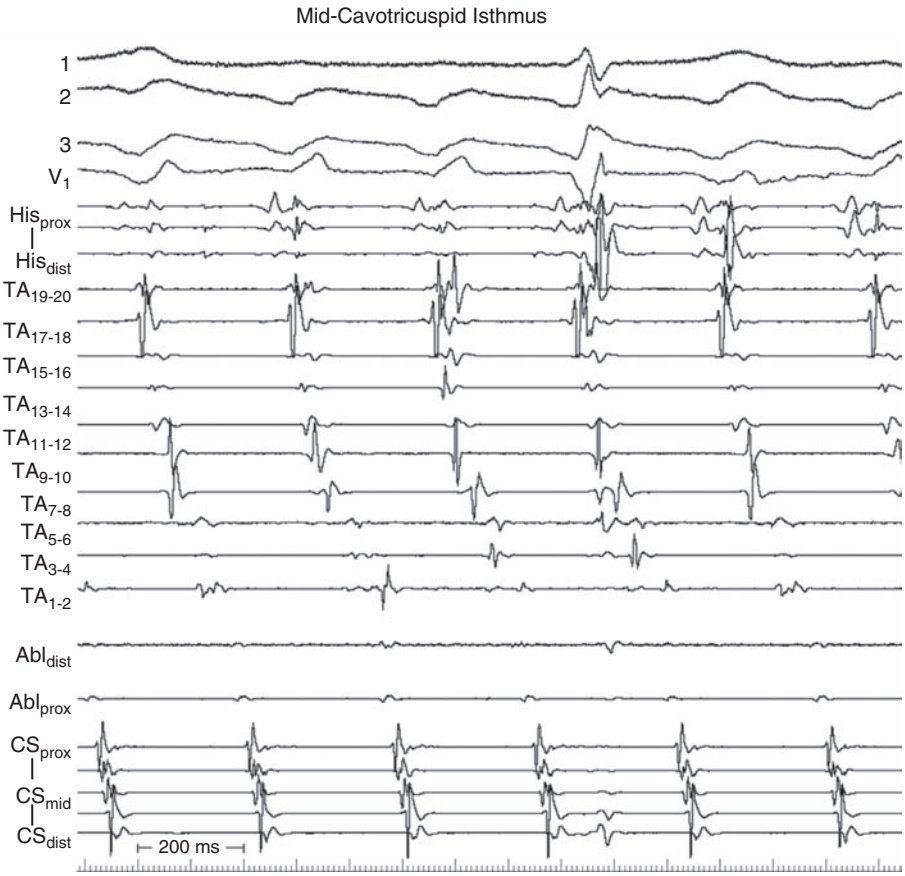
Pacing now from the proximal CS electrodes (Fig. 12-7) shows a PPI minus TCL difference of 18 ms, suggesting that it is close to or within the circuit. These electrodes are at the coronary sinus ostium. However, this does not distinguish among the three remaining possibilities—all of which are reentry, and all of which include the region of the CS os in the circuit.

Recording from CTI



Why Is There No Recording at the Abl_{dist} and Abl_{prox} Leads?

Figure 12-8

In the midcavotricuspid isthmus (Fig. 12-8), there are no remaining electrograms at standard recording gain (Abl recordings). This is anticipated because of the prior extensive ablation.

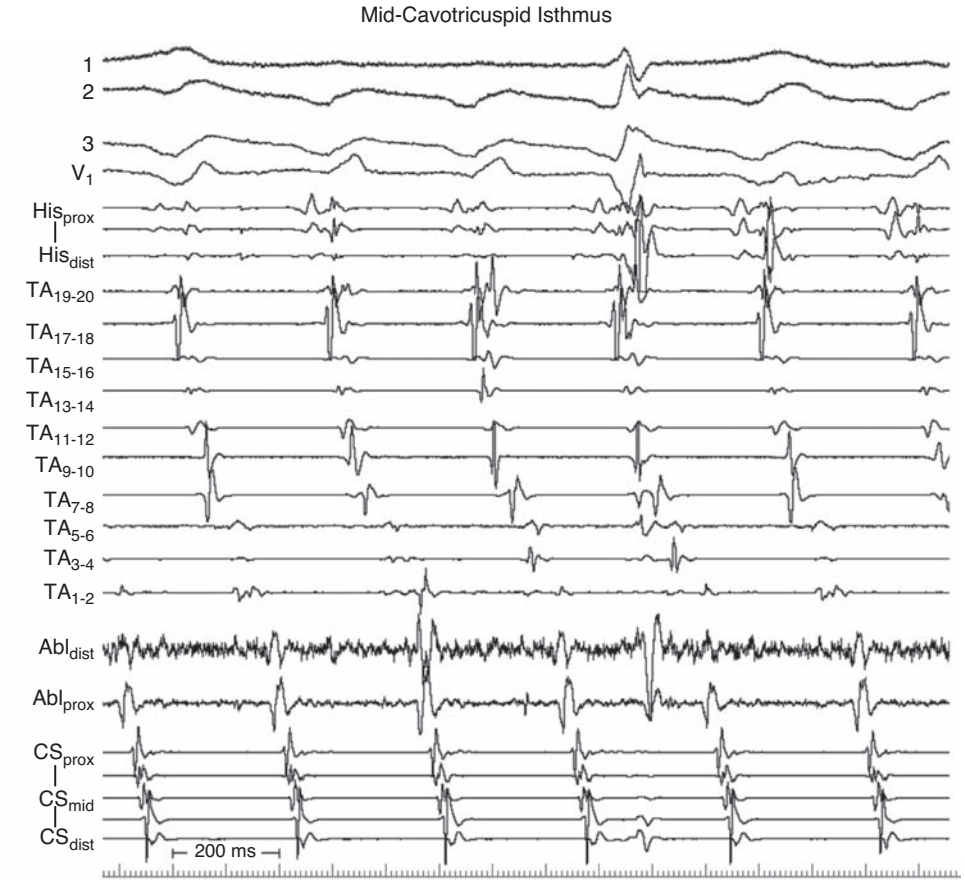


Figure 12-9

However, when the recordings are adequately gained (Fig. 12-9), it is evident that a small but discrete electrogram remains. Two of the three diagnostic possibilities use the cavotricuspid isthmus, but because one does not, it is important to clarify whether this tissue is part of the circuit or not.

Pacing from CTI

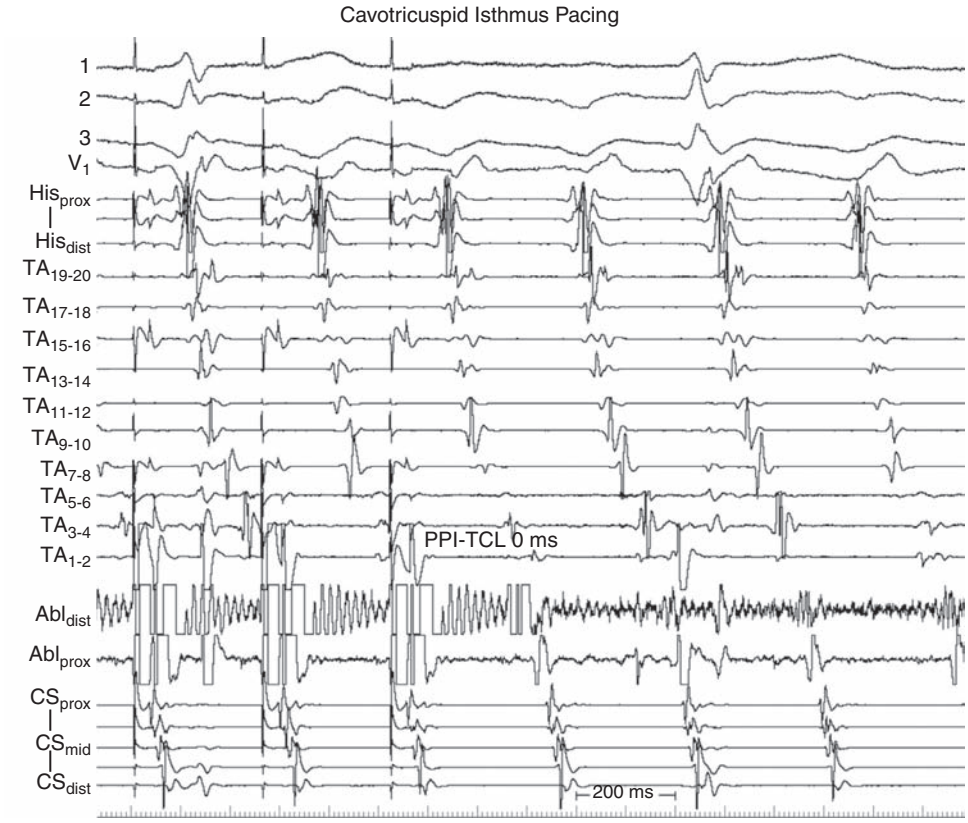

Figure 12-10A

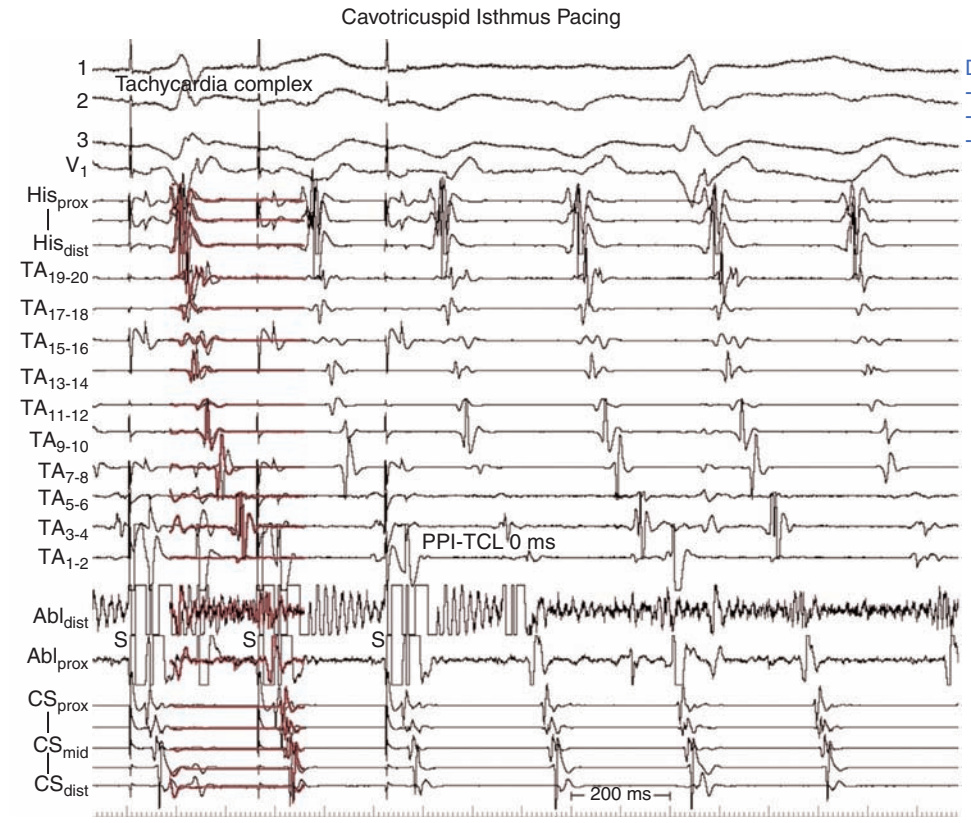

Figure 12-10B

Pacing from the cavotricuspid isthmus (Fig. 12-10A) produces a perfect match with the superimposed tachycardia complex (*red*, Fig. 12-10B) as well as the PPI minus TCL difference of zero, indicating that it is part of the circuit. However, this still does not establish a final diagnosis, because two of the remaining possible diagnoses include this tissue in their circuit.

Pacing from Lateral TA

Differential Diagnosis: [Fig. 12-11]

A. Typical CCW flutter

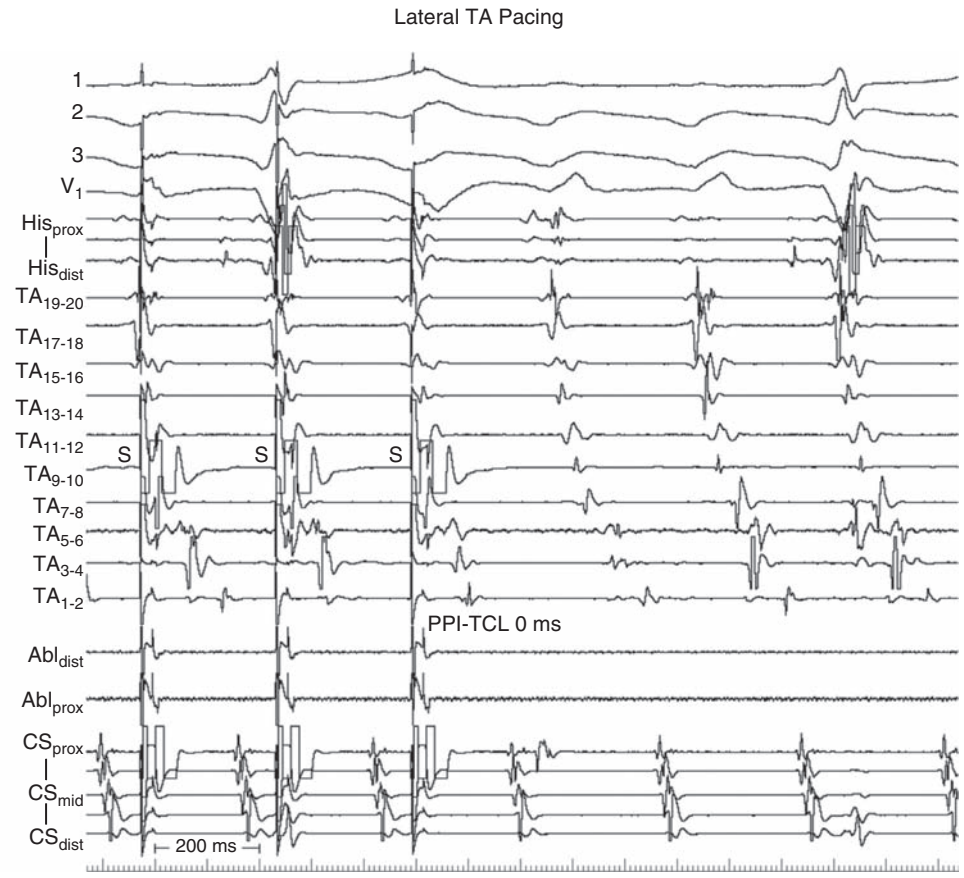

Figure 12-11

Pacing from the lateral tricuspid annulus as shown in Fig. 12-11 produces a PPI minus TCL difference of zero, indicating that it is part of the tachycardia circuit. Of the remaining diagnostic possibilities, only typical counterclockwise flutter incorporates the lateral tricuspid annulus in the circuit. Thus two more diagnostic possibilities have been eliminated and a definitive diagnosis has finally been established. Of note, macroreentry is established with certainty with this pacing maneuver because the stimulus artifact occurs after the onset of an accelerated flutter wave on the surface ECG and the activation pattern with pacing is unlike what would be expected with pure pacing from the lateral tricuspid annulus—signifying fusion, and diagnosing macroreentry. Ablation in the cavotricuspid isthmus at remaining surviving tissue can commence.

Electroanatomic Mapping

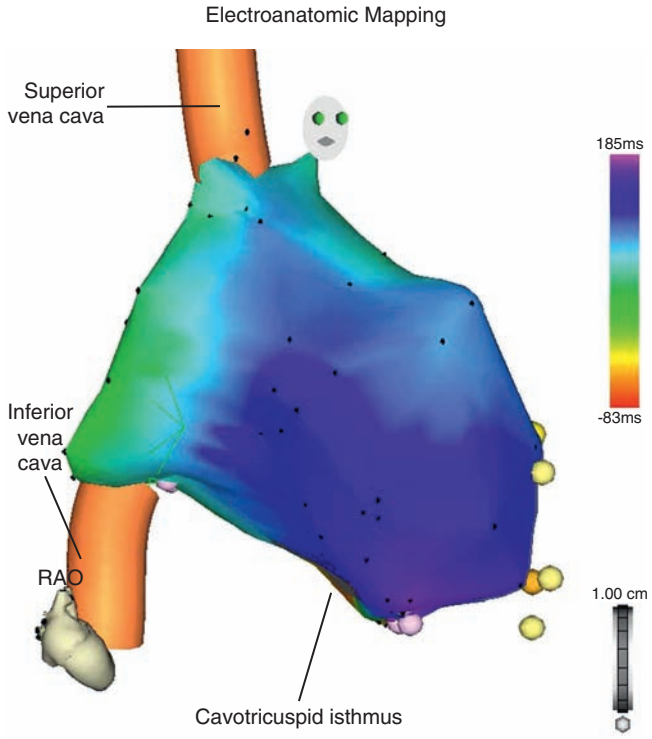

Figure 12-12

In Fig. 12-12, the electroanatomic map of this flutter in the right anterior oblique view is shown; not much useful information can be gathered from this alone.

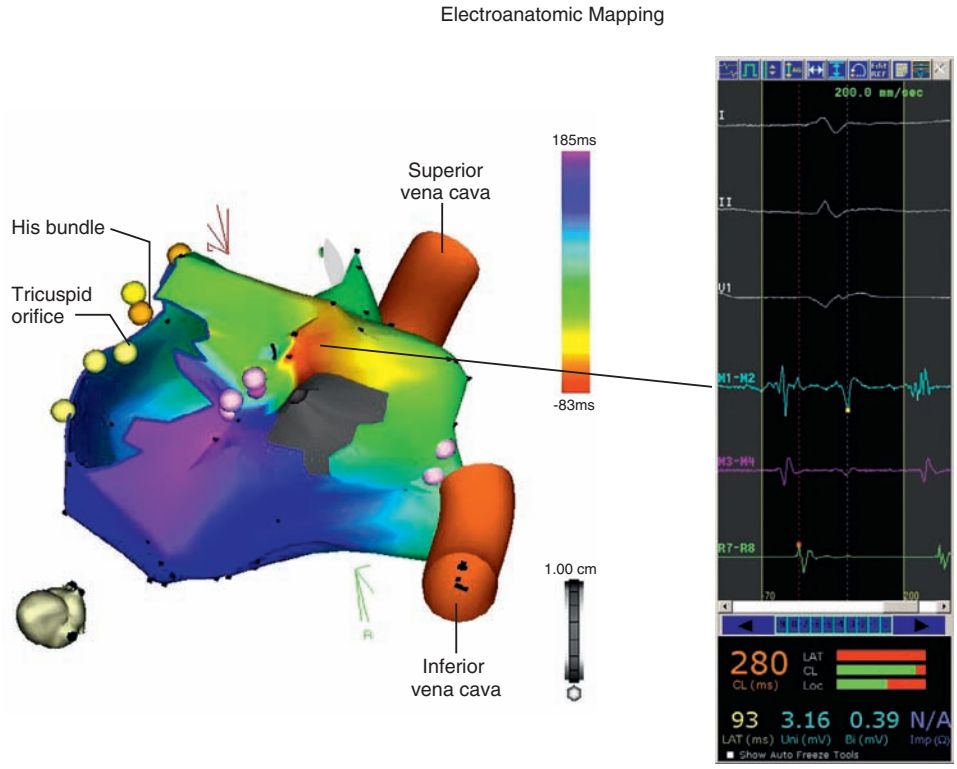

Figure 12-13

In this view from the bottom of the right atrium (Fig. 12-13), the electroanatomic map seems to suggest focal propagation from around the CS os region; the electrogram at the site of earliest activation is shown at right. Unfortunately, the electroanatomic mapping system automatically selected a point on the *ventricular* electrogram as the time of local activation.

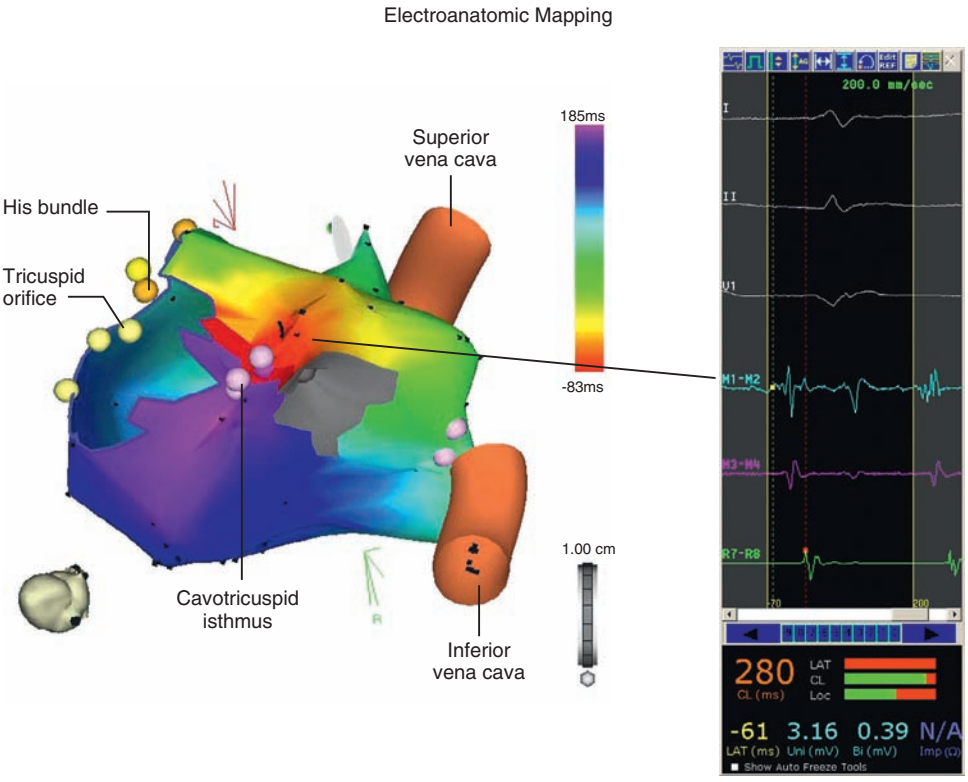

Figure 12-14

In Fig. 12-14, the same map is shown, however with the atrial electrogram correctly annotated to represent local activation. Now, the appearance of a circuit in a counterclockwise fashion around the tricuspid annulus is evident (colors of red-orange-yellow-green-blue-purple).

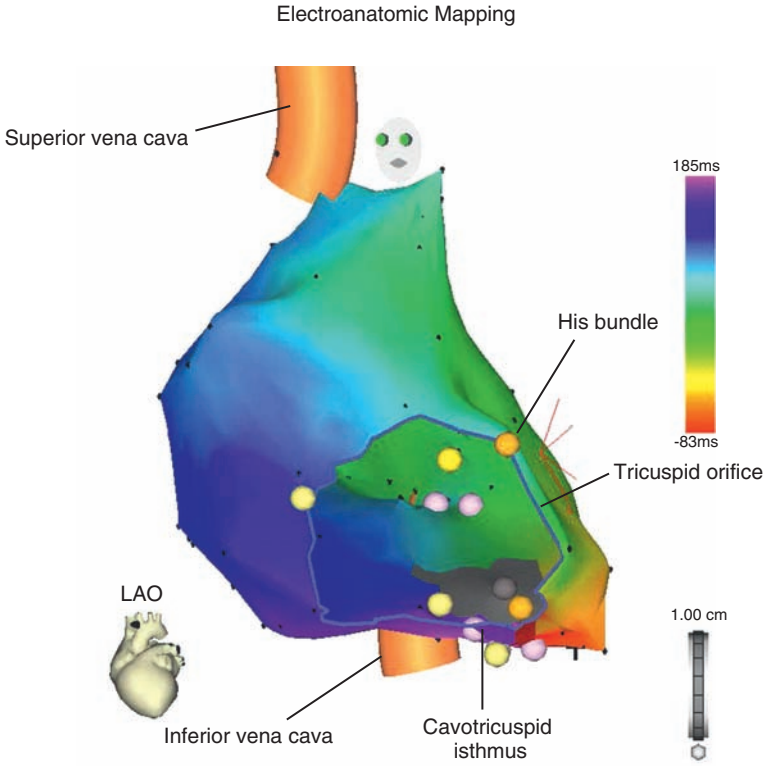

Figure 12-15

A left anterior oblique view (Fig. 12-15), looking at the tricuspid orifice, shows the propagation around the tricuspid annulus in counterclockwise direction.

Ablation

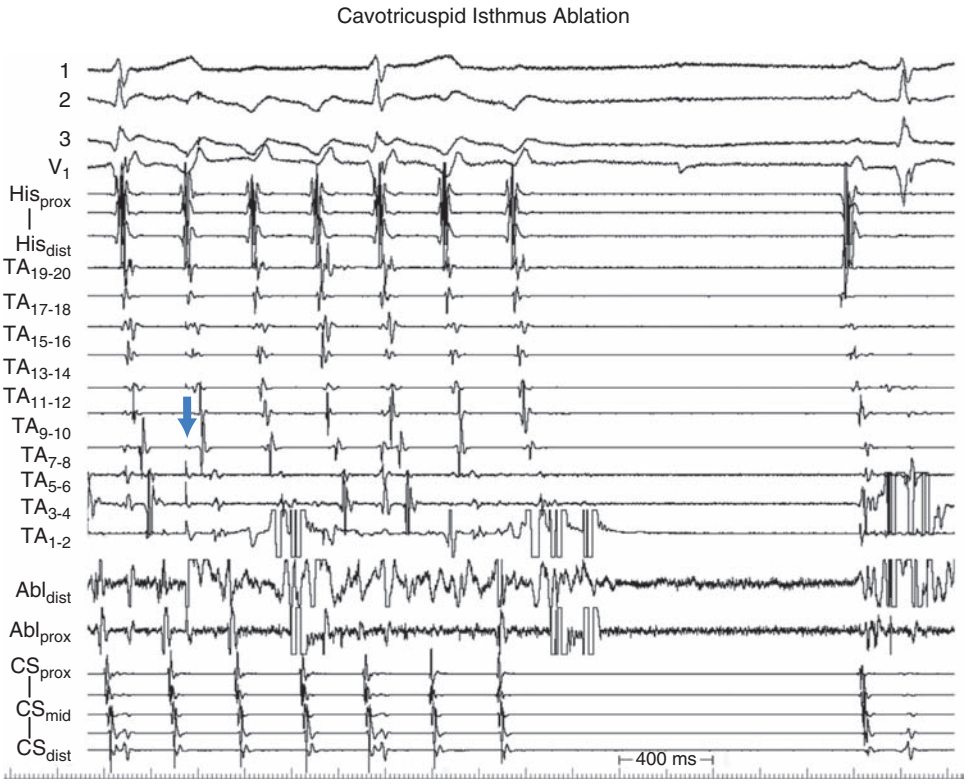

Figure 12-16

The first application of RF energy (onset at *blue arrow*, Fig. 12-16) on the cavotricuspid isthmus at the electrogram shown earlier in Fig. 12-9 results in termination of flutter to sinus rhythm. This corresponded to TA 1-2.

Assessment of Bidirectional Block

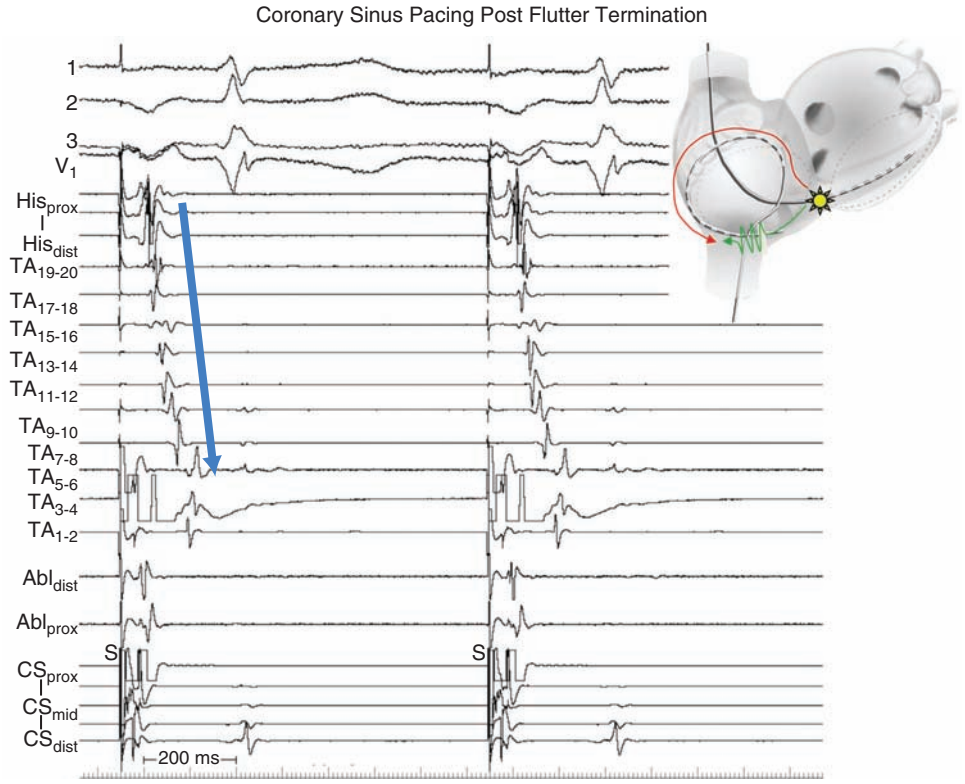

Figure 12-17

In Fig. 12-17, pacing from the CS after flutter termination shows propagation along the tricuspid annulus *(red arrow)* from *top* (TA 19-20) toward the *bottom* (TA 1-2); however, when the wavefront arrives at TA 5-6, it appears to meet a wavefront from the opposite direction (from TA 1-2, *green arrow*). Thus there is still some element of conduction across the isthmus (see diagram at *top*).

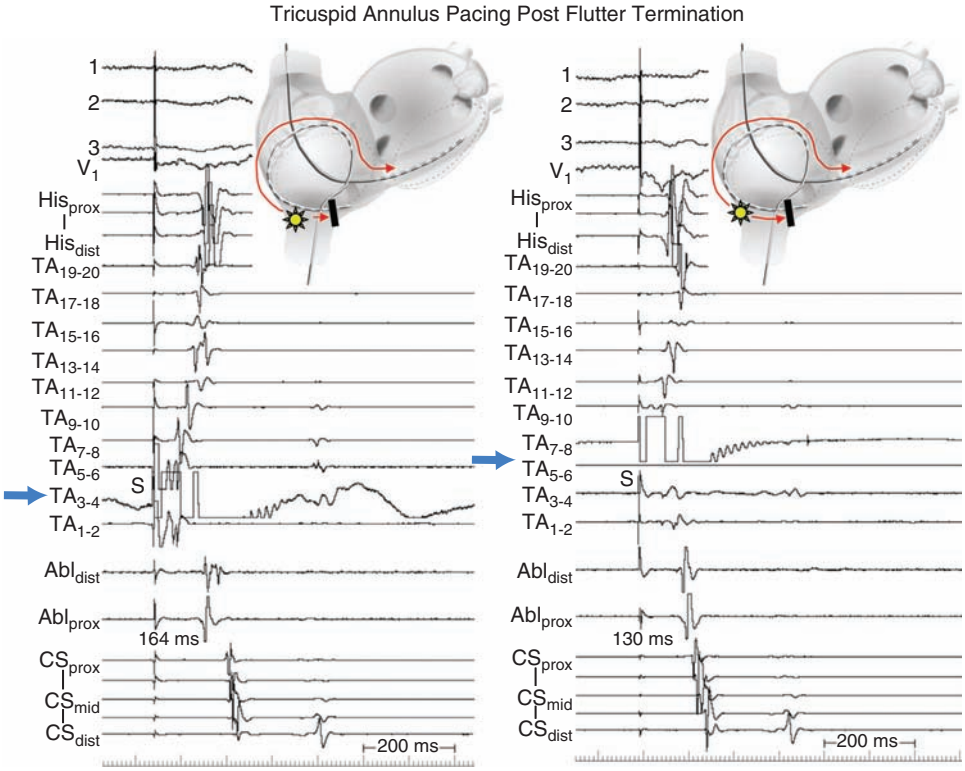

Figure 12-18

Additional ablation was performed at the isthmus (Fig. 12-18). Thereafter, pacing from the indicated electrodes of the halo catheter, lateral to the ablation line, shows a longer interval from stimulus to CS electrodes when pacing from a site closer to the ablation line than when pacing from a site further from the line (see diagrams at top). Though anatomically closer to the CS than TA 5-6 electrodes, the TA 3-4 pacing site is electrically further away. Thus block in the lateral-medial direction is present.

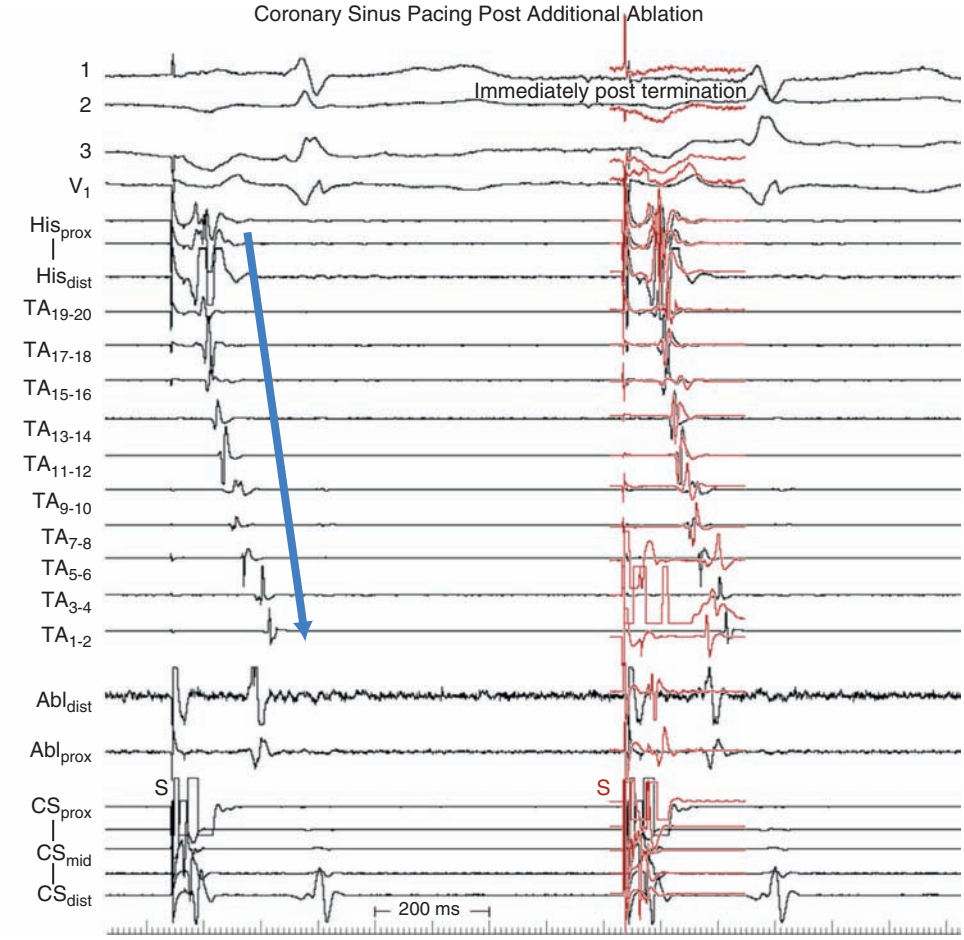

Figure 12-19

After the additional ablation at the isthmus (Fig. 12-19), conduction along the halo catheter is in a straight line (no longer a "chevron"). The activation pattern from immediately after flutter termination is superimposed in *red* (Fig. 12-19) to highlight the difference in activation of atrial electrograms in electrodes TA 1-2 and TA 3-4 in the two settings.

Final ECG

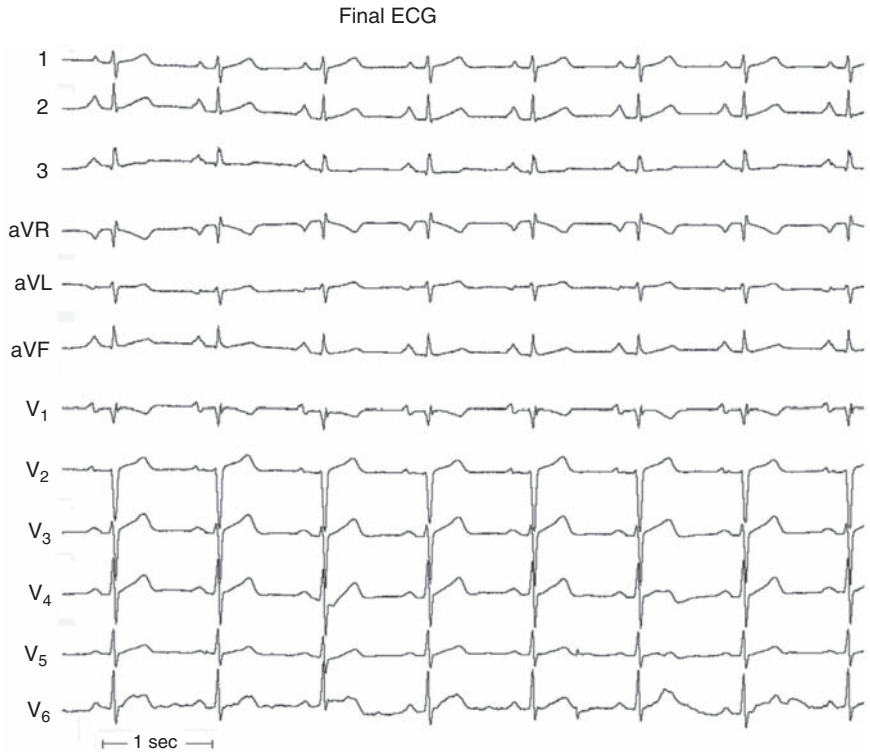

Figure 12-20

At the end of the procedure, sinus rhythm is present (Fig. 12-20), cavotricuspid isthmus block persisted throughout the waiting period and flutter could not be initiated. The procedure took 2 hr, most of which was diagnostic time.

Summary

With recurrent atrial flutter postablation

- Plan for anything (consents, setup, available equipment)
- Prove the nature of the arrhythmia before ablating
- Plan the ablation strategy before ablating (new line, targeting areas of fragmented electrograms, high residual voltage, etc.)
- Terminating flutter during ablation is not an adequate endpoint
- Bidirectional block can be difficult to demonstrate (vs slowing of conduction)
- Electroanatomic mapping is very helpful but
  - Does not make a diagnosis
  - Can be extremely misleading with even one point incorrectly annotated

Atrial Reentry After Valve Surgery

13

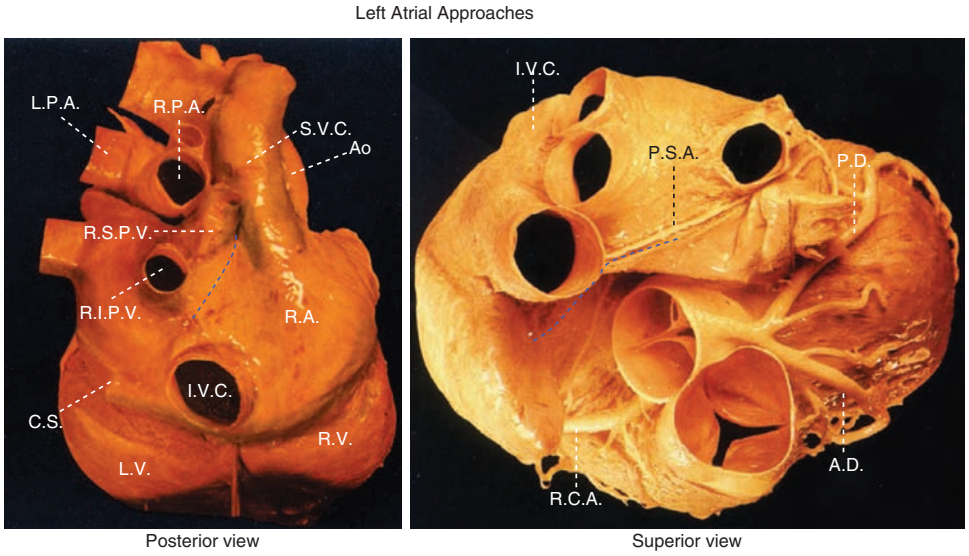
Case Presentation

The patient is a 41-year-old woman with rheumatic mitral valve disease. Mitral valve repair was attempted but required replacement in 3/2010, re-replacement was performed in 4/2010 because of dehiscence of valve, and another re-replacement was done in 6/2010 as a result of perivalvular leak. Then she had perioperative atrial fibrillation, and recurrent regular atrial tachycardias were terminated with adenosine injection. Cavotricuspid isthmus (CTI) ablation was performed in 1/2011; in that procedure, flutter terminated during CTI radiofrequency (RF) delivery; bidirectional conduction block was effected across the CTI, and no other arrhythmias were induced. She was referred for ablation because of recurrent episodes of supraventricular tachycardia (SVT) at 145/min. Echocardiographic findings were as follows: LA 4.1 cm, enlarged RA, moderate TR, and normal LV function; estimated right ventricular systolic pressure 30 mm Hg; and normally functioning mechanical mitral valve. Operative reports were as follows: #1 and #2, Waterston's groove left atrium (LA) access; #3, LA dome incised through top of septum to right atrium (RA). There was no mention of atrial septal patching. EP report was as stated previously, and ECG was recorded during SVT.

Approaches to Mitral Surgery

Figure 13-1

(Adapted from McAlpine, WA. *The Heart and Coronary Arteries,* Springer-Verlag, New York, 1975 with permission of Kalyanam Shivkumar, MD, UCLA.)

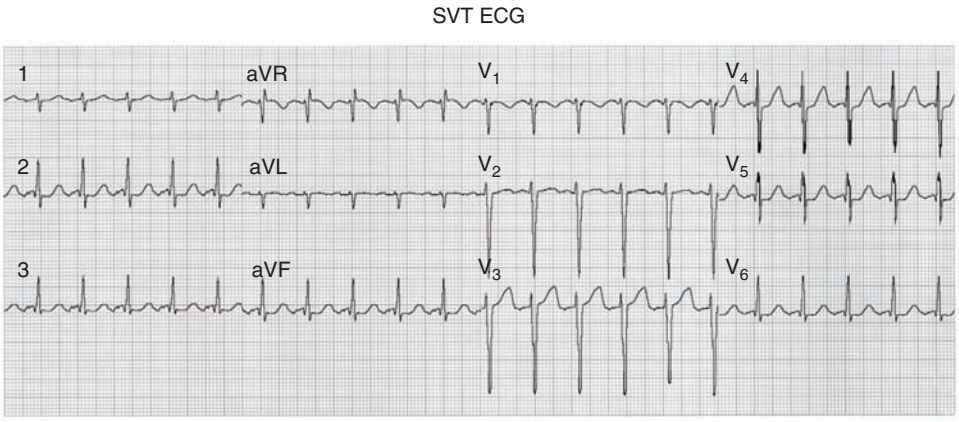


At left of Fig. 13-1, the heart is viewed from behind. A standard mitral approach incision is through Waterston's groove, just on the left atrial side of the interatrial septum *(dashed blue line)*. This rarely results in macroreentrant arrhythmias. At right, another approach (especially for repeat procedures) is through the atrial roofs; the incision *(dashed blue line)* goes through both atria roughly along Bachmann's bundle, anterior to the superior vena cava and pulmonary veins. *AD*, left anterior descending coronary artery; *Ao*, aorta; *CS*, coronary sinus; *IVC*, inferior vena cava; *LPA*, left pulmonary artery; *LV*, left ventricle; *PD*, posterior descending coronary artery; *PSA*, posterior sinus node artery; *RA*, right atrium; *RCA*, right coronary artery; *RIPV*, right inferior pulmonary vein; *RPA*, right pulmonary artery; *RSPV*, right superior pulmonary vein; *RV*, right ventricle; *SVC*, superior vena cava.

Prior SVT ECG

Any Clues as to SVT Diagnosis? [Fig. 13-2]

Figure 13-2



In the "long RP" SVT shown in Fig. 13-2, it looks like there is only 1 P wave per QRS, and that is inverted in the inferior leads and positive in aVL; thus a first approximation would be that this indicates a low right atrial focus or exit from a circuit.

Baseline ECG and Intracardiac Recordings

Any Clues as to SVT Diagnosis? [Fig. 13-3]

Figure 13-3

The sinus rhythm P wave in Fig. 13-3 is remarkably close to normal despite the history of extensive atrial surgery. In scar-based macroreentry, the P wave in sinus rhythm is often very prolonged and fragmented (more so than is seen here).

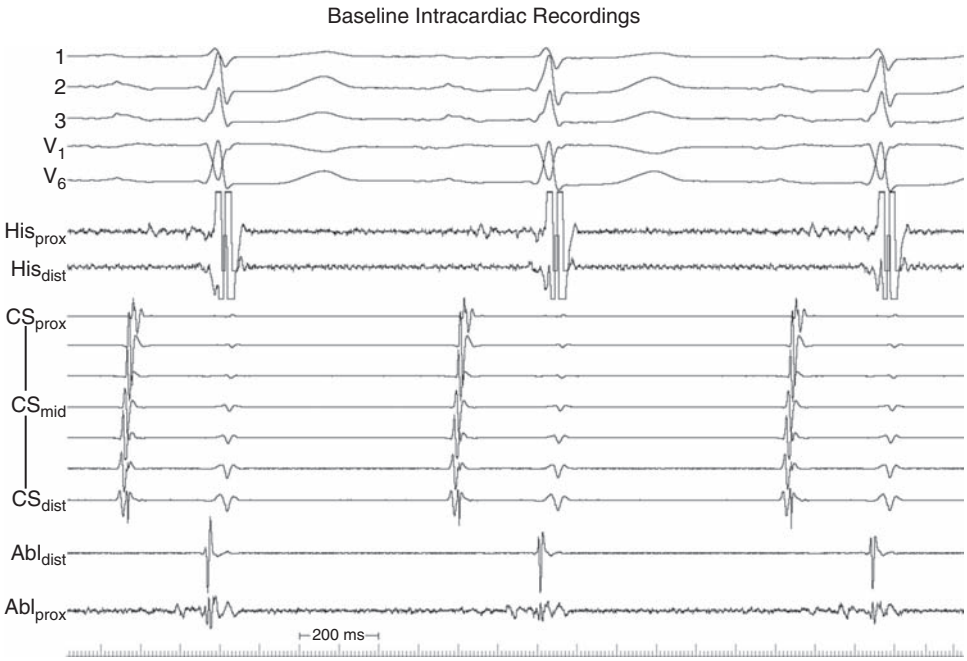


Figure 13-4

Consistent with the relatively normal surface ECG appearance of the P wave, intracardiac activation also appears relatively normal in Fig. 13-4 without much hint of scar that could result in slow conduction, a constituent of macroreentry.

Figure 13-5

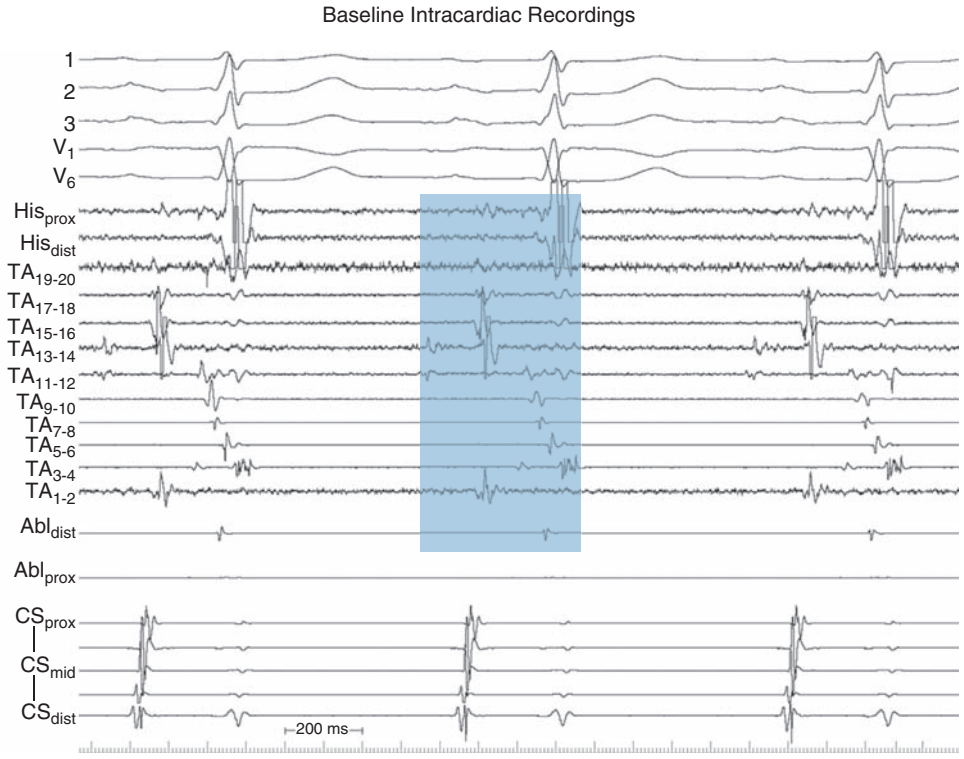

Fig. 13-5 shows the same events as in Fig. 13-4, but with another multielectrode catheter in the right atrium. Now that there are more extensive recordings from the right atrium (RA), dramatically disordered conduction is revealed (duration of RA activation shown in *shaded box* [430 ms]). All of the recordings in the tricuspid annular (TA) catheter are from atrium, despite some of them timing with the QRS complex. With this degree of slow conduction, macroreentry is a real possibility.

Catheter Induction of SVT and ECG and Intracardiac Recordings

Focal or Macroreentry? [Fig. 13-6]

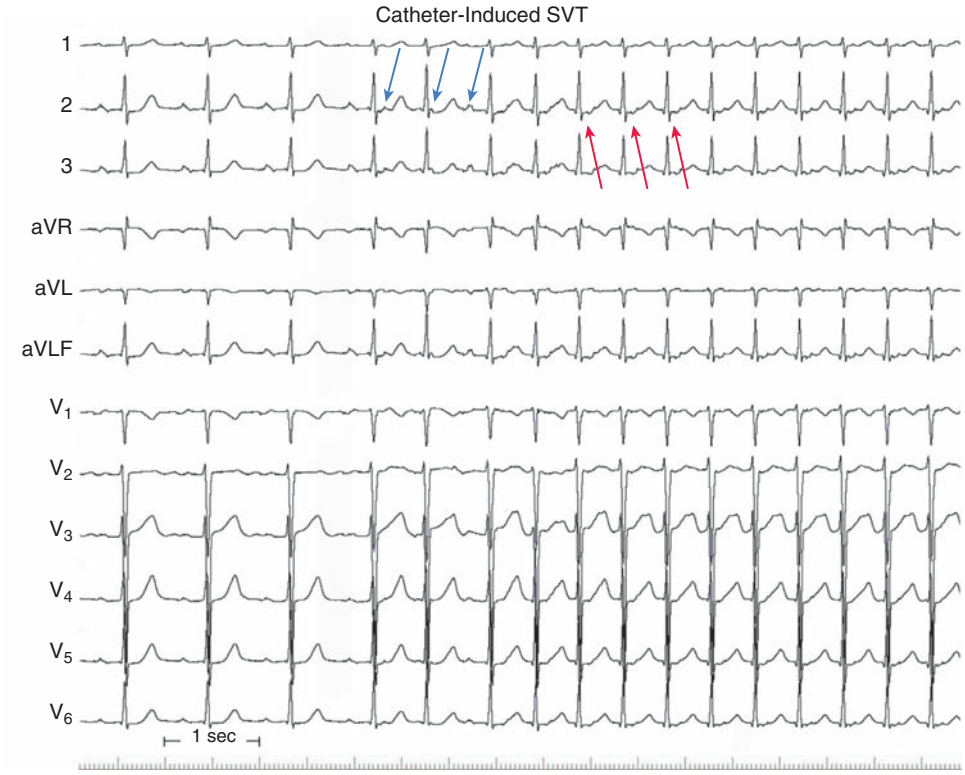

Figure 13-6

Central to achieving a successful ablation outcome is the determination of what the target site of ablation should look like—for focal tachycardias, it is a potential just 30 to 40 ms before the P wave onset, whereas for macroreentry, a middiastolic potential is generally sought. Because the ablation target is very different depending on mechanism, it is important to delineate mechanism (focal vs macroreentry) relatively early in the procedure. A clue to mechanism can sometime be found in how an episode starts (Fig. 13-6); here one or several premature atrial complexes *(blue arrows)*, positive in the inferior leads, seem to start SVT that has inverted P waves in inferior leads *(red arrows)*. A focal tachycardia typically has the same P-wave configuration throughout, whereas in reentrant tachycardias, the initiating P wave is often different from those during tachycardia.

Focal or Macroreentry? [Fig. 13-7]

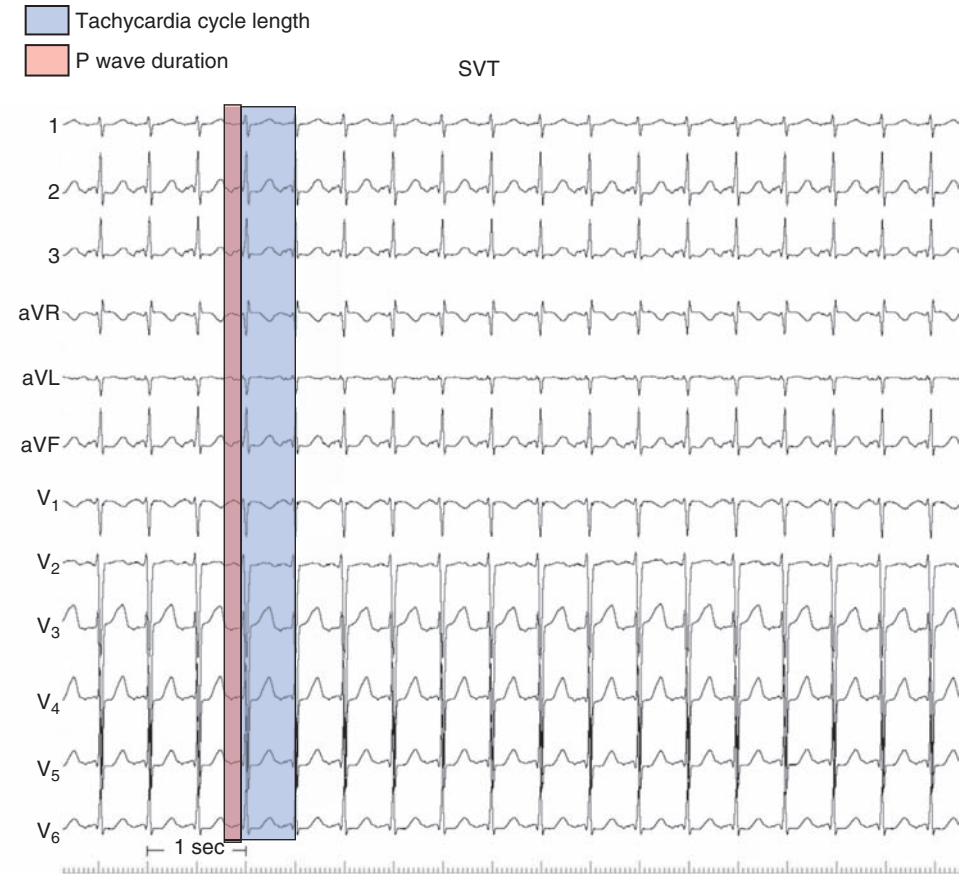

Figure 13-7

A useful principle for distinguishing a focal process from macroreentry is that, in macroreentry, some of the atrium is always being activated throughout the tachycardia cycle length (TCL) and slow conduction is present (required for tachycardia to continue); this leads to a relatively large portion of the cycle length being occupied by P wave. In focal tachycardias, slow conduction is not needed, and once the focus fires, the atria are depolarized relatively quickly, leading to a P wave that takes up a small portion of the tachycardia cycle length. In Fig. 13-7, it appears that the P wave *(red shading)* is pretty narrow compared to cycle length (*blue shading*, that includes *red shading*). This suggests focality.

Focal or Macroreentry?

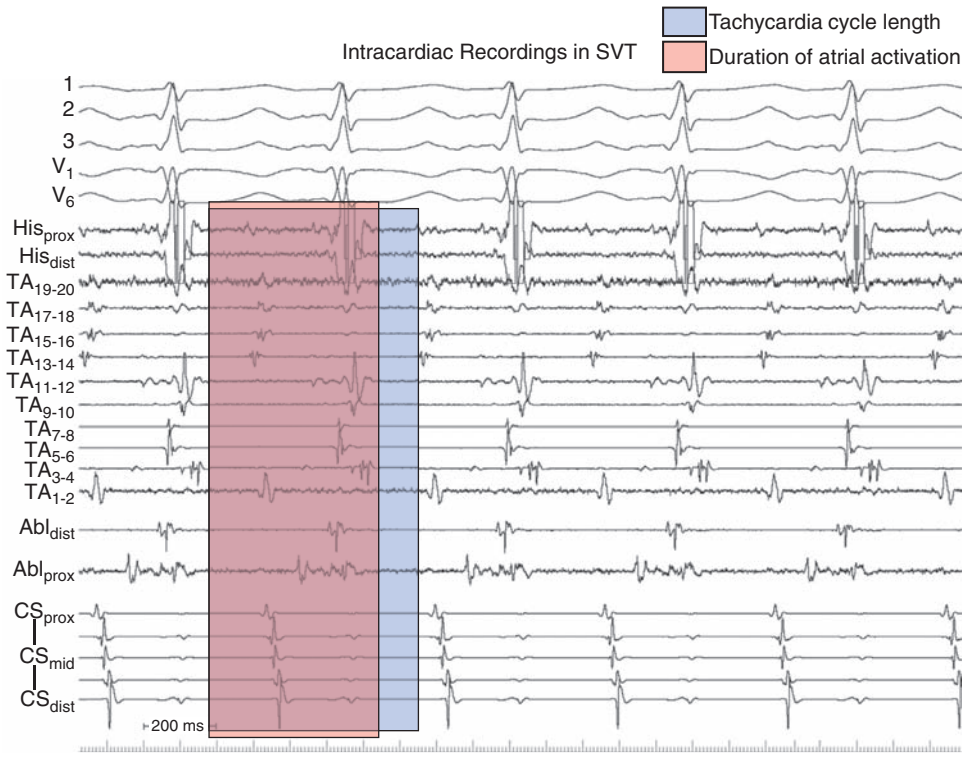

Figure 13-8

With the aid of intracardiac recordings, it becomes clear that atrial activation *(red shading)* takes up much of the TCL (*blue shading*, encompassing *red shading*; Fig. 13-8), now suggesting macroreentry. Specifically, most of the TCL is accounted for in *right atrial* recordings.

Clarifying P-Wave Onset During SVT with Ventricular Pacing

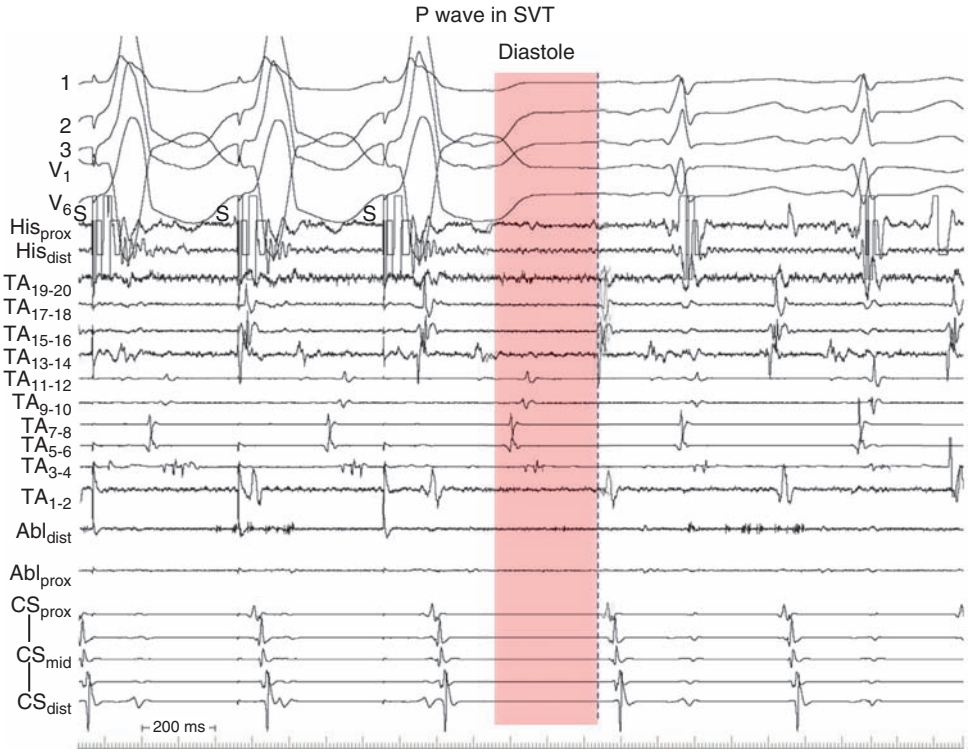

Figure 13-9

Clarifying the limits of the P wave during SVT helps in mapping, so that the onset of the P wave is clear. However, it may not be evident during ongoing SVT and thus some tricks are needed to reveal a partially obscured P-wave onset, such as introduction of premature ventricular complexes (PVCs) or ventricular pacing during tachycardia. The resulting long diastolic period should provide a P wave standing by itself (Fig. 13-9), allowing clear determination of its onset (as well as end of the prior P wave, for designating window of interest with electroanatomic mapping systems). Atrial diastole (end of 1 P wave to beginning of next P wave) is shown in *red shading*.

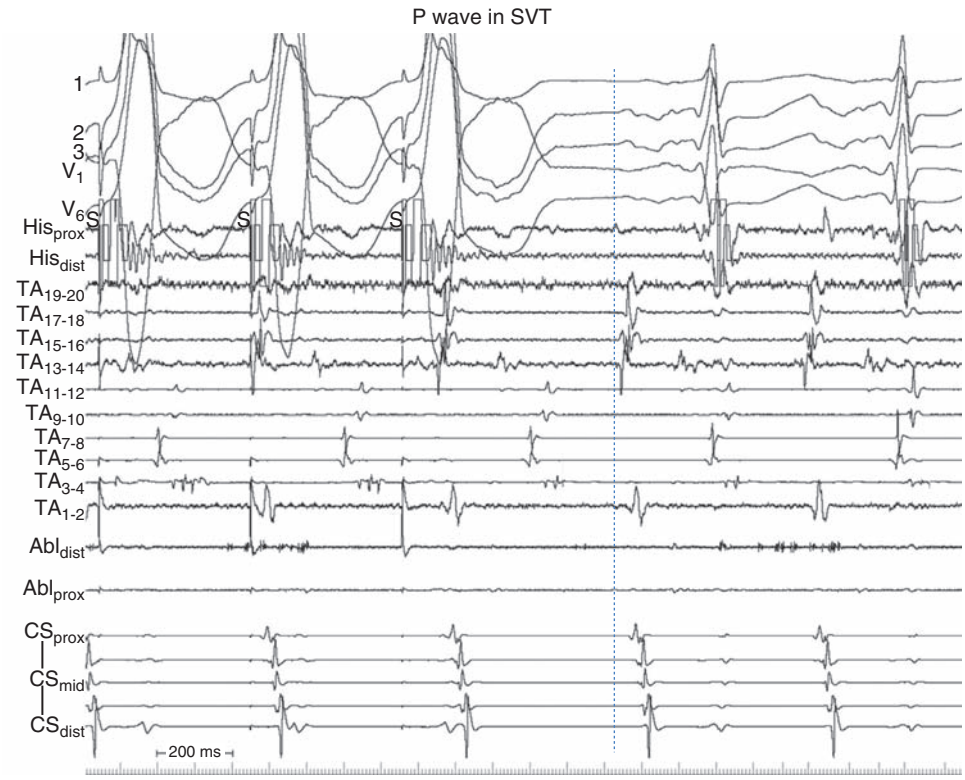

Figure 13-10

Surface ECG leads are shown in Fig. 13-10 with increased gain to better determine P-wave onset *(dashed line)* and morphology. This also shows VA block during SVT, excluding orthodromic SVT as well as almost all cases of AV nodal reentry. The setting (scarred atrium) is perfect for atrial tachycardia.

Overdrive Pacing During SVT

From Distal and Proximal Coronary Sinus

Focal or Macroreentry?

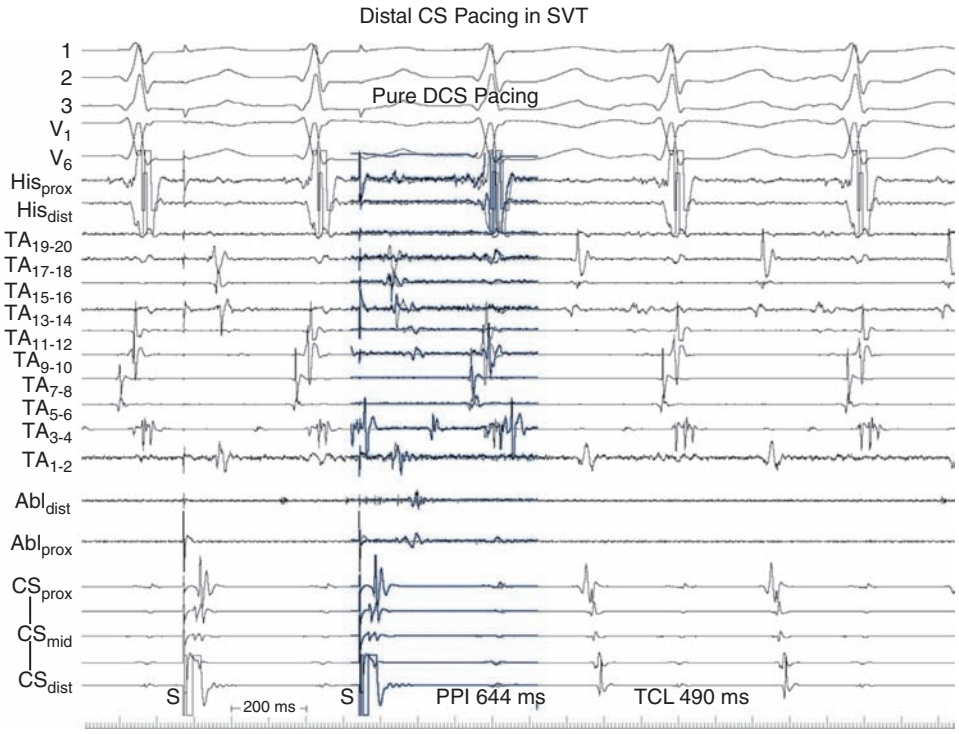

Figure 13-11

To answer the important question of focal versus macroreentry as tachycardia mechanism, overdrive pacing from distal CS—activated late during SVT—is performed, showing a paced sequence during SVT that is a little different from pure CS pacing earlier in the procedure (superimposed in blue) as well as different from SVT (Fig. 13-11). However, the differences are not striking and it is difficult to be definitive that fusion is present. Note also that whatever the mechanism, the distal CS is far from either the focus or exit from a circuit (post-pacing interval [PPI] − TCL = 154).

Focal or Macroreentry?

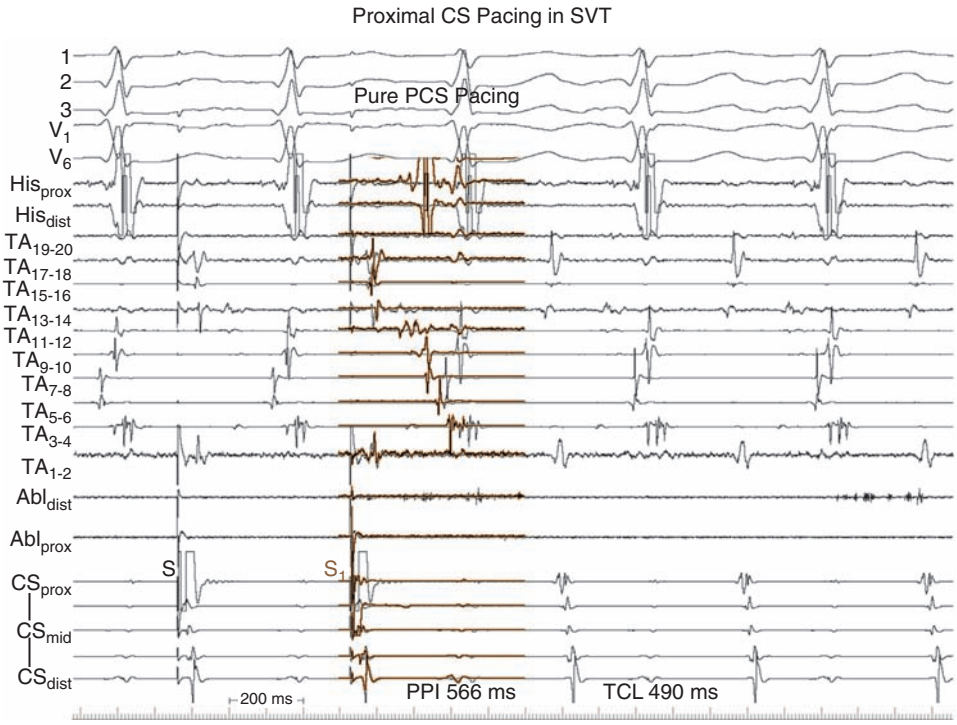

Figure 13-12

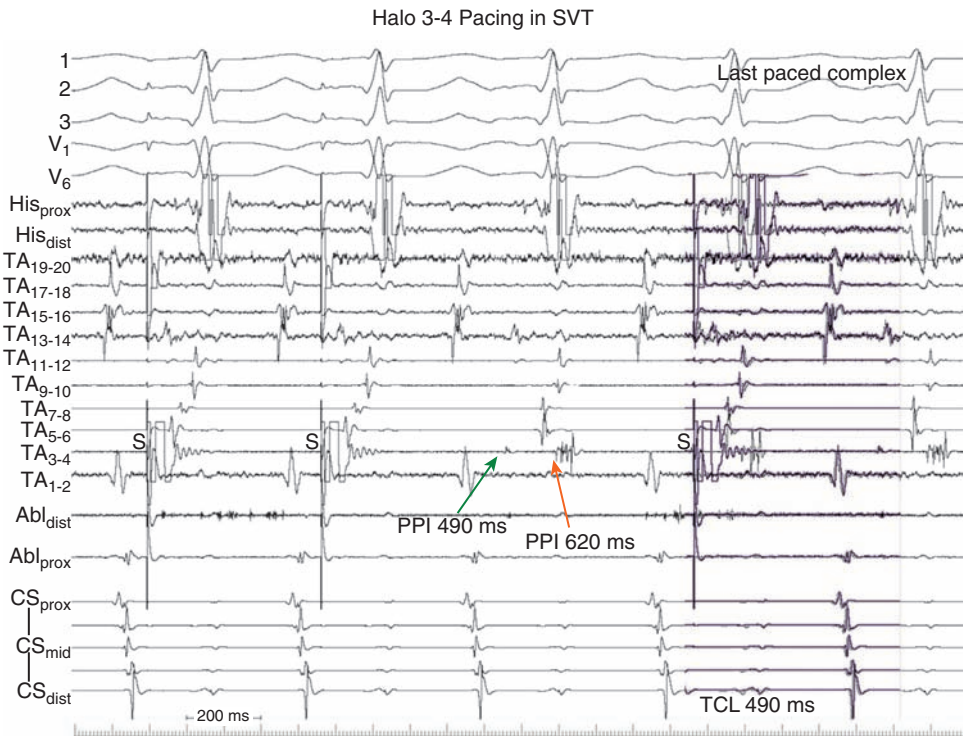
Because overdrive pacing from distal CS was equivocal, we should try pacing from a different site, such as the proximal CS. Fig. 13-12 clearly shows a sequence during pacing in SVT that is very different from pure CS pacing earlier in the procedure (superimposed in *orange*), as well as different from SVT. Thus fusion has been demonstrated and macroreentry is diagnosed. The proximal CS pacing site is, like the distal site on the last slide, remote from the circuit but not as far away as the distal CS was (smaller PPI-TCL difference).

From Different Halo Catheter Sites

Figure 13-13



Pacing from a portion of the TA catheter (Fig. 13-13) shows a paced sequence (superimposed in *purple* on a tachycardia complex) that is nearly identical to that during tachycardia (thus almost concealed fusion). The postpacing interval is problematic because the natural place to measure (largest recording) yields a very long PPI (620 ms); however, although that portion is captured, so is the small potential before it, with a PPI identical to TCL. This should be within the circuit; the lack of concealed fusion is likely because of excessive current used in pacing, which captures more than the intended tissue.

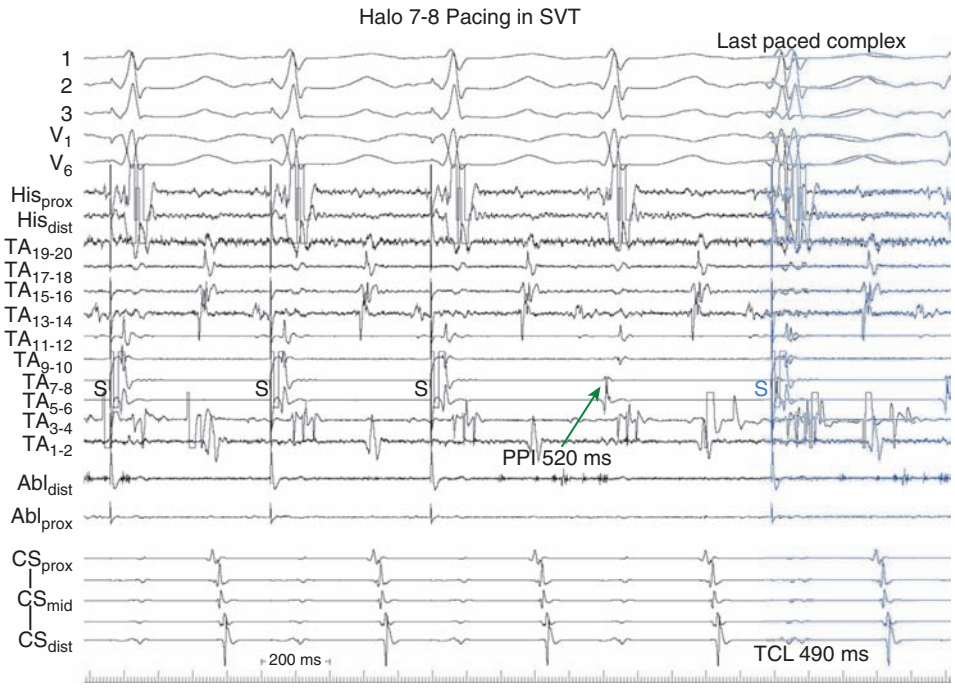


Figure 13-14

Pacing a couple of electrodes away on the TA catheter (Fig. 13-14) shows a less perfect pace match (sequence superimposed on tachycardia complex) and PPI-TCL difference; thus the pacing site is further from the circuit.

From Coronary Sinus Again

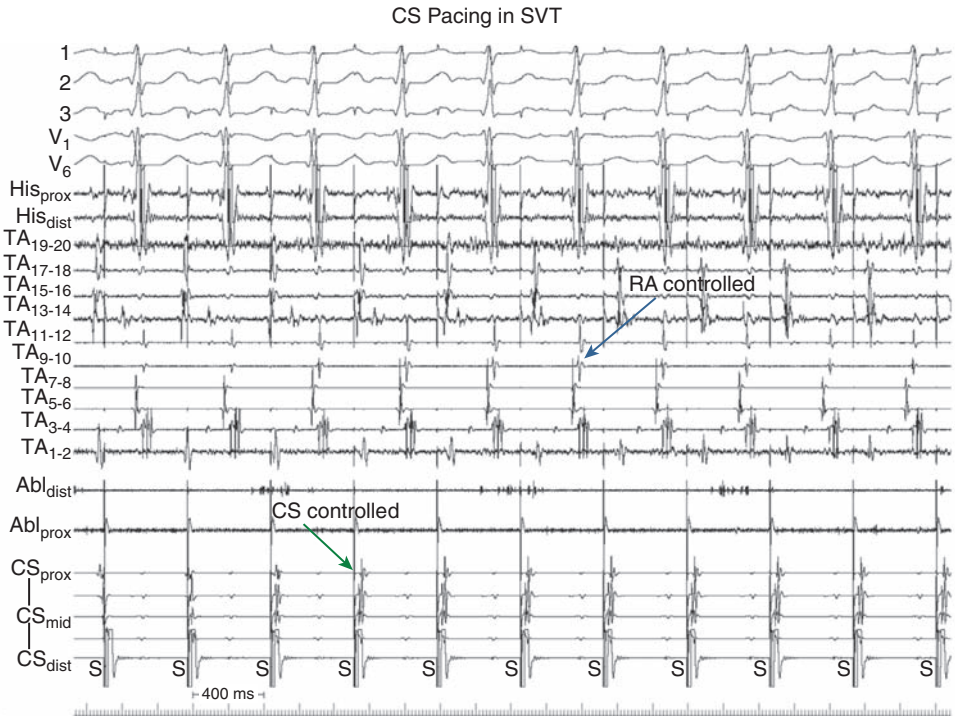

Figure 13-15

In Fig. 13-15, pacing from the distal CS controls all CS recordings long before the TA (RA) is controlled; this signifies that the RA is the chamber of origin (or else it would be controlled coincidently with the control of the LA [CS] if the LA were the chamber of origin).

Spontaneous Change in Atrial Activation Pattern in SVT

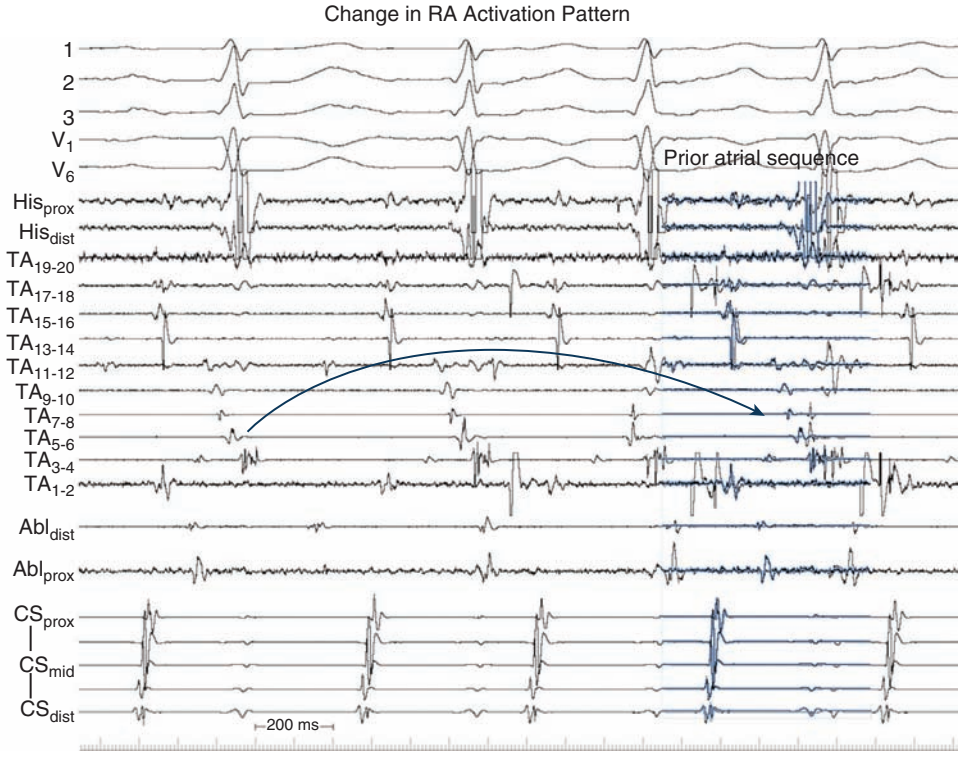

Figure 13-16

Just when we are honing in on the area of interest, the tachycardia changes (Fig. 13-16); the activation sequence on the left half is superimposed in *blue* on the right half to highlight the differences. This may be a change to another circuit, or another path within the same general circuit. It cannot be a sudden reversal of the circuit, as some tissue that had just been activated would have to be activated again too early for its refractory period to have ended (retracing steps during SVT). At some time earlier, another change has occurred: the CS activation was proximal to distal, now reversed.

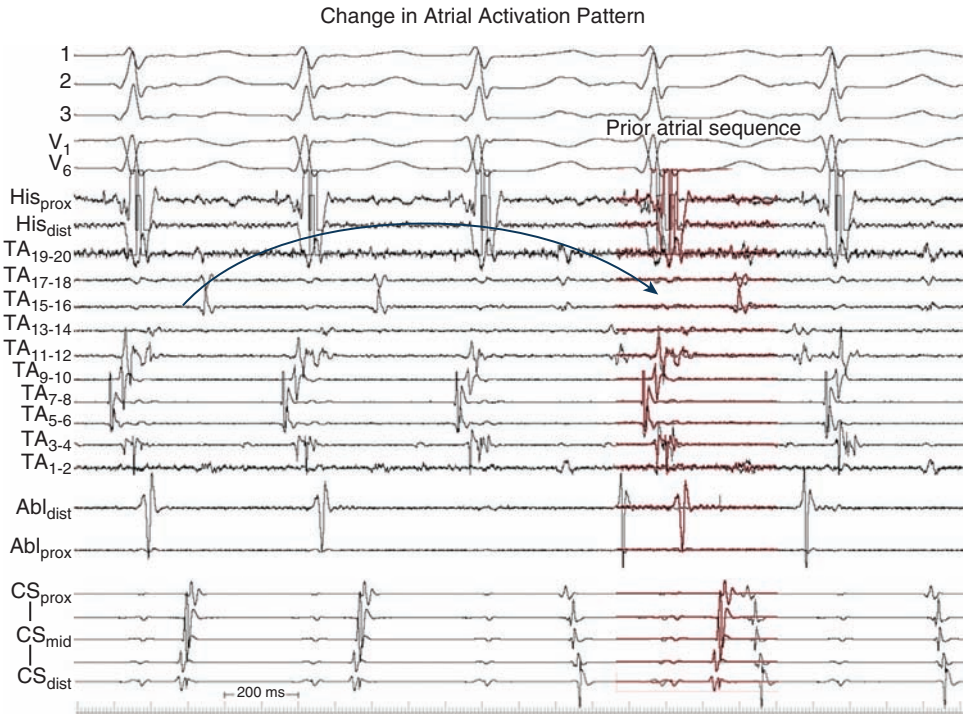

Figure 13-17

A few minutes later, activation changes again (Fig. 13-17). Portions of the TA (RA) are unchanged in both morphology and, largely, cycle length, suggesting that the same basic tachycardia (determined by the diastolic corridor) is continuing, but activation of the rest of the atrium may change (see the CS recordings; although the fundamental tachycardia may not change, the P wave can be altered [not evident here]).

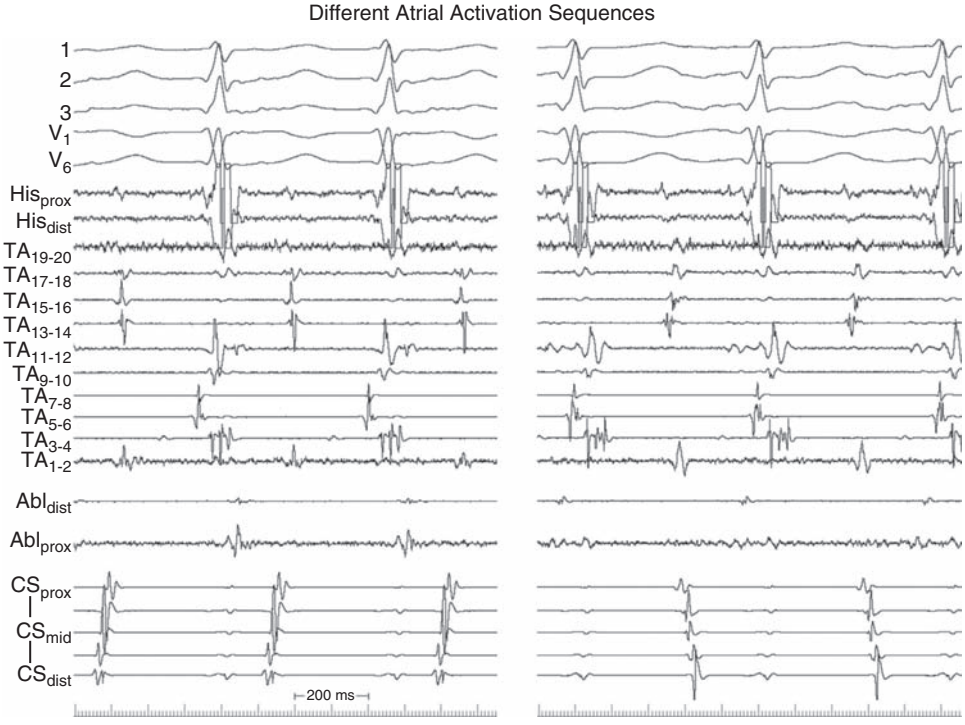

Figure 13-18

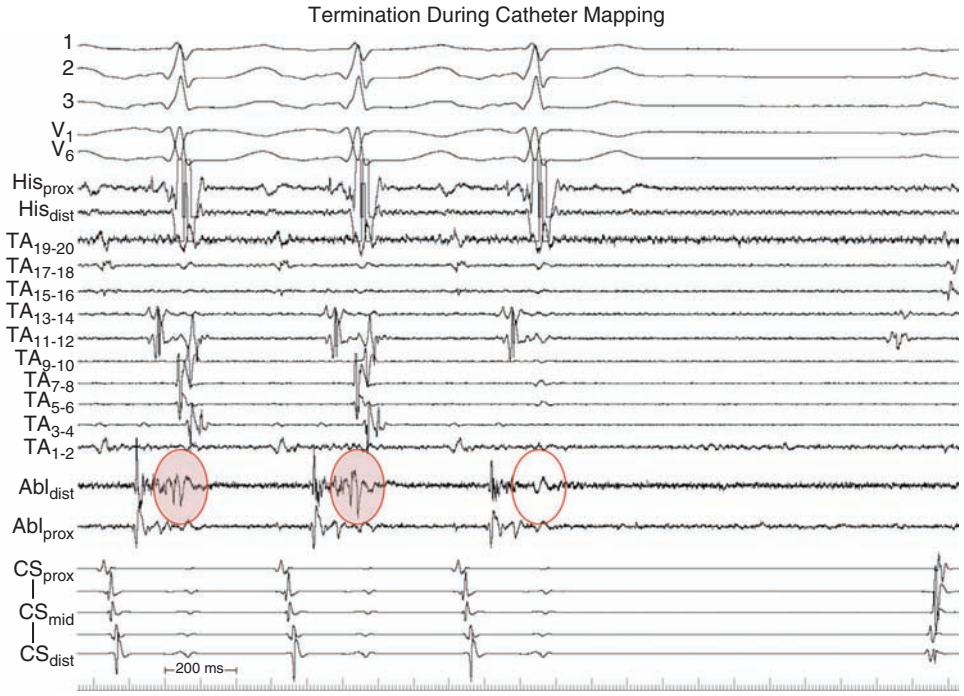
Two different atrial activation sequences are compared in Fig. 13-18.

SVT Termination During Catheter Mapping

Figure 13-19



As mapping continues in Fig. 13-19, tachycardia suddenly terminates. Note the change in the electrogram on the ablation distal recording, and the absence of electrograms from TA 9-10 through 1-2 (because of block before they were activated).

Entrainment Mapping: Is It a Good Site?

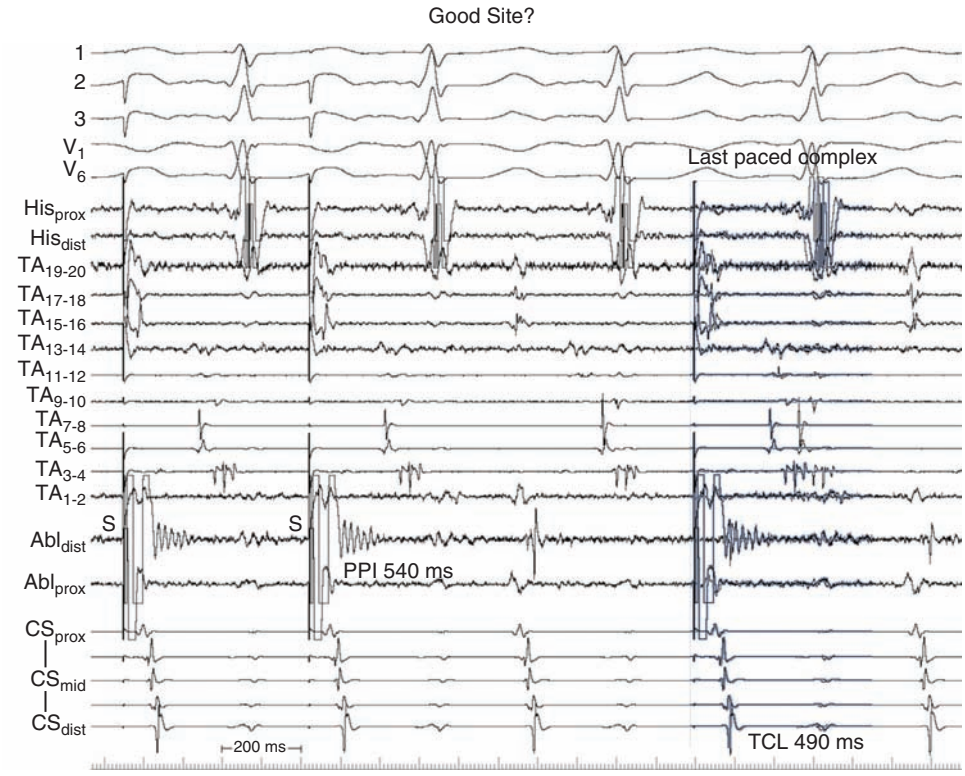


Figure 13-20

Tachycardia was reinitiated and a slightly different site with a diastolic electrogram was chosen for pacing. Fig. 13-20 displays a poor pace match (superimposed on tachycardia) and a long PPI-TCL difference from here—don't ablate at this site.

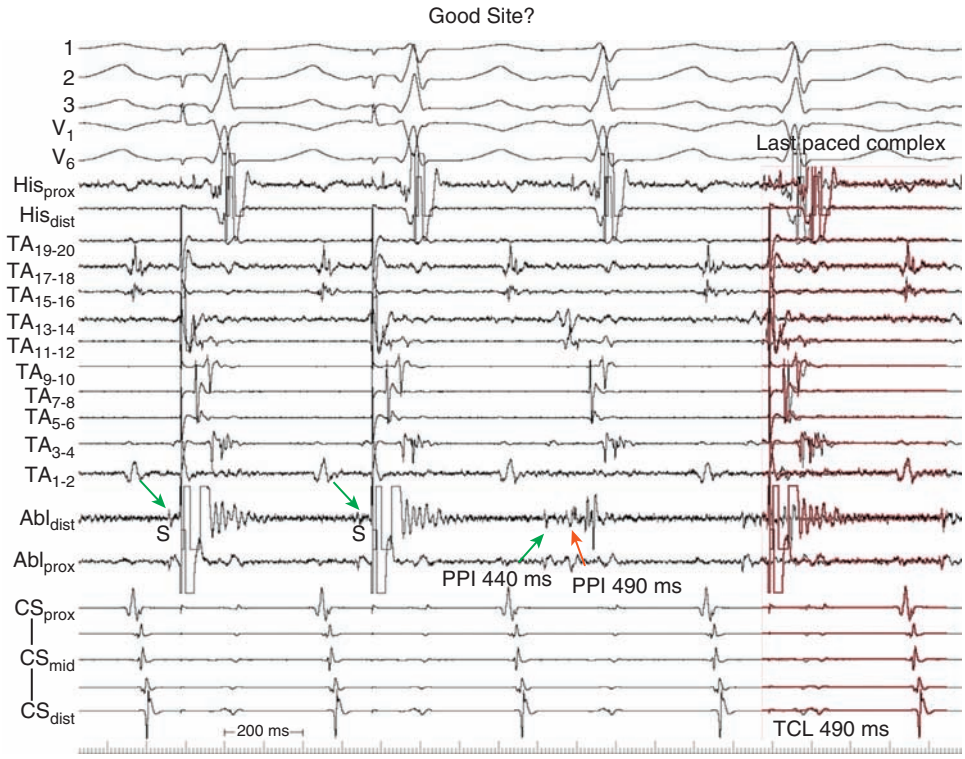

Figure 13-21

Pacing at a slightly different site—close to TA 13-14—produces a nearly perfect pace match but the PPI is again a problem (Fig. 13-21). If measured to the beginning of the complex electrogram *(orange arrow)*, PPI-TCL is perfect; but if measured to the small diastolic potential as before *(upward green arrow)*, the PPI is too short. The problem with the latter is that the small potential is clearly not captured during pacing because it appears before the stimulus artifact *(downward green arrows)*. The conclusion: this site, with a nearly perfect pacematch and perfect PPI-TCL, is a good site for ablation.

Ablation at Site

Are We Done Yet?

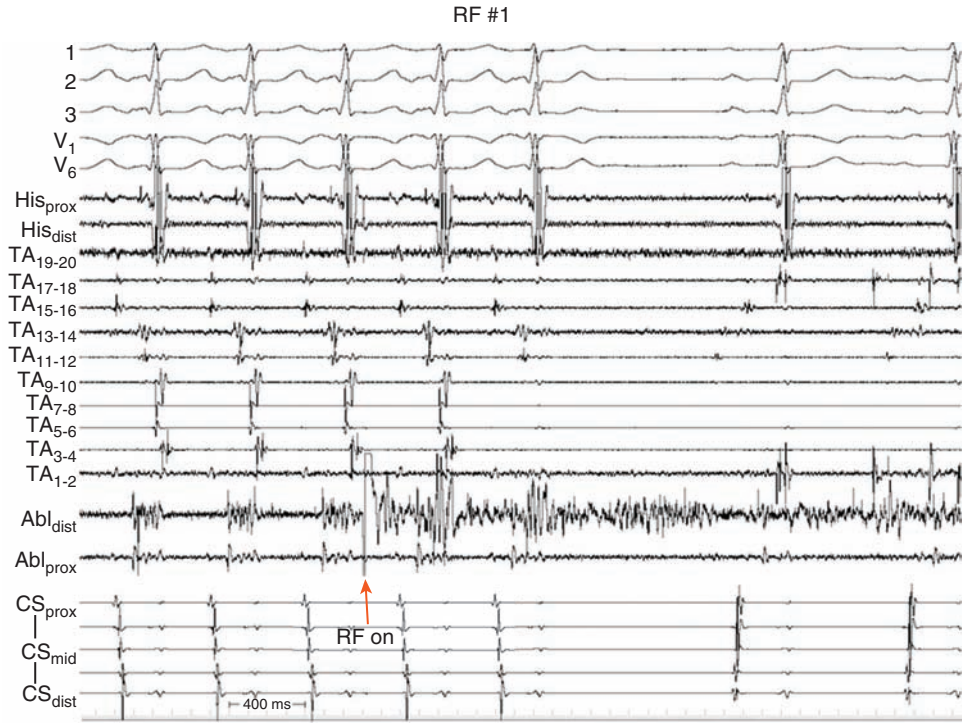

Figure 13-22

RF delivery (as indicated) at the site predicted to be a good ablation site is rewarded by immediate tachycardia termination (Fig. 13-22).

Electroanatomic Maps

Figure 13-23A

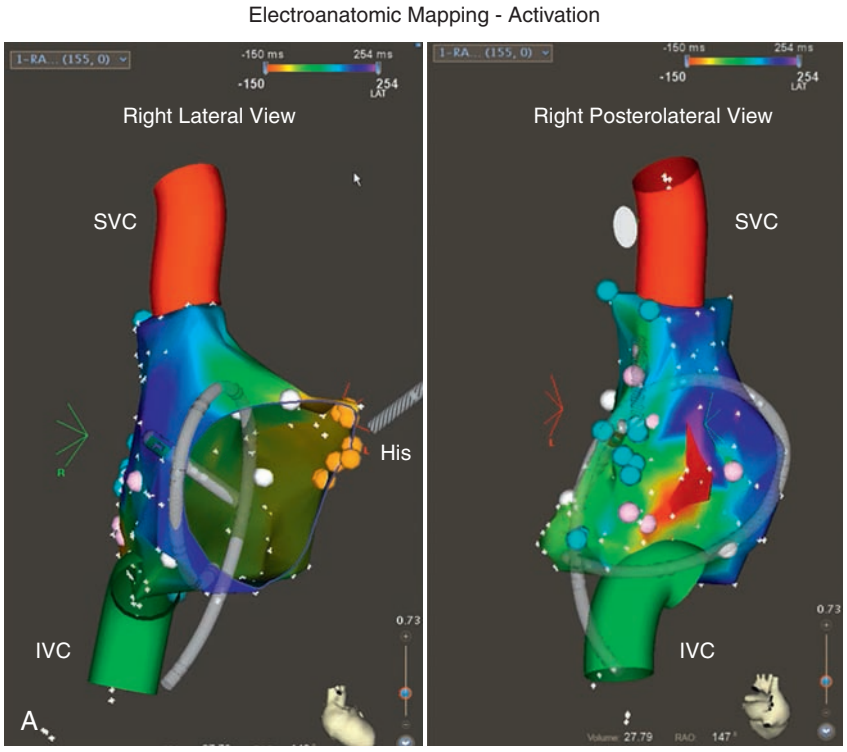

Figure 13-23B

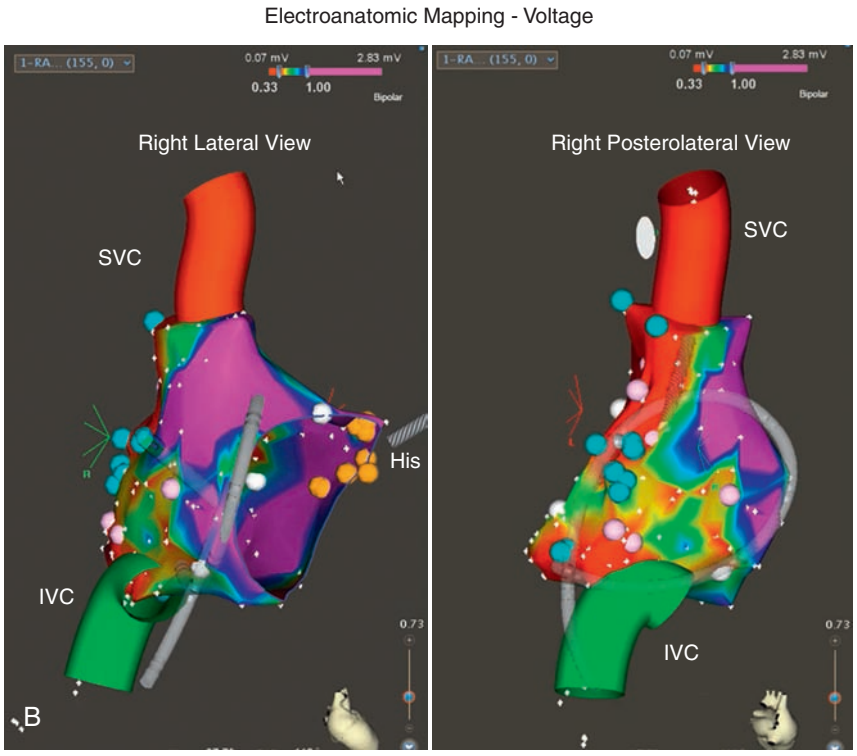

The electroanatomic maps (Fig. 13-23) demonstrate (A) electroanatomic activation mapping of right atrium in tachycardia; (B) electroanatomic voltage map of right atrium; and

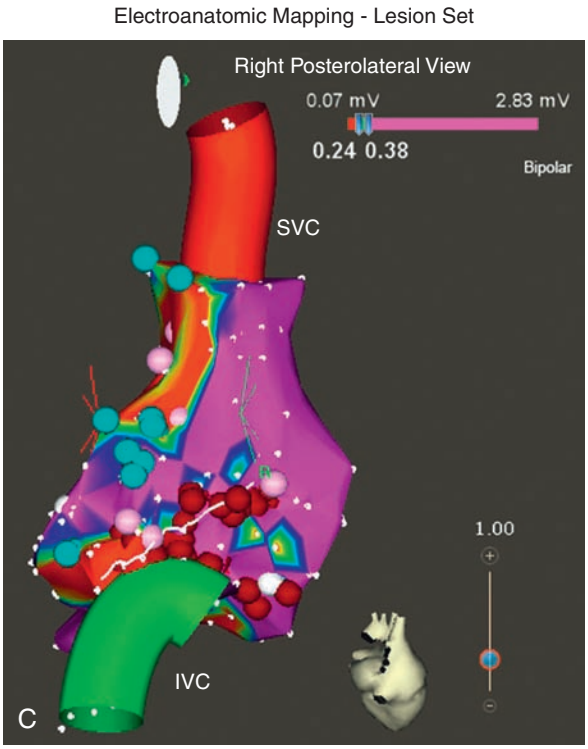

Figure 13-23C

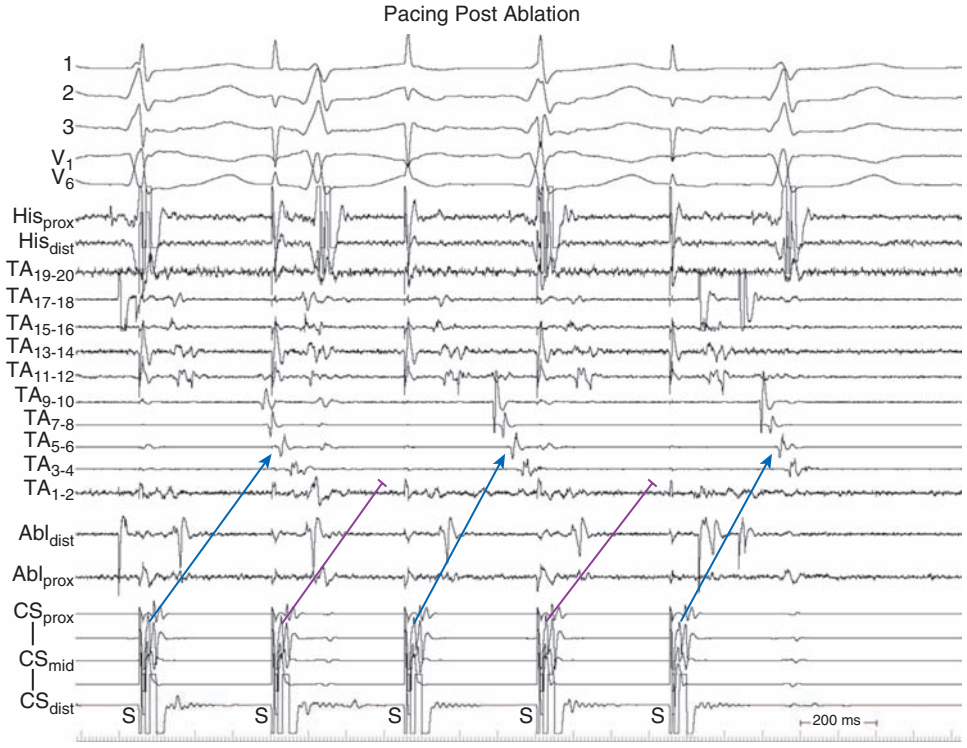
(C) lesion set eventually used to transect the diastolic path and the segment of atrium from this region to the inferior vena cava, to preempt further reentry. In (A), a *red area* corresponding to the diastolic corridor is shown. Representations of the catheters (TA, His, and ablation) are faintly visible.

The prior right atrial cavotricuspid isthmus was evaluated and shown to have persistent bidirectional block from the prior ablation procedure.

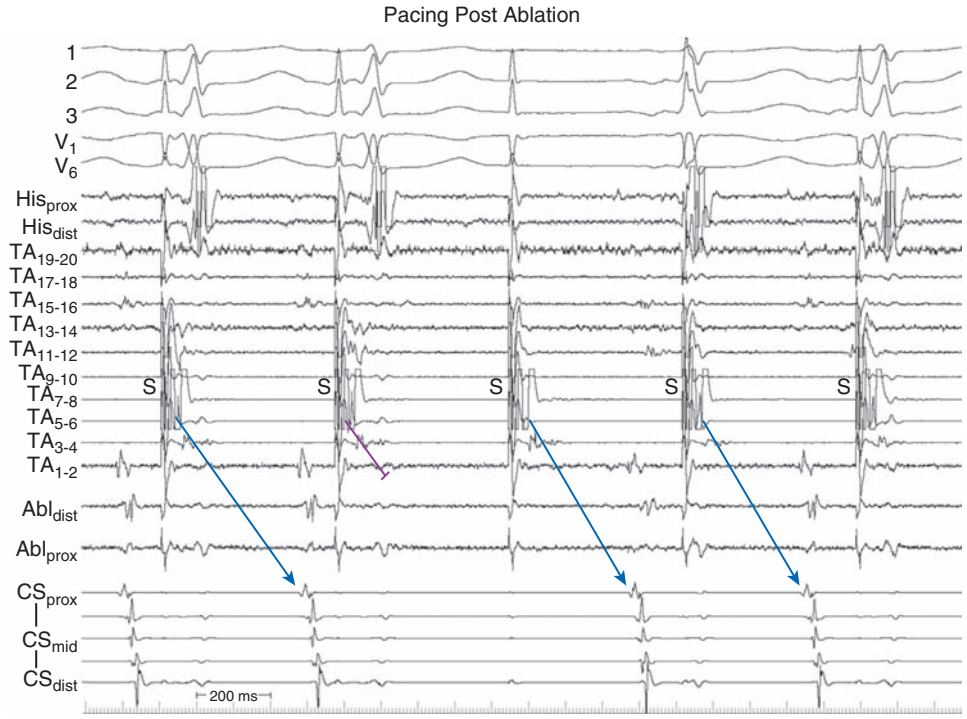
Pacing from Various Sites Postablation

Figure 13-24



Conduction is so disrupted in Fig. 13-24 that pacing from the CS does not get to the RA each time (indicated by *arrows* and *stopped lines*).

Figure 13-25



The same is true for pacing from RA (not conducting each time to CS), in Fig. 13-25.

Final ECG

Figure 13-26

The patient's final ECG is shown in Fig. 13-26. She has been free of tachycardia recurrence for several years since the procedure.

Summary

- Atrial tachycardias after (non-maze) atrial surgery are common:
  - Right atrial macroreentry is much more common than left atrial
  - Atrial flutter is as common as (or more than) free wall macroreentrant circuits
  - Right atrial pathology (and circuits) can be present despite absence of prior extensive right atrial incisions
  - Entrain from multiple sites before concluding a focal mechanism
  - Circuits may be "bump-sensitive"—plan your mapping strategy before starting
- In areas of very slow/disrupted conduction, mapping systems:
  - May not be as helpful for tracking activation during AT as they are in other cases
  - May still be very useful for:
    - Delineation of scar/circuit boundaries
    - Designing strategies for ablation (connecting barriers)

14 Atrial Microreentry After Lung Transplantation

Case Presentation

The patient was a 60-year-old man with palpitations, lightheadedness, and dyspnea and referred for catheter ablation of atrial arrhythmias. He had a history of idiopathic pulmonary fibrosis. He underwent bilateral lung transplant in 2002; he had never shown any rejection. Palpitations began in 2013. ECGs showed supraventricular tachycardia ~190/min, and he was treated with metoprolol (failed); diltiazem (failed); flecainide (failed); and flecainide + metoprolol (partially successful?). Dyspnea continued despite "normal" heart rate (~100/min). He stated that his heart rate was constant all day and night unless he tried to exercise, at which point it sped up to twice as fast (200/min). He was referred for EP study and possible ablation.

Differential Diagnosis and Time Course of ATs After Lung Transplantation

What kinds of tachycardias do patients get after lung transplantation?

- Atrial fibrillation
- Atrial flutter/macroreentrant atrial tachycardia
  - Typical right atrial cavotricuspid isthmus-dependent flutter
  - Perimitral reentry
  - Peripulmonary vein cuff reentry
- Pulmonary vein tachycardias with donor–recipient atrial anastomotic electrical connection
- Other SVTs (which anyone may have)
  - AV nodal reentry
  - AV reentry (accessory pathway—WPW)
  - Focal atrial tachycardia

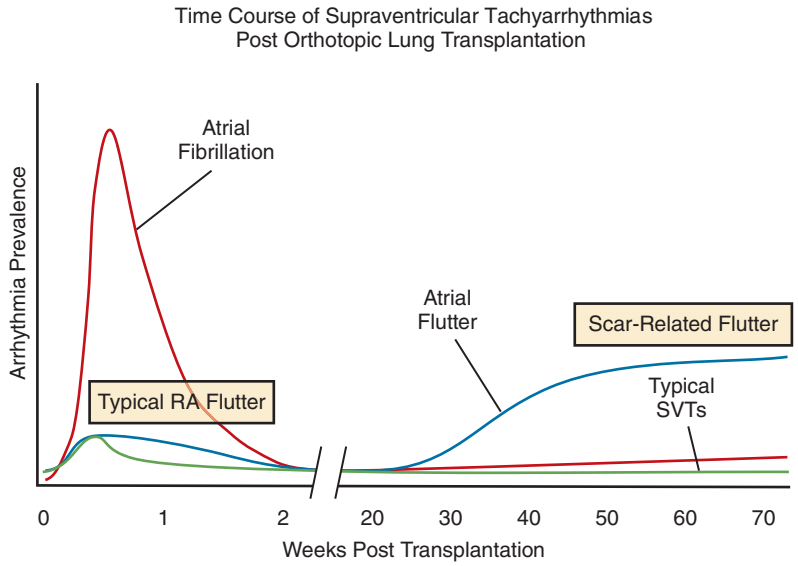


Figure 14-1

Fig. 14-1 demonstrates the time course of supraventricular tachyarrhythmias after lung transplantation. RA, right atrial; SVT, supraventricular tachycardia.

Types of Lung Transplantation Procedures

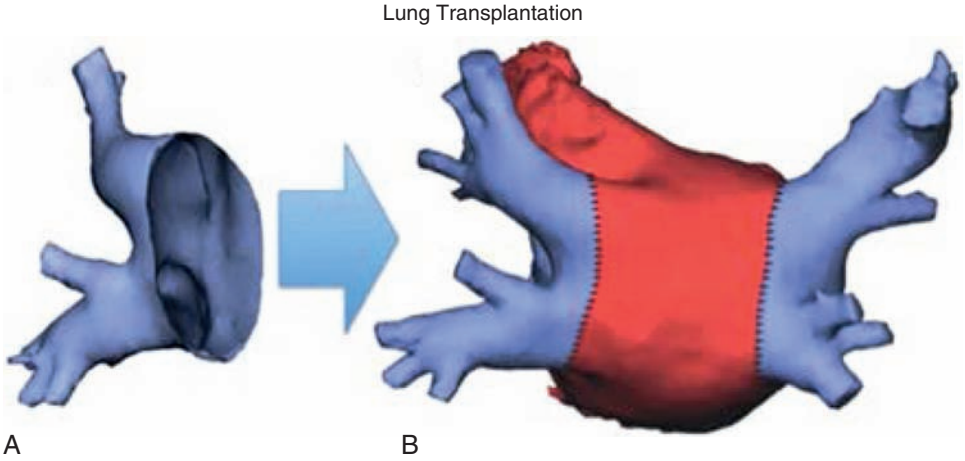

Figure 14-2

(From Lee, G et al. Atrial fibrillation following lung transplantation: double but not single lung transplant is associated with long-term freedom from paroxysmal atrial fibrillation. *Eur Heart J* (2010) 31: 2774-2782.)

A common technique for lung transplantation is to mate the donor lung and pulmonary vein (PV) cuff *(blue)* to the recipient atrium *(red)* (Fig. 14-2).

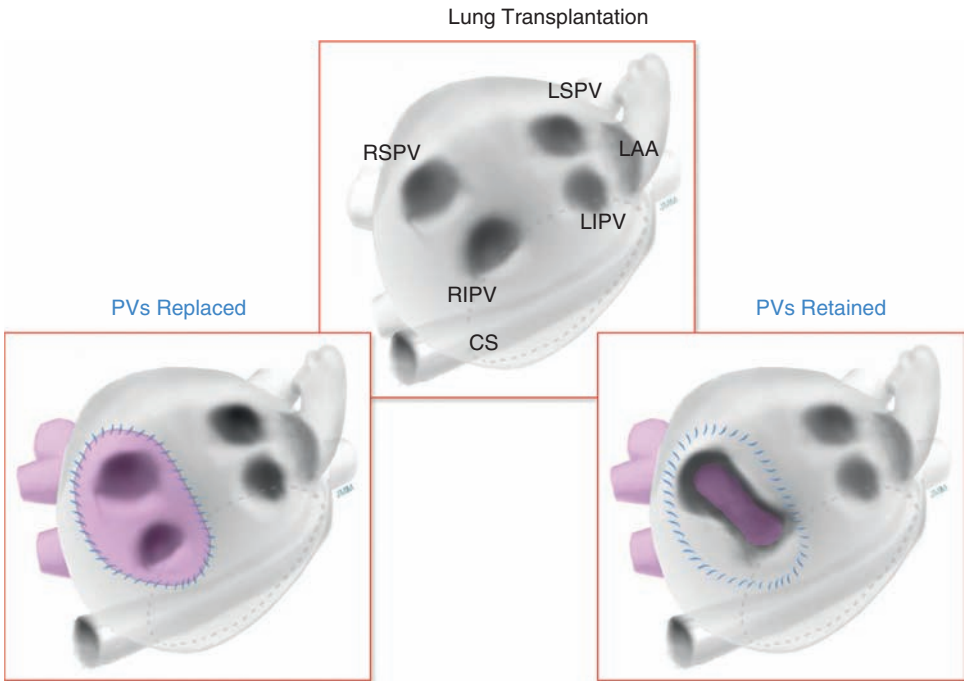

Figure 14-3

Pulmonary veins (PVs) may be replaced as in Fig. 14-2, or retained (with the donor PV cuff sewn around the perimeter of the recipient PVs), as shown in Fig. 14-3. LIPV, left inferior PV; LSPV, left superior PV; RIPV, right inferior PV; RSPV, right superior PV.

Baseline ECG and Intracardiac Recordings

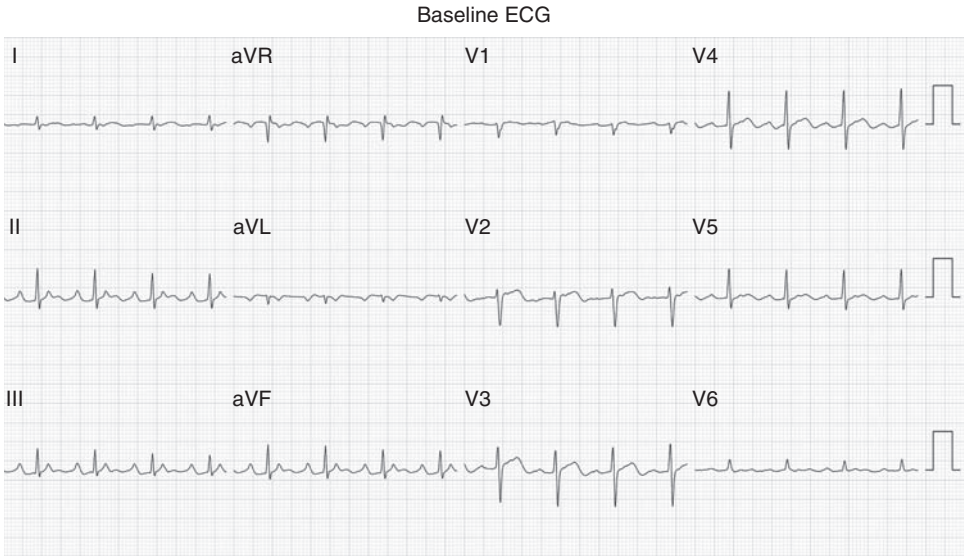

Figure 14-4

Differential diagnosis is only atrial tachycardia; the 2:1 AV relationship excludes orthodromic SVT and the positive P wave excludes AV nodal reentry. What particular kind of atrial tachycardia, however, remains to be diagnosed. The ECG shown in Fig. 14-4 was mistaken as sinus rhythm, which it superficially resembles. However, the rate never varies unless the patient exercises and suddenly conducts 1:1.

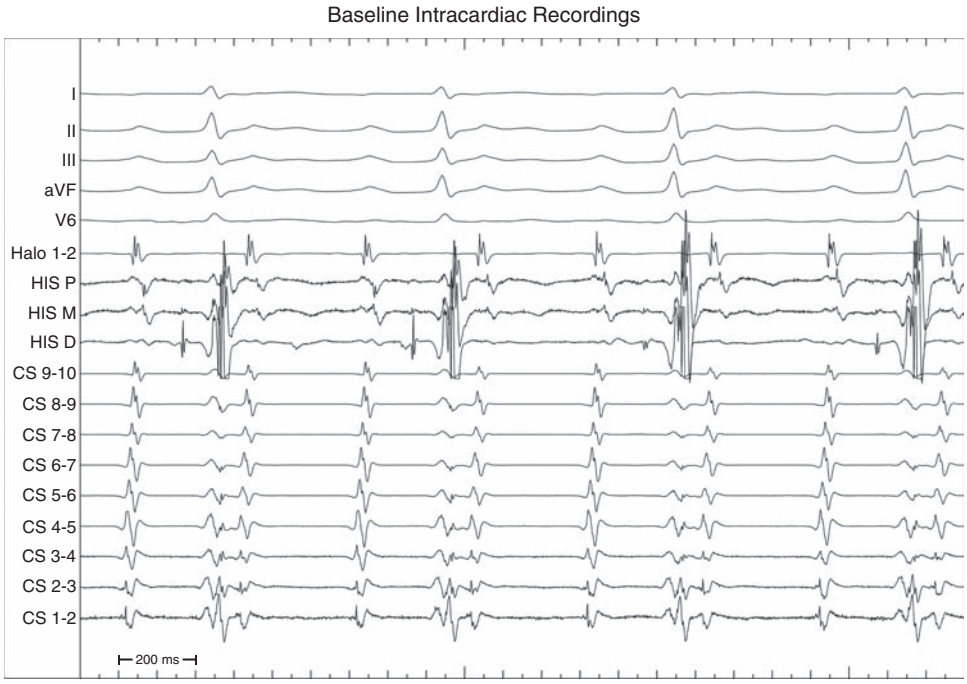

Figure 14-5

In Fig. 14-5, it is hard to tell where the P wave starts because of low-gain ECG channels.

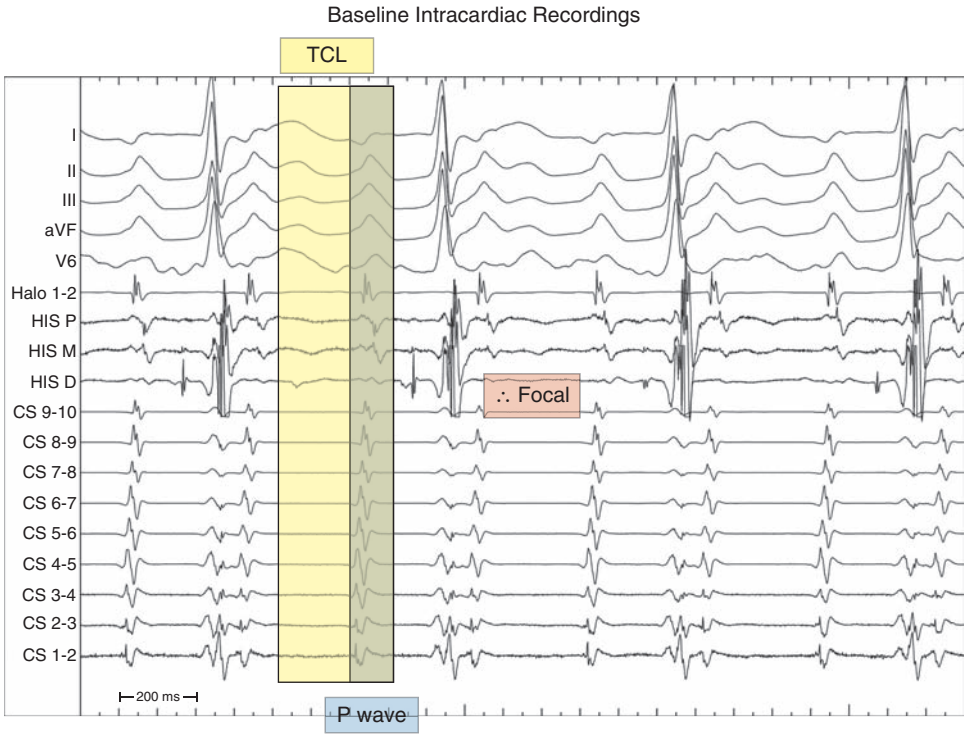

Figure 14-6

One can often infer a mechanism of atrial tachycardia by comparing P-wave duration (and intracardiac electrogram "envelope") to tachycardia cycle length (TCL). The narrower the P wave, especially relative to TCL, the more likely a focal process is involved, but a broader P wave in relation to TCL suggests macroreentry (Fig. 14-6). Specifically, a ratio <0.5 suggests a focal process, because after the focus fires and the atria are activated from that source, there is a pause (diastole) until the next firing of the focus and another P wave begins.

Figure 14-7

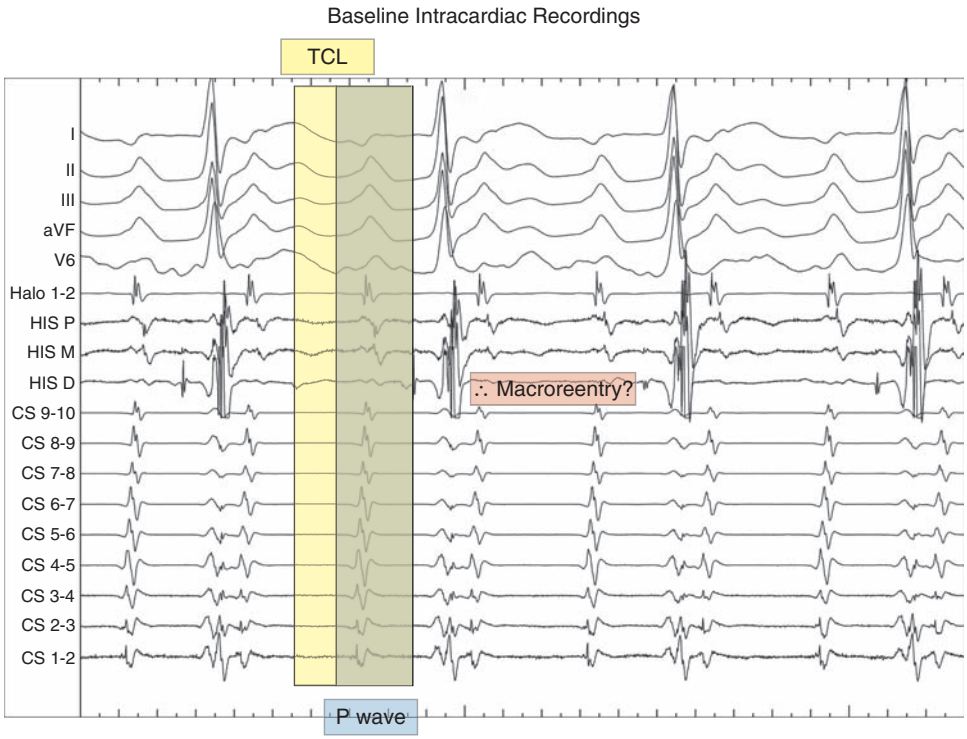

Fig. 14-7 shows a different interpretation of the P-wave duration, while the TCL remains the same. Now, a P-wave duration to TCL ratio >0.7 suggests that atrial activation spreads slowly through large portions of the atrium and thus the mechanism is likely macroreentry. There is considerable overlap with this index (ratio of P duration to TCL) and it is at best suggestive, but not diagnostic, of mechanism.

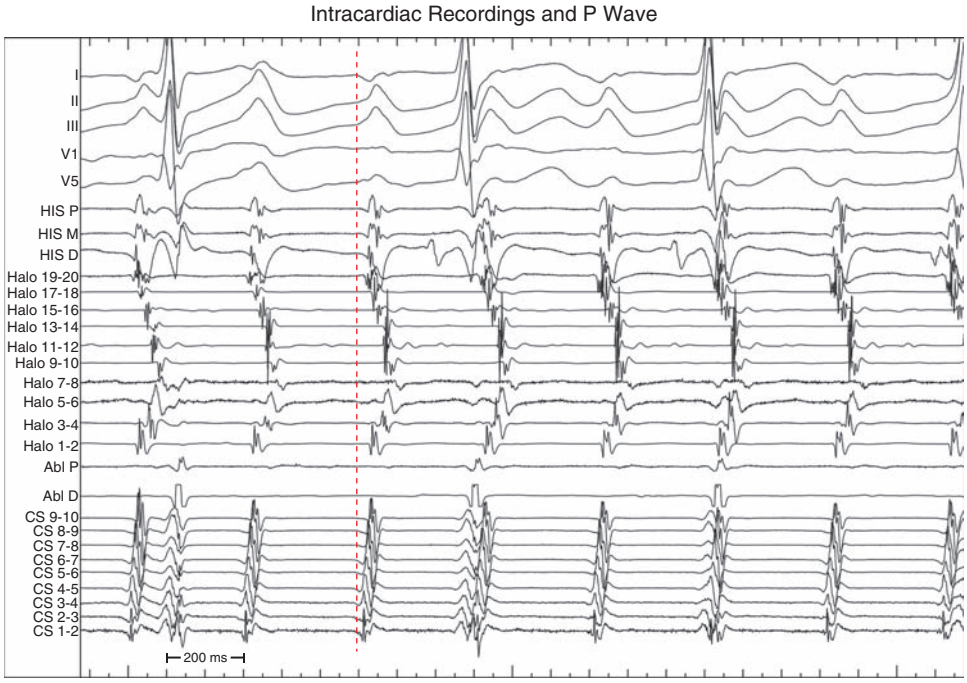
Figure 14-8



The P-wave morphology (initial negative component) suggests a left atrial origin (Fig. 14-8), as does distal-to-proximal CS activation sequence. None of the recordings show pre–P-wave electrical activity, however (P wave onset denoted by dashed red line).

Status

- Sustained (incessant) SVT is present
- All electrical activity recorded is after P-wave onset
- Recordings suggest left atrial process
  - Initial negative P in lead 1
  - CS activation sequence slightly distal-to-proximal
- Mechanism: unclear
- Choices of strategy at this juncture:
  - Activation mapping
    - Can give idea of where origin/exit is, scar borders
    - Does not designate mechanism
    - Catheter bump-termination can occur
  - Overdrive pacing during tachycardia
    - Can designate mechanism, thus ablation target features
    - Can designate which atrium is involved
    - May terminate tachycardia

Electroanatomic Mapping

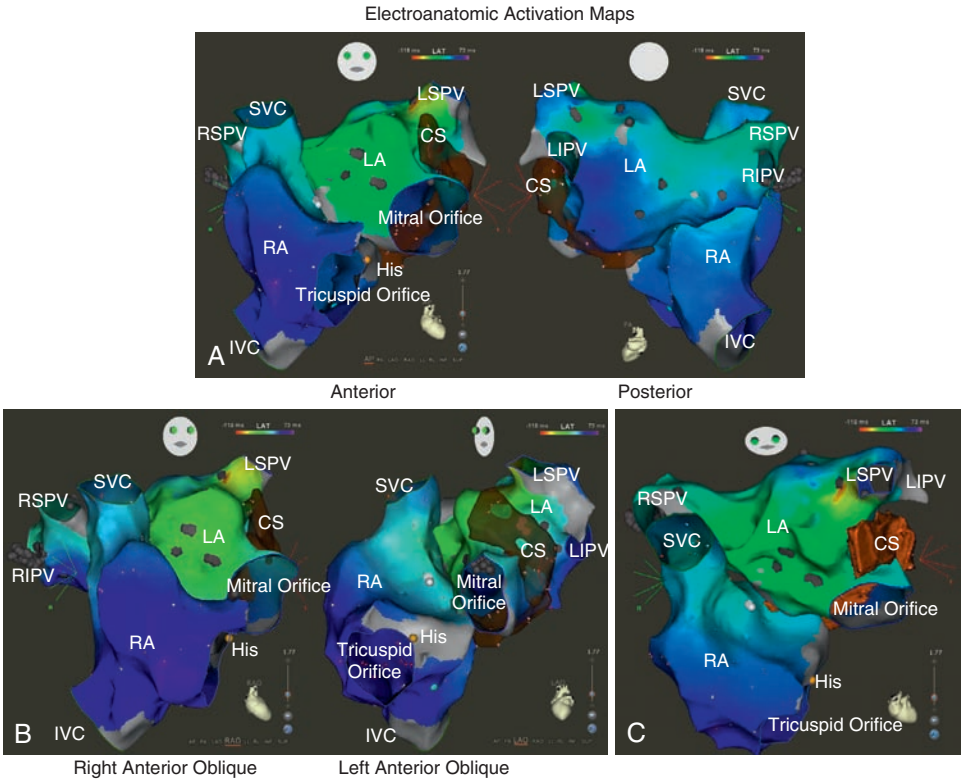


Figure 14-9

We chose activation mapping as the initial strategy, and mapped both atria (Fig. 14-9). The right atrium is clearly activated late in the P wave, but so is everywhere else except for a tiny spot in the top of the left atrium. Note that the span of activation times (−118 to 73 ms, or a total of 291 ms) is almost exactly the TCL (300 ms). This is usually the case with macroreentry but not with focal tachycardias; however, a focus with slow propagation through a scarred atrium can have a total activation time similar to TCL. CS, coronary sinus; IVC, inferior vena cava; LA, left atrium; SVC, superior vena cava.

Mapping

What Does This Mean? [Fig. 14-10]

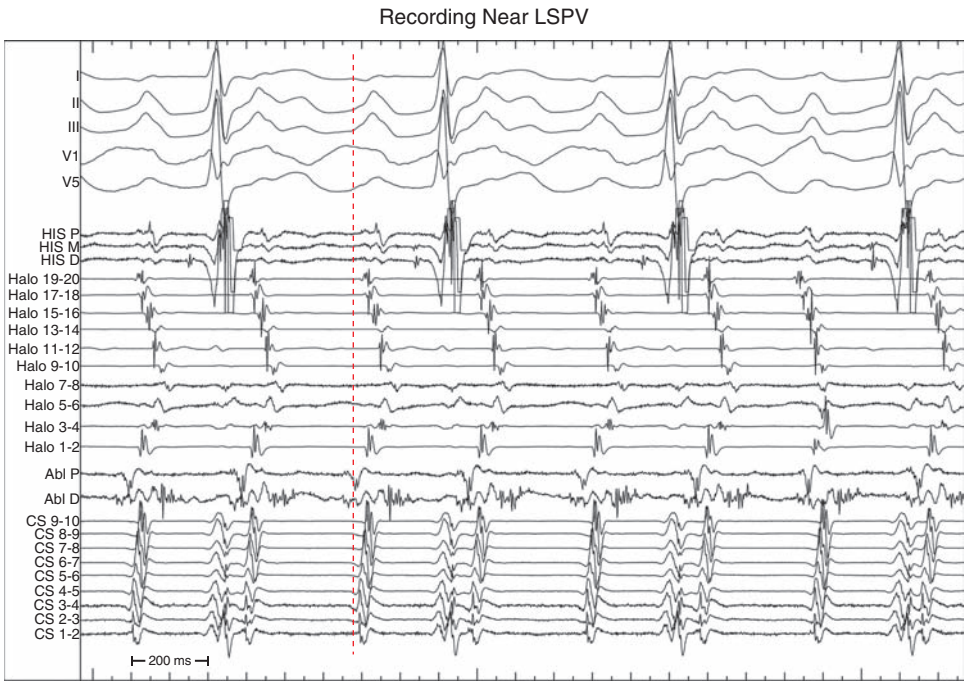

Figure 14-10

A very fractionated electrogram is present near the ostium of the left superior PV, at the site of earliest activation during tachycardia (Fig. 14-10). Although this could still be focal, it raises the question of reentry because the electrogram is so very prolonged and fractionated. At this point, a ring catheter was introduced into the left atrium to interrogate the PVs.

Overdrive Pacing During Tachycardia from Various Sites

Now that we have an idea where the tachycardia exit is (high lateral left atrium), we can clarify the mechanism in order to know what the ideal ablation target site looks like. If a small focus is the cause, a site with minimal pre–P-wave activation (30 to 40 ms) will suffice. If macroreentry, we need a site with middiastolic activation. Responses to overdrive pacing, often from several sites, should provide the answer. In the ablation recording, we already have a middiastolic site near the left superior PV; this could still be a focus there with slow conduction out of it (near a suture line, or conduction from focus in donor PV to recipient LA?), or macroreentry.

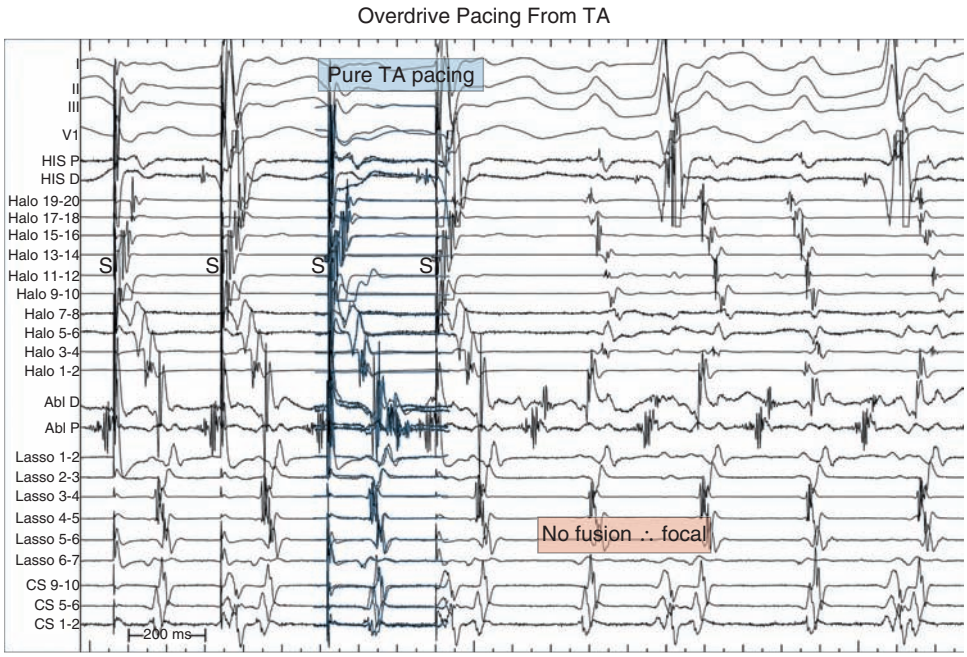

Figure 14-11

In Fig. 14-11, we are overdrive pacing from the lateral right atrium, one of the last places to be activated during tachycardia. Pacing from such a late-activated site makes it easy to see if fusion is present during pacing, because the wavefront caused by pacing and that caused by tachycardia are in theory on opposite sides of the heart. The response to pacing shows that the lateral RA pacing site is indeed among the last to come back on the first beat of resumed tachycardia; superimposition of an example of pure pacing from this site in sinus rhythm shows there to be little, if any, difference between pure pacing and pacing during tachycardia (the ablation catheter position changed between the two recordings and cannot be compared). Thus there is no fusion, further suggesting a focal process.

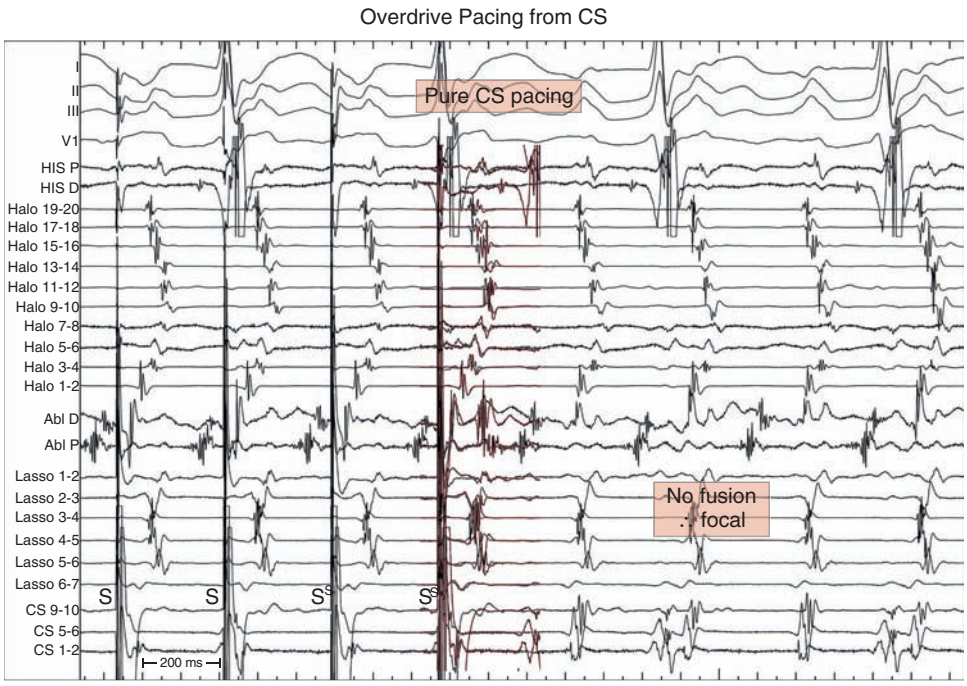

Figure 14-12

Pacing from another site (Fig. 14-12) yields the same findings as before: no fusion, thus likely a focus (as noted before, the position of the ablation catheter had changed between the two recording times and is thus not comparable). However, we had not seen anything but tachycardia to this point in the procedure; the pure pacing examples were obtained only after tachycardia terminated. Thus the comparison of pure pacing versus pacing during tachycardia was not available at the time pacing during tachycardia was performed (it was before ablation, however).

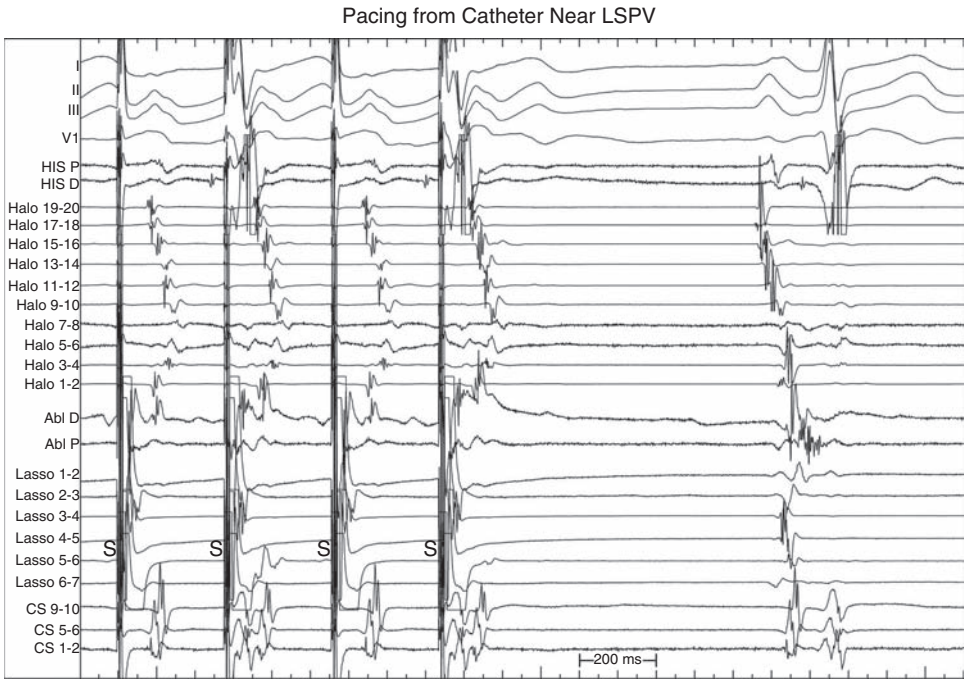

Figure 14-13

Unfortunately, pacing from the ring catheter in the LSPV, near the earliest site of activation during tachycardia, terminated the arrhythmia to sinus rhythm (Fig. 14-13).

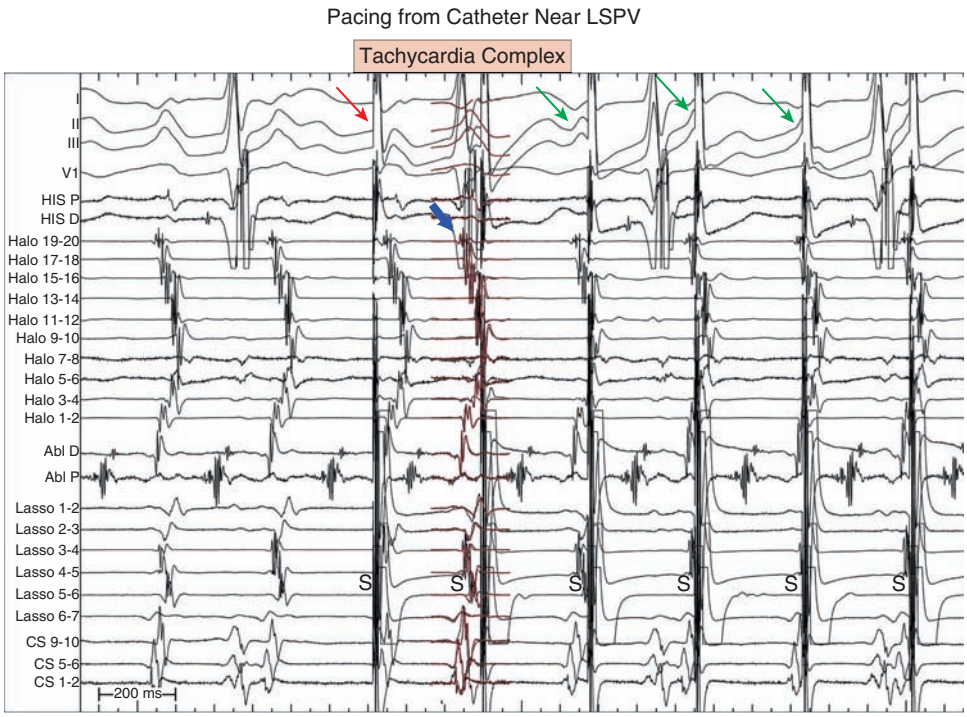

Figure 14-14

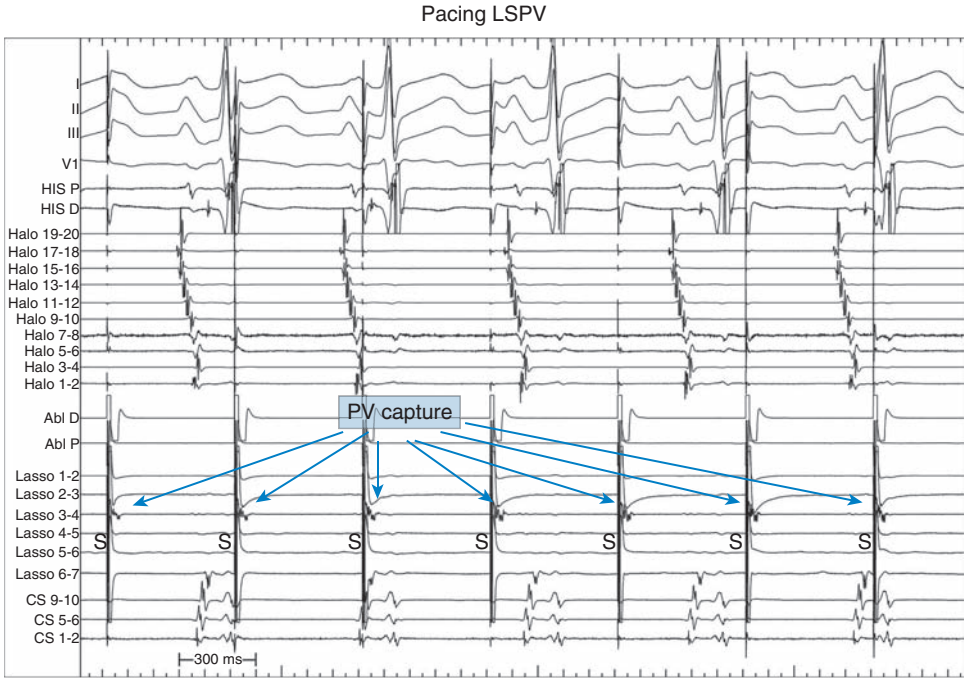
All is not lost, however. Looking back at the initiation of pacing at this site in Fig. 14-14 shows some interesting findings. The first complex controlled by pacing, indicated by the *large blue arrow*, appears to have an identical activation sequence to that of tachycardia (superimposed). That in itself is not so unusual; however, the fact that the stimulus artifact occurred at the onset of the P wave that had already been made by the previous tachycardia cycle *(small red arrow)* is suggestive of a circuit with separate entrance and exit locations; this is further exemplified in subsequent complexes, when the stimulus artifact clearly follows the beginning of an accelerated P wave *(green arrows)*. A focus could not do this.

Pacing Donor Left Superior Pulmonary Vein During Sinus Rhythm

Figure 14-15



Now that tachycardia has accidentally been terminated, we take advantage of the situation. Pacing from the right atrial and coronary sinus sites used in pacing during tachycardia can now be used as examples of "pure" pacing from these sites for comparison. Further, to prove that this was not a pulmonary vein (PV) tachycardia from the donor PV that had made an electrical connection to the recipient atrium, pacing from the left superior PV (Fig. 14-15) showed it to be electrically separate from the rest of the atrium (which is in sinus rhythm at this point).

Pacing from Ablation Catheter Near Ablation Site

Approximates Appearance of SVT

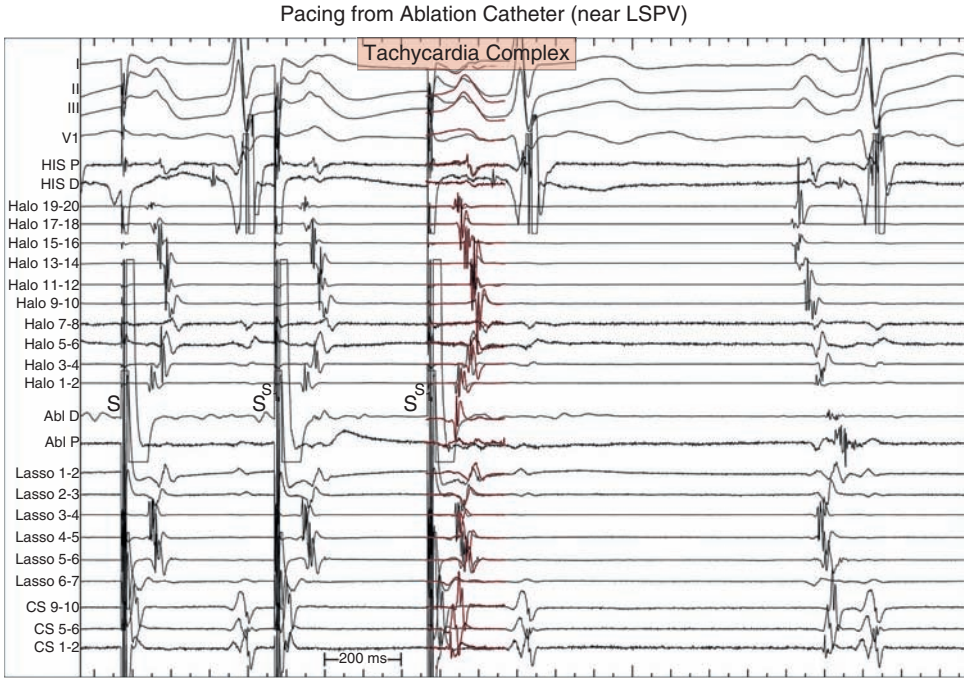


Figure 14-16

In Fig. 14-16, pacing from the ablation catheter (located near the site of the earliest activation during tachycardia) shows an activation sequence almost identical to that of tachycardia—except for the coronary sinus recordings, which are completely different. If this were a focal tachycardia, pacing from the site of the focus should exactly replicate the tachycardia activation sequence and P-wave configuration. The fact is that it does not raise further suspicions about this being a focal firing process.

Initiates SVT

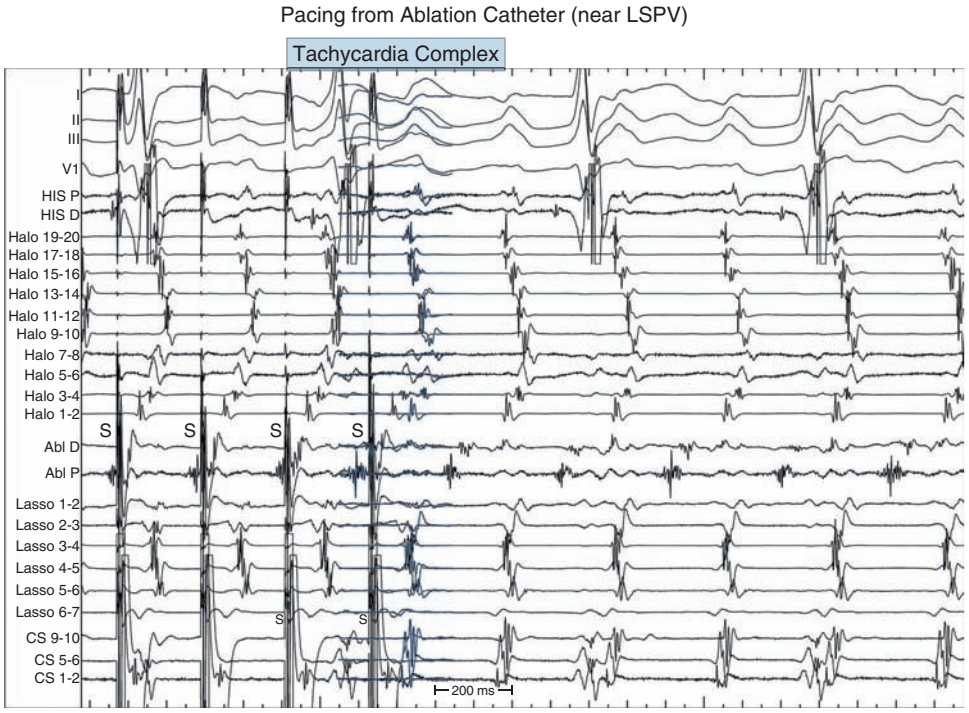

Figure 14-17

Pacing from near the LSPV initiates tachycardia; this would be unusual for a focal firing process (unless it were related to delayed afterdepolarizations). In Fig. 14-17, a complex of tachycardia is again superimposed on the last paced cycle; once again, if this were a focus, pacing here should look very similar to tachycardia. The fact that it does not further calls into question the focal firing hypothesis.

Replicates SVT Appearance

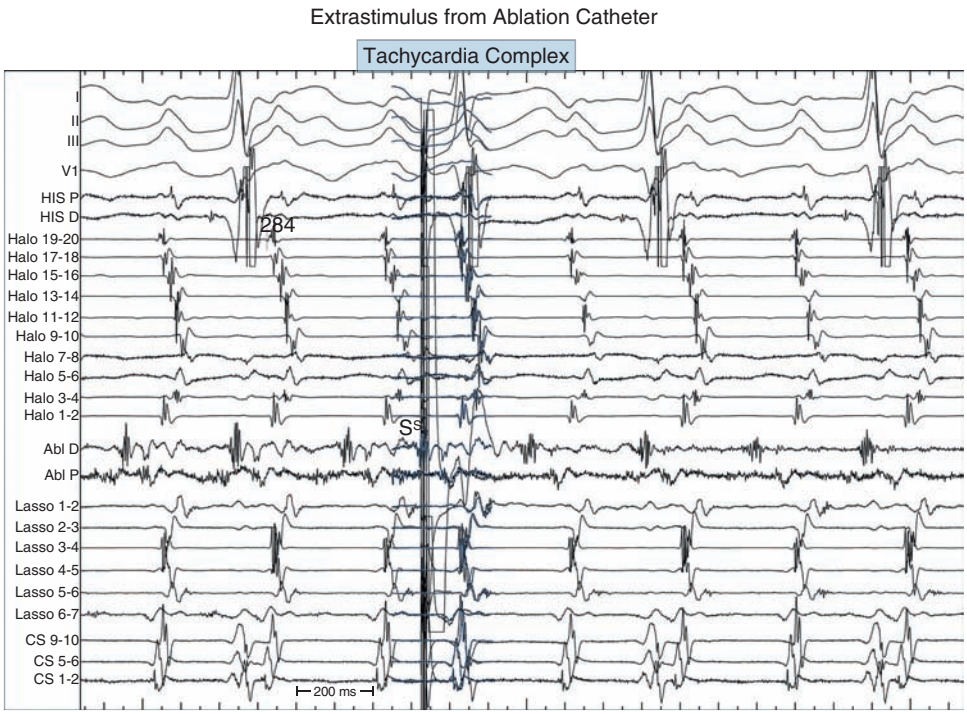

Figure 14-18

An extrastimulus delivered from ablation catheter (recording of a site of middiastolic ablation) captures, resulting in an atrial activation sequence identical to that of tachycardia (Fig. 14-18). This in itself does not differentiate between a focus and reentrant circuit, as one could stimulate from a focus during tachycardia, depolarize the focus, and have a resulting complex that looks identical to tachycardia, and one can certainly stimulate during a reentrant arrhythmia and have the same result.

Terminates SVT Without Propagation

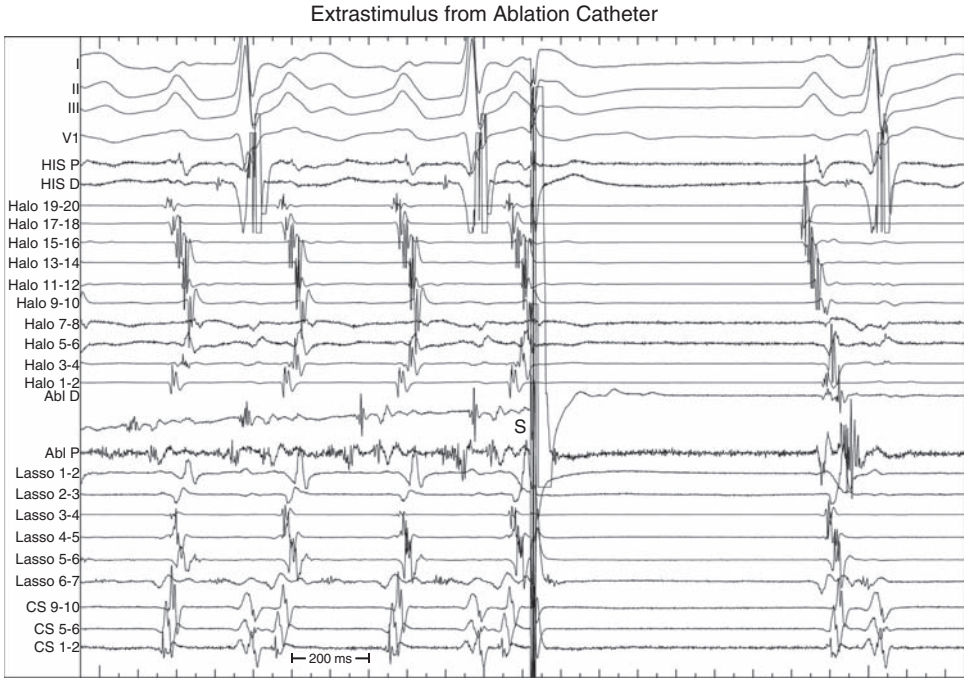

Figure 14-19

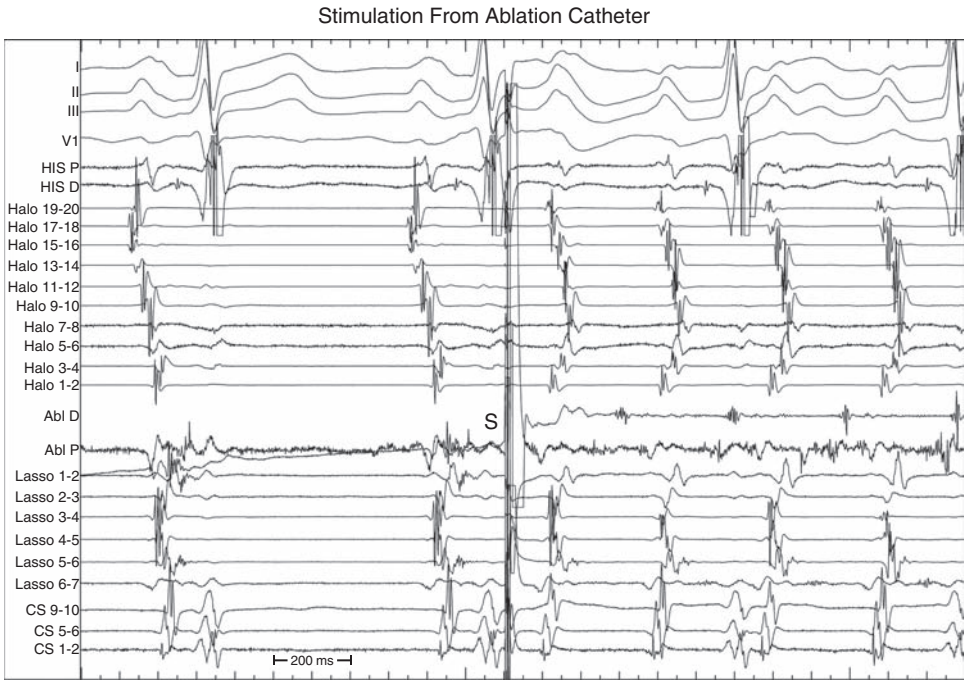
As extrastimuli are brought more prematurely (Fig. 14-19), tachycardia terminates, without apparent propagation; this was a reproducible phenomenon during this procedure. This would be extraordinarily unusual behavior for a focus, and strongly suggests reentry (during which this phenomenon is reasonably commonly observed). The very prolonged diastolic electrogram goes along with this. But what kind of reentry? Fusion was never demonstrated, and the activation map did not show an "early-meets-late" juxtaposition of earliest activations to latest activations (in fact, these were on the opposite side of the heart in the right atrium). This could be *micro*reentry, fulfilling all the requirements for reentry (inducible, terminable with pacing, entrainable) but never showing manifest fusion because the circuit is so small. An additional feature of microreentry is an electrogram at the ideal ablation site that nearly spans the tachycardia cycle length. A focus because of delayed afterdepolarizations could conceivably have accounted for most, if not all, of the phenomena encountered before this; however, termination of tachycardia by a nonpropagated stimulus excludes any focal firing process. Instead, this indicates that a reentrant circuit is responsible, and because fusion was not demonstrable from any far-away pacing site, the activation pattern on electroanatomic mapping suggested a small area from which activation emanated simulating a focus, and the electrogram from this site was extremely prolonged, microreentry is the most likely mechanism of tachycardia.

Reinitiates SVT

Figure 14-20



A single extrastimulus (S) delivered from the ablation catheter at the site of the earliest activation during tachycardia easily reinitiates tachycardia (Fig. 14-20). This would again be extremely unusual for a focal-firing process (automaticity), which is typically not inducible.

Recording at Ablation Site

Figure 14-21

In Fig. 14-21, a nearly continuous electrogram is seen in the proximal recording of the ablation catheter, again consistent with microreentry. Note also a small electrogram recorded from the catheter in the LSPV ("Lasso 6-7"), near this site.

Ablation

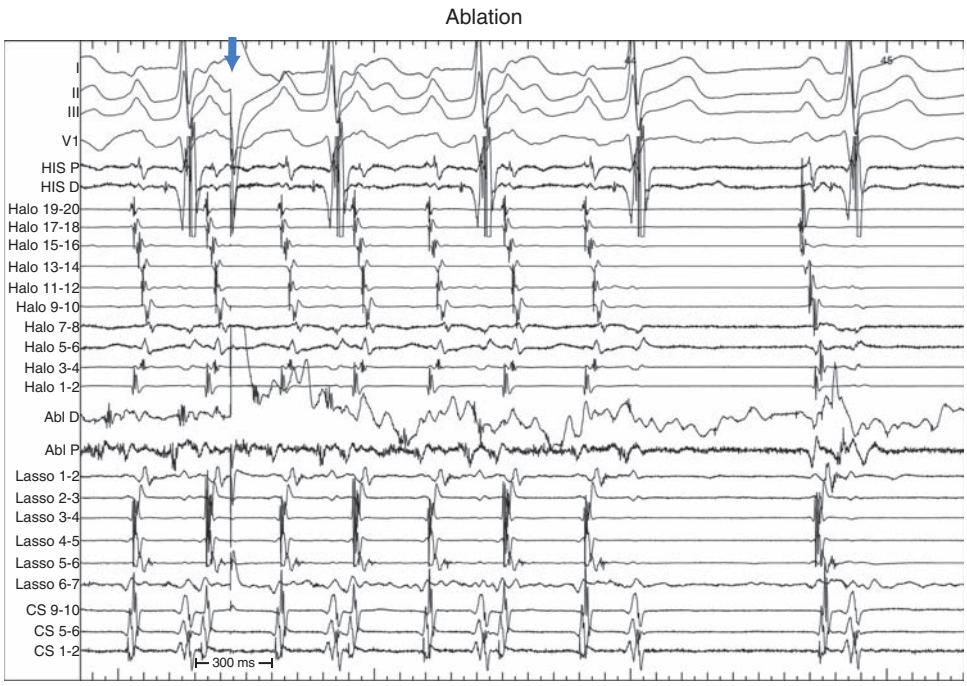


Figure 14-22

After withdrawing the ablation catheter slightly so that the tip was at the site of very prolonged diastolic activation, radiofrequency (RF) energy was applied (Fig. 14-22, *arrow*). Tachycardia terminated in less than 2 seconds. and could not be initiated after this (including with high-dose isoproterenol), whereas it was readily initiated before ablation. A few more RF applications were made in this general area for consolidation of the ablation effect.

Sinus Rhythm at End

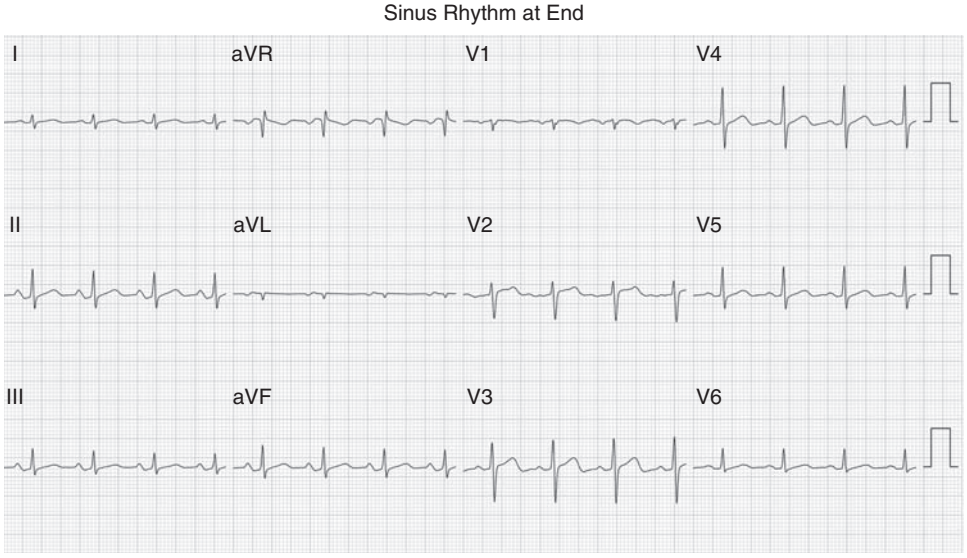

Figure 14-23

The final ECG (sinus rhythm) is shown in Fig. 14-23; the patient has remained free of tachycardia in follow-up and dyspnea is gone.

Summary

- Supraventricular tachyarrhythmias in patients after lung transplantation can have a variety of causes:
  - Atrial fibrillation
  - Atrial flutter/macroreentrant atrial tachycardia
  - Other SVTs (which anyone can have): AV nodal reentry, AV reentry, focal atrial tachycardia
- Successful ablation hinges on correct diagnosis and selection of appropriate target sites
- Microreentry is an unusual but important cause of arrhythmias in patients who have had prior surgery or ablation (practically never occurs in a pristine heart)
  - Overall chamber activation is focal; other features suggest reentry
  - A markedly prolonged diastolic electrogram is a target

Atrial Reentry After Pulmonary Vein Isolation for Atrial Fibrillation

15

Case Presentation

The patient is a 55-year-old man with end-stage renal disease (dialysis, renal allografts + rejection, now on dialysis again), coronary artery disease (CAD) (stents), pericarditis (stripping), pulmonary hypertension, and atrial fibrillation (AF). Longstanding persistent AF was ablated 5 years ago, consisting of pulmonary vein (PV) isolation, left atrial (LA) roof line, mitral isthmus line, complex fragmented atrial electrogram (CFAE) ablation (LA), and cardioverted at the end. He did well initially but then had recurrent atrial tachyarrhythmias despite multiple cardioversions and amiodarone administration. He was very symptomatic despite rate control, and referred for repeat electrophysiologic (EP) study and possible ablation. This is an increasingly common situation, in which ablation either is not completely successful or leads to other arrhythmias.

Baseline ECGs and Intracardiac Recordings

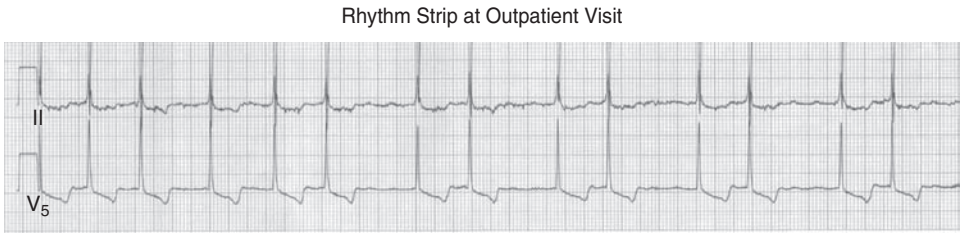

Figure 15-1

The rhythm in Fig. 15-1 appears to be rather irregular (R-R intervals) with no discernible atrial activity and would be appropriately interpreted as atrial fibrillation. However, the last half of the tracing shows QRS complexes that are paired and makes one wonder if there isn't some more organized atrial arrhythmia causing this.

Figure 15-2

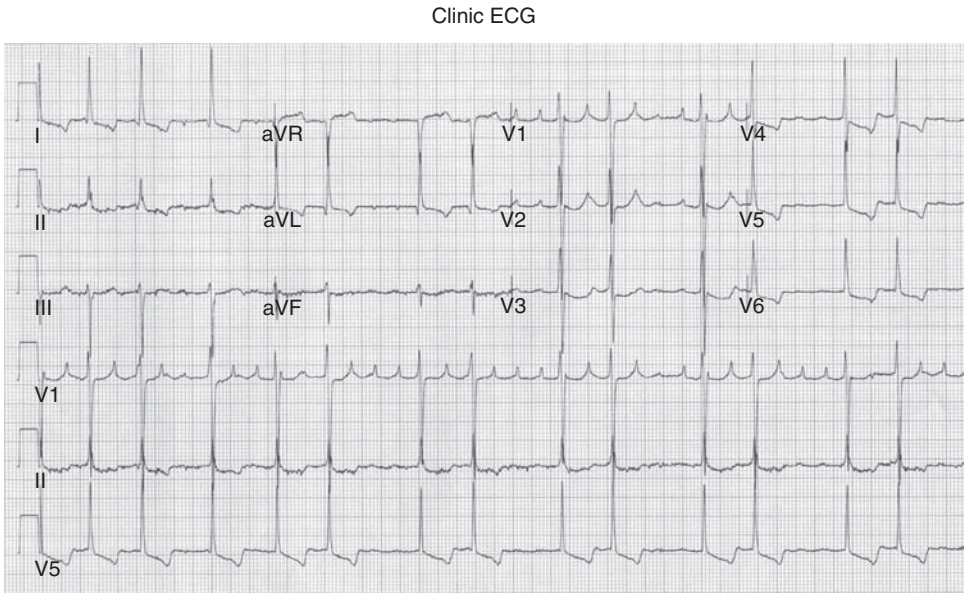

Fig. 15-2 is the rest of that same ECG, showing quite organized activity that is really only evident in lead V1; leads 1 and aVL show very small and narrow P waves.

Figure 15-3

At the beginning of the EP study, the same rhythm was still present. Shown in Fig. 15-3 in 12 simultaneous ECG leads, it is evident that the P wave is quite narrow.

What Is the Likely Mechanism? [Fig. 15-4]

Figure 15-4

Fig. 15-4 is the same ECG, with increased gain on all of the leads. Now, it is evident that there is a very narrow P wave also in lead 1, not readily appreciated on the prior figure. Based on this evidence, the rhythm is clearly not atrial fibrillation, rather an atrial tachycardia (cycle length [CL] 330 ms). But what is the mechanism of the tachycardia? The narrower the P wave relative to tachycardia cycle length, the more likely a focal mechanism is present. If focal, a very late diastolic (ie, just barely presystolic) electrogram will be sought for the ideal ablation target, whereas if it were instead macroreentry, a middiastolic site should be sought. Clearly, it is important to determine whether a focal process or macroreentry is present.

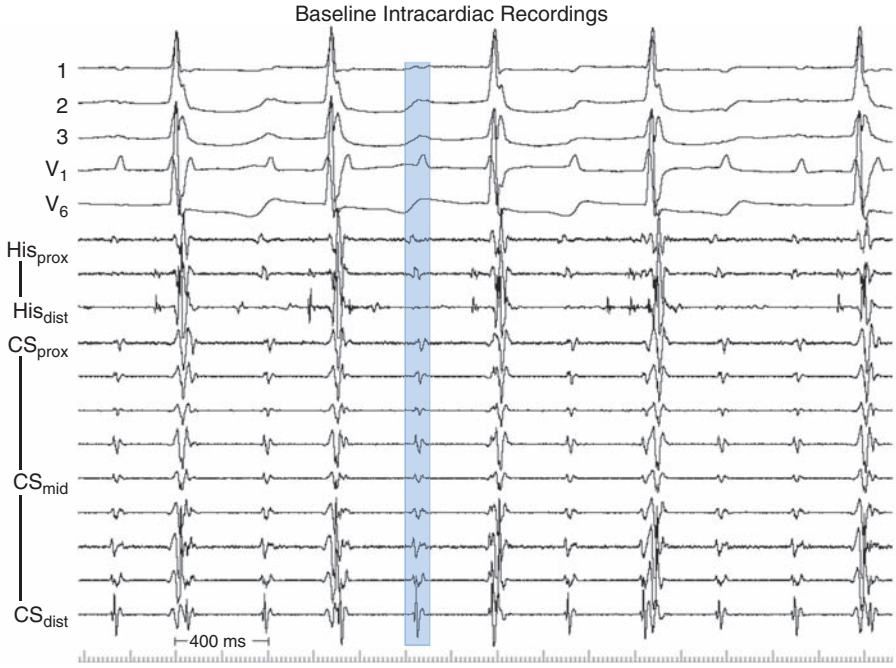

Figure 15-5

After obtaining vascular access and placing electrode catheters in the coronary sinus and His bundle region, the electrograms in Fig. 15-5 are recorded. Again, the "envelope" of atrial activation is very narrow, similar to the P wave during tachycardia.

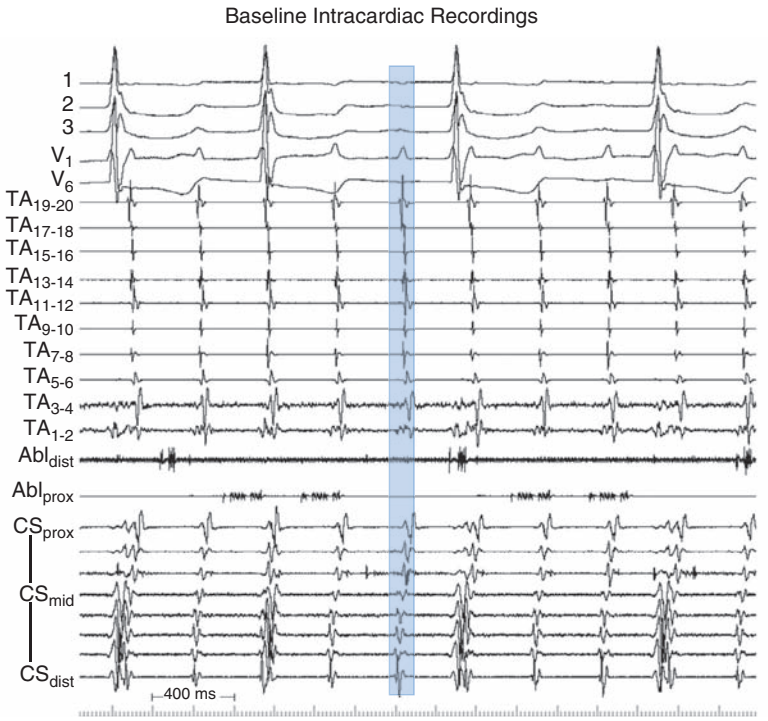

Figure 15-6

Another catheter is placed, this one around the tricuspid annulus (TA), hoping to get more information about atrial activation (Fig. 15-6). All of its electrograms, representing much of right atrial activation, are in the same general "envelope," and all occur within the timing of the surface P wave. This is again suggestive of a focal process. However, this is not certain, and we have to do more to prove or disprove whether it is focal before deciding what our ablation target should look like.

Table 15-1 is a brief comparison of features of different forms of focal propagation from an apparent point source, versus macroreentry.

TABLE 15-1 Atrial Tachycardias

	Focal			
	Automaticity	**Triggered Activity**	**Microreentry**	**Macroreentry**
Onset	Spontaneous	Induced (Burst > PES)	Induced (PES >> Burst)	Induced (PES >> Burst)
Occurrence	Incessant, bursts	Variable	Sporadic, sustained	Sporadic, sustained
P wave vs TCL	Small fraction	Small fraction	Small fraction	Large portion
Atrial envelope vs TCL	Small fraction	Small fraction	Small fraction	Large portion
Isoproterenol effect	Facilitates onset; acceleration	Facilitates onset; acceleration	Minimal effect	Minimal effect
Adenosine effect	Variable effect	Termination	Minimal effect	No affect/acceleration
Response to single premature extrastimuli	Reset or fusion; flat/increasing	Reset or fusion; decreasing	Reset or fusion; flat/increasing	Reset + fusion; flat/increasing
Response to overdrive pacing	Suppression; ↑RC with ↓PCL	Acceleration; ↓RC with ↓PCL	Entrainment; No Δ RC w/↓PCL	Entrainment; No Δ RC w/↓PCL
Ablation target	Late diastolic; unipolar QS	Late diastolic; unipolar QS	Prolonged diastolic	Middiastolic
Response to RF	Accelerate/stop	Accelerate/stop	Slow/stop	Slow/stop

PCL, paced cycle length; PES, programed electrical stimulation; RC, return cycle; TCL, tachycardia cycle length.

Diagnostic Pacing Maneuvers

Pacing from RA at Different Rates

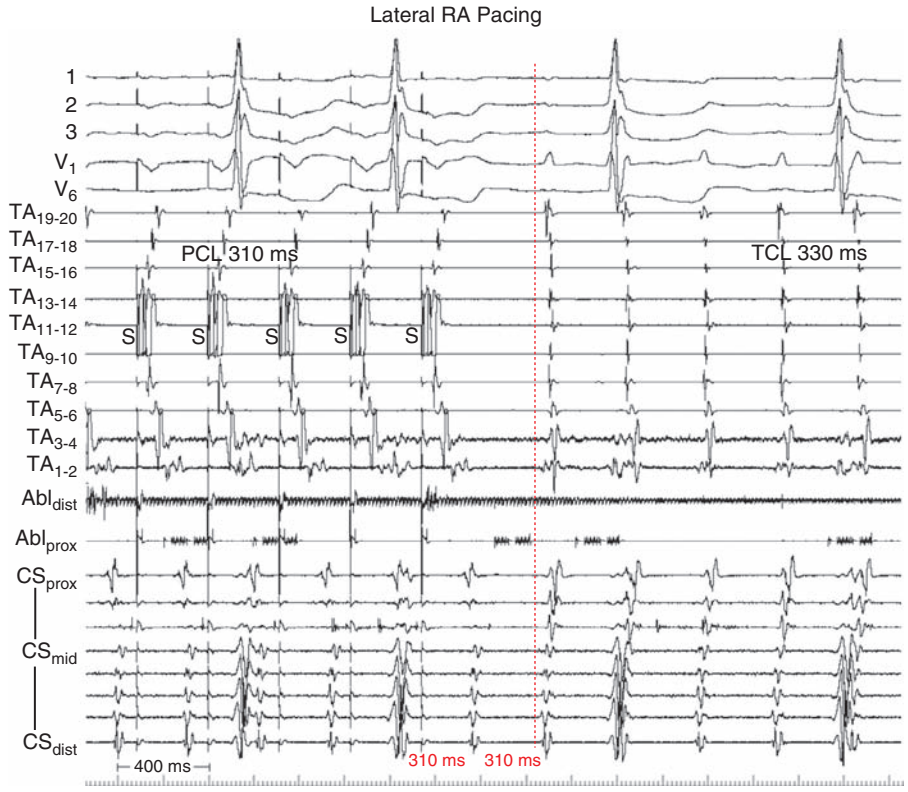

Figure 15-7

In order to try to determine whether a focal process or macroreentry was responsible for the arrhythmia, the first test used was overdrive pacing from the lateral right atrium (RA). We are careful to say "overdrive pacing" rather than "entrainment" at this point, because until we know fusion is present, it is simply "overdrive pacing." In Fig. 15-7, the last five stimuli (S) from the lateral right atrium are shown, after which the same tachycardia resumes. It appears that the right atrium is not part of the process because there is such a long delay until those electrograms are seen again, whereas recordings from the coronary sinus (CS) appear to occur slightly earlier when the tachycardia resumes. However, recordings in the distal half of the coronary sinus catheter are actually controlled by a prior pacing stimulus, because the interval between the first and second CS electrograms after pacing is the same as the paced cycle length. Thus a tremendous amount of slow conduction is present between the stimulation site and the distal coronary sinus, indicating that slow conduction (a necessary constituent of reentry) is certainly present. This in itself does not mean that the arrhythmia is reentrant, however.

Figure 15-8

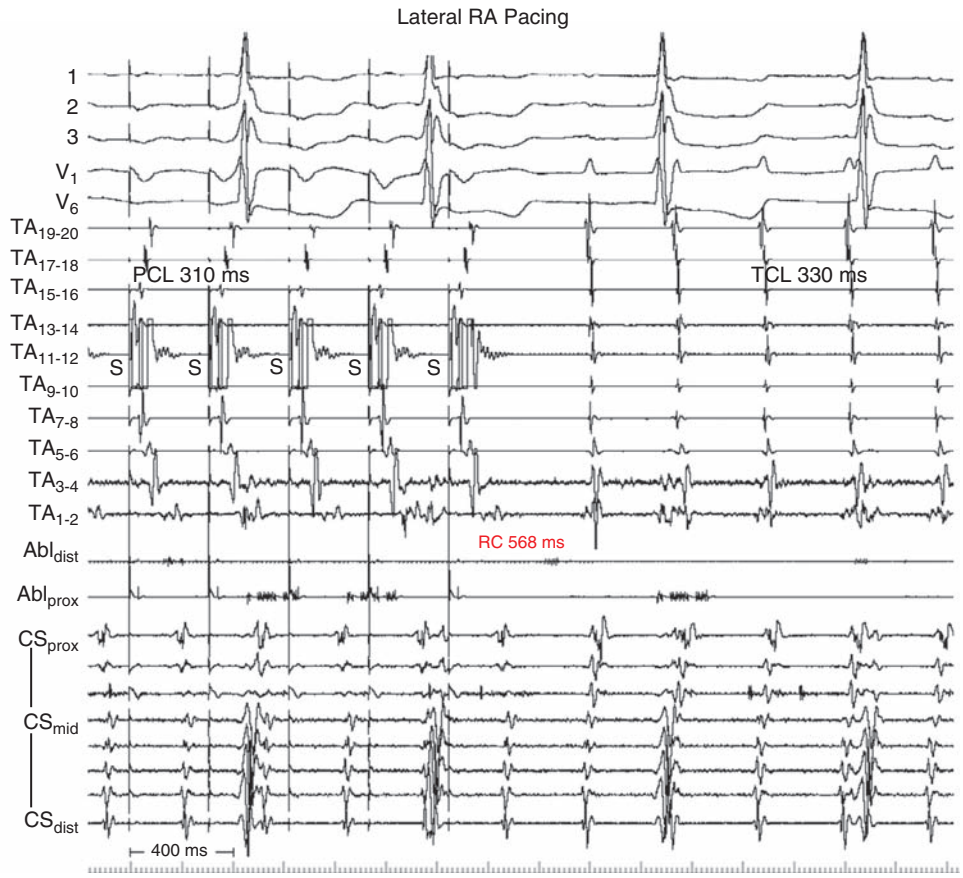

Fig. 15-8 is another burst of pacing at the same cycle length, from the same right atrial site. Here, the "return cycle" (RC) to right atrial recordings is measured at 568 ms, considerably longer than the tachycardia cycle length (TCL). This disparity is not commonly seen in reentry, but may be seen in overdrive suppression of discharge from an automatic focus.

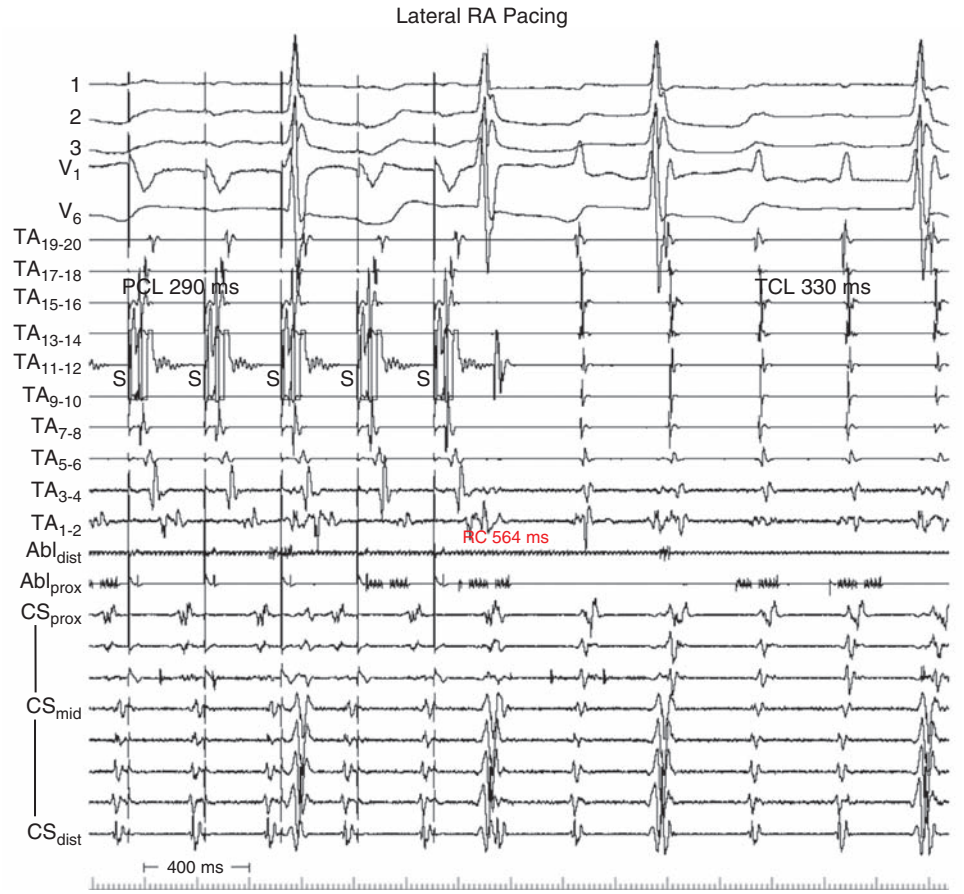

Figure 15-9

In Fig. 15-9, pacing again from the same site, now at a more rapid cycle length, produces a return cycle similar to what was seen earlier. With an automatic focus, more rapid pacing results in more overdrive suppression and a longer return cycle. Thus what is seen here is not entirely keeping an automatic focus.

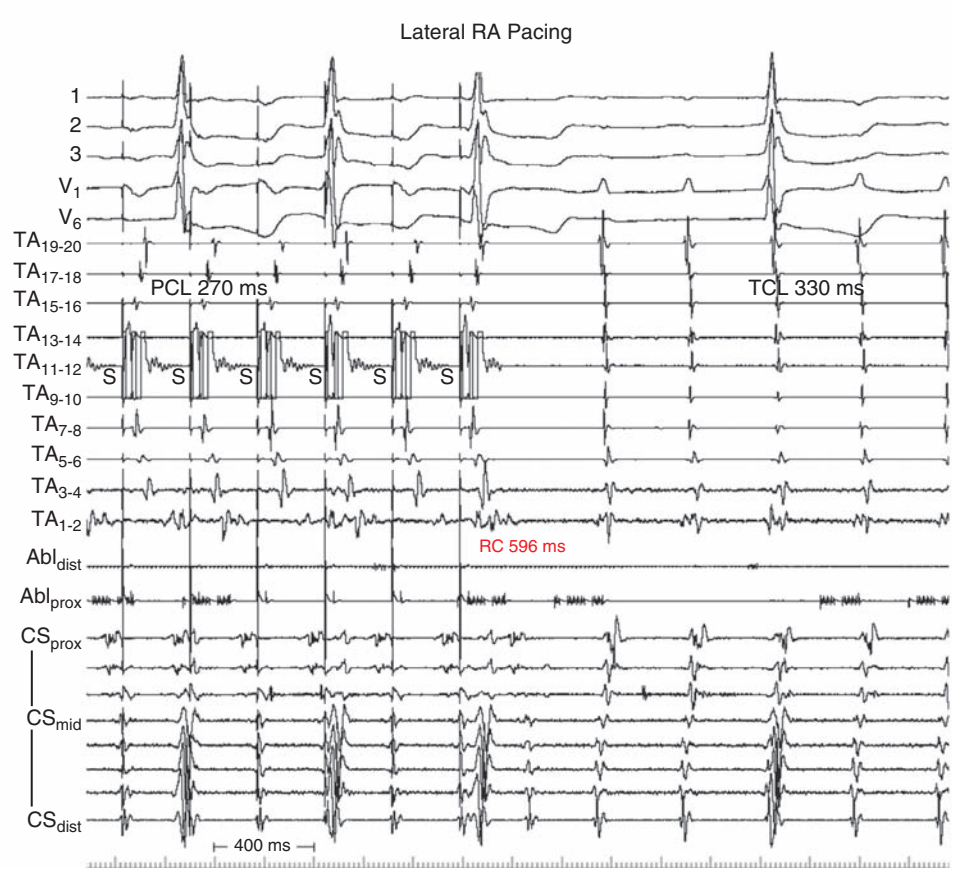

Figure 15-10

However, pacing faster still (270 ms) from the same right atrial site results in a longer return cycle (596 ms), as seen in Fig. 15-10. This *is* consistent with overdrive suppression of an automatic focus.

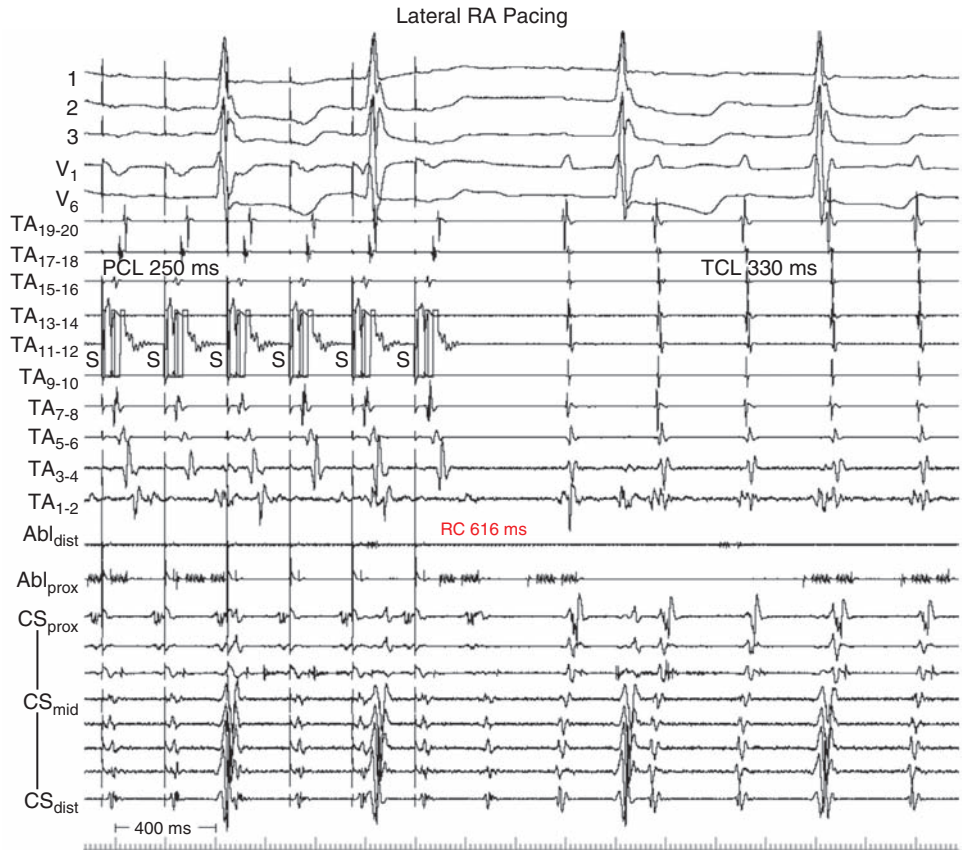

Figure 15-11

Pacing faster still (250 ms), as shown in Fig. 15-11, results in further prolongation of the return cycle to 616 ms, again consistent with overdrive suppression of a focus.

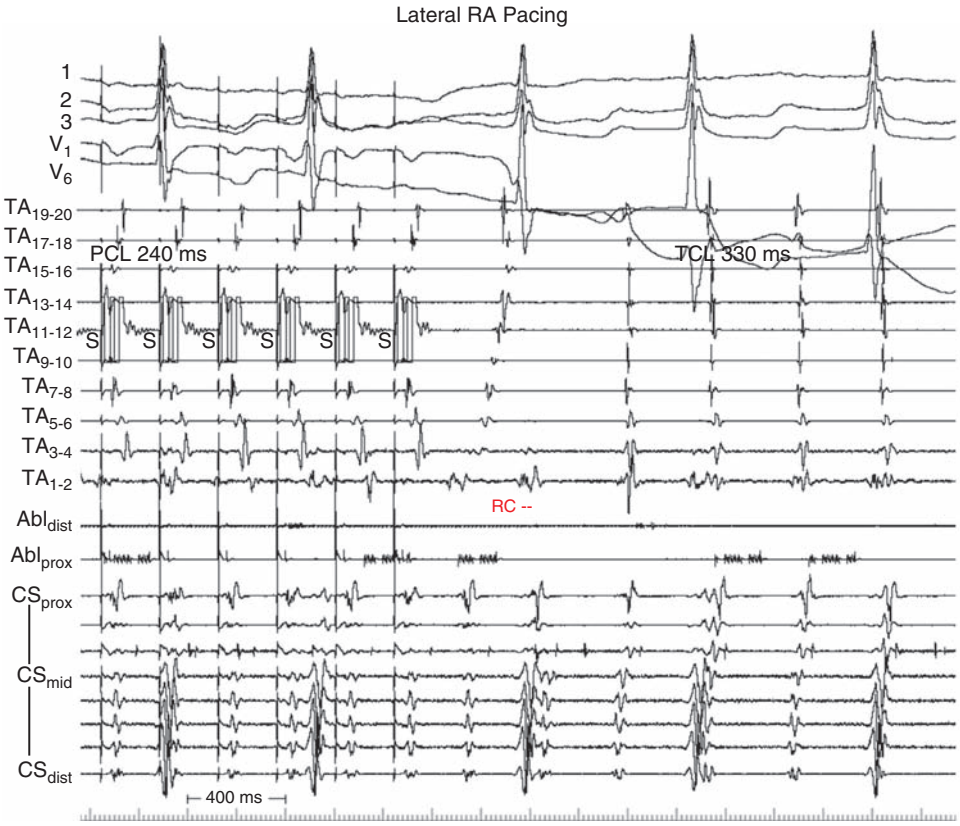

Figure 15-12

Pacing faster still (240 ms) from the same right atrial site (Fig. 15-12) yields uninterpretable results, because the first beat after cessation of pacing is not a tachycardia complex.

Pacing from Different Sites at Same Rate (Figures 15-13 to 15-16)

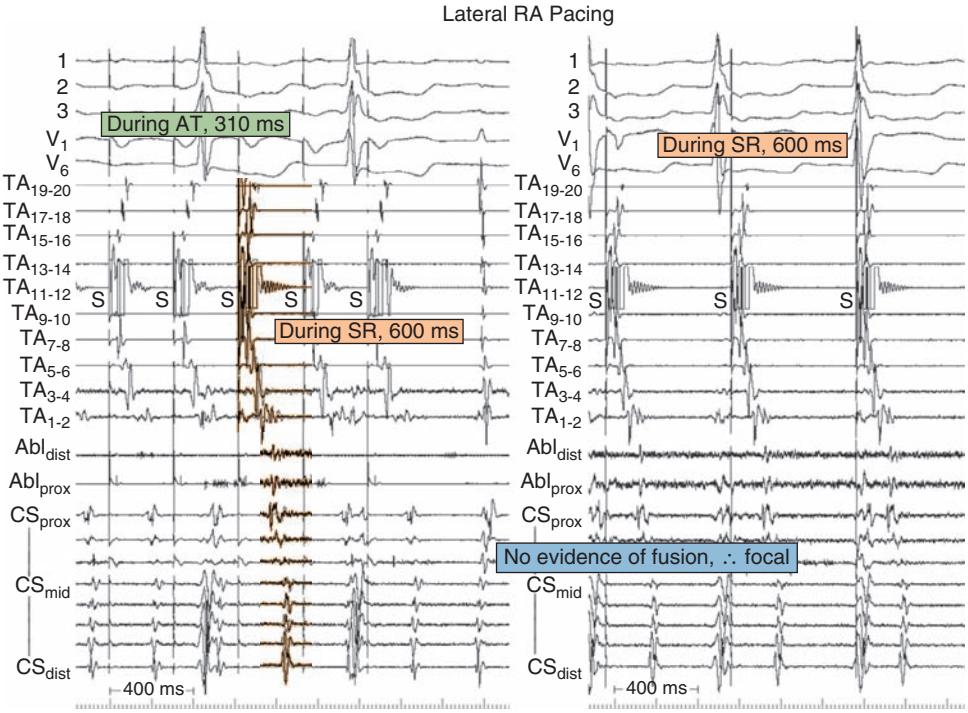

Figure 15-13

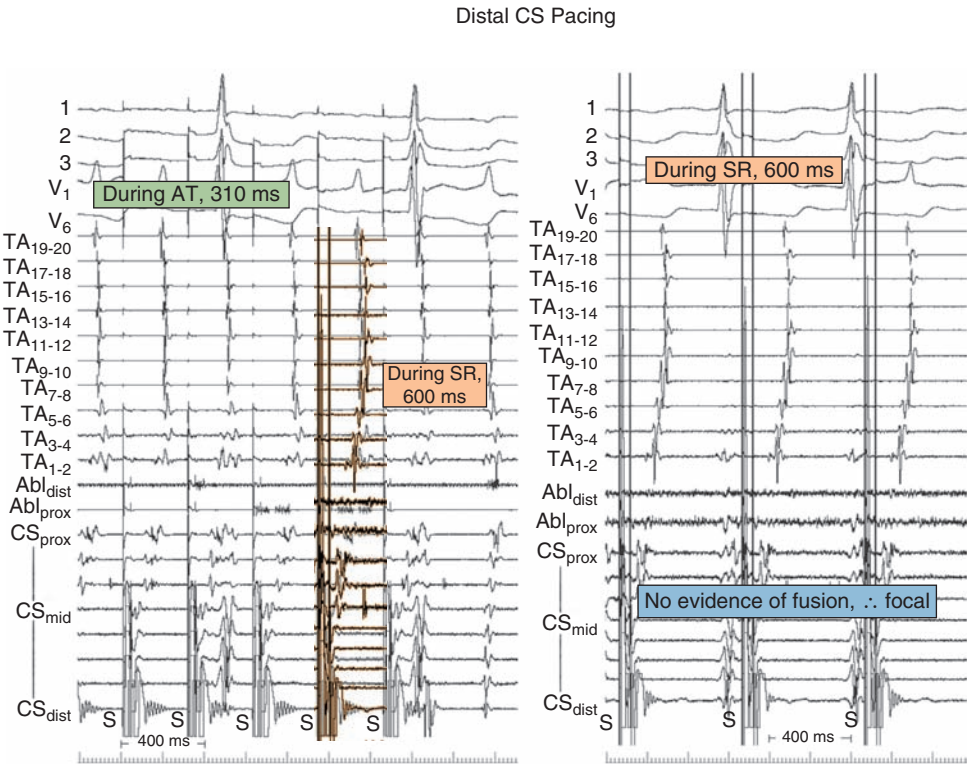
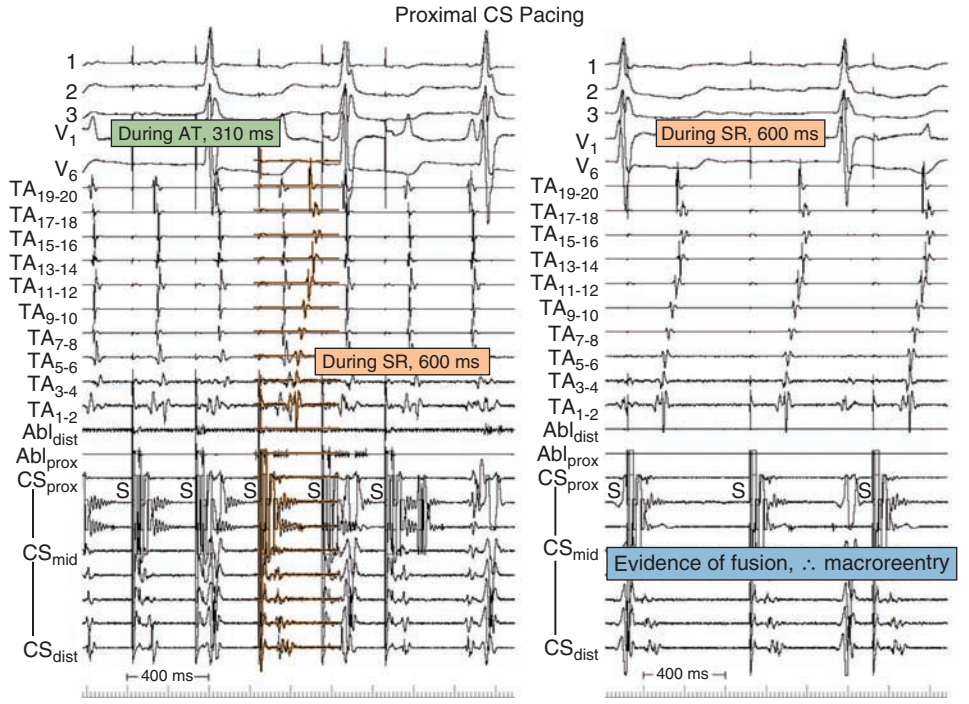
So far, there is evidence for and against the presence of an automatic focus. Further information can be obtained by evaluating activation sequences of pacing from different sites during tachycardia; if pacing during tachycardia does not resemble either tachycardia or "pure" pacing from that site during sinus rhythm, fusion is present, and macroreentry is the diagnosis. On the left of Fig. 15-13, pacing from the lateral right atrium at 310 ms (shown previously) is seen, and on the right, pacing from the same site but later in the procedure after tachycardia has terminated ("pure" pacing). A single complex of "pure" pacing from the site is superimposed on pacing during tachycardia (in *brown*). The activation sequences look identical, and thus there is no fusion. This is consistent with, but not diagnostic of, a focal process. If the same results are obtained when pacing from multiple other sites, a diagnosis of a focal process will be more certain.

Figure 15-14



In Fig. 15-14, pacing from the distal coronary sinus is shown both during tachycardia at left and during sinus rhythm at right ("pure" pacing). Again, a single complex of "pure" pacing is superimposed on a complex of pacing during tachycardia, which it again very closely resembles. Thus there is again no evidence of fusion, and brings us closer to a diagnosis of a focal process.

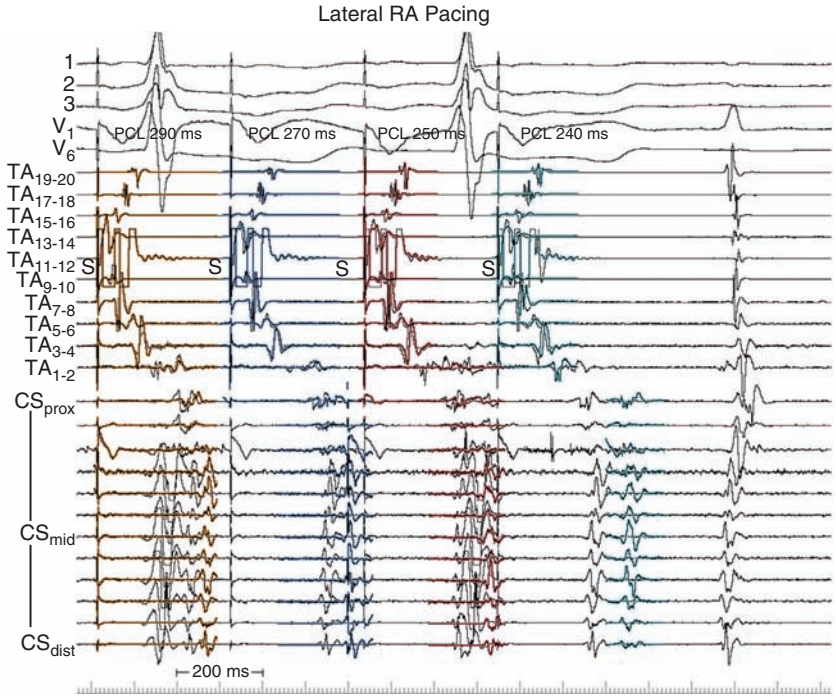
Figure 15-15



Another site is tested, the proximal coronary sinus (Fig. 15-15). As before, pacing during tachycardia is shown at left and pacing during sinus rhythm at right ("pure" pacing). Again, a single complex of "pure" pacing is superimposed on a complex of pacing during tachycardia. In this instance, however, the activation sequences are quite different, indicating the

presence of fusion when pacing during tachycardia. This changes everything, and establishes a diagnosis of macroreentry. It is important to note that a single instance of pacing that shows fusion can diagnose macroreentry, whereas it is much more difficult to prove that fusion is *absent,* requiring pacing from multiple sites sometimes at multiple cycle lengths.

Pacing from RA at Different Rates Superimposed



When Looking for Fusion:

A. Pace far away from presumed exit/focus
B. Evaluate signals far away from pacing site

Figure 15-16

Another way in which macroreentry can be diagnosed is the demonstration of *progressive fusion.* This is performed by pacing at the same site, but different cycle lengths. If macroreentry is present, the faster one paces from the same site, more of the chamber will be governed by the wavefront emanating from the pacing site, and less from the circuit. Thus the faster one paces, the more the resultant activation sequence looks like pure pacing and less like tachycardia. In Fig. 15-16, pacing from the lateral tricuspid annulus is shown over five different cycle lengths. The black recordings are at 310 ms, with a single complex of pacing at progressively shorter cycle lengths superimposed on sequential complexes. It is evident that 1) the faster one paces, as stated previously, the more the resultant activation sequence looks like pacing and less like tachycardia, and 2) when evaluating electrograms near the pacing site, they usually look the same, whereas evaluating electrograms more distant from the pacing site shows greater differences at different cycle lengths. Thus to have the greatest chance of demonstrating fusion, one should choose a pacing site far away from the presumed exit of a focus or circuit, and evaluate recordings far from the pacing site.

Mapping in Left Atrium

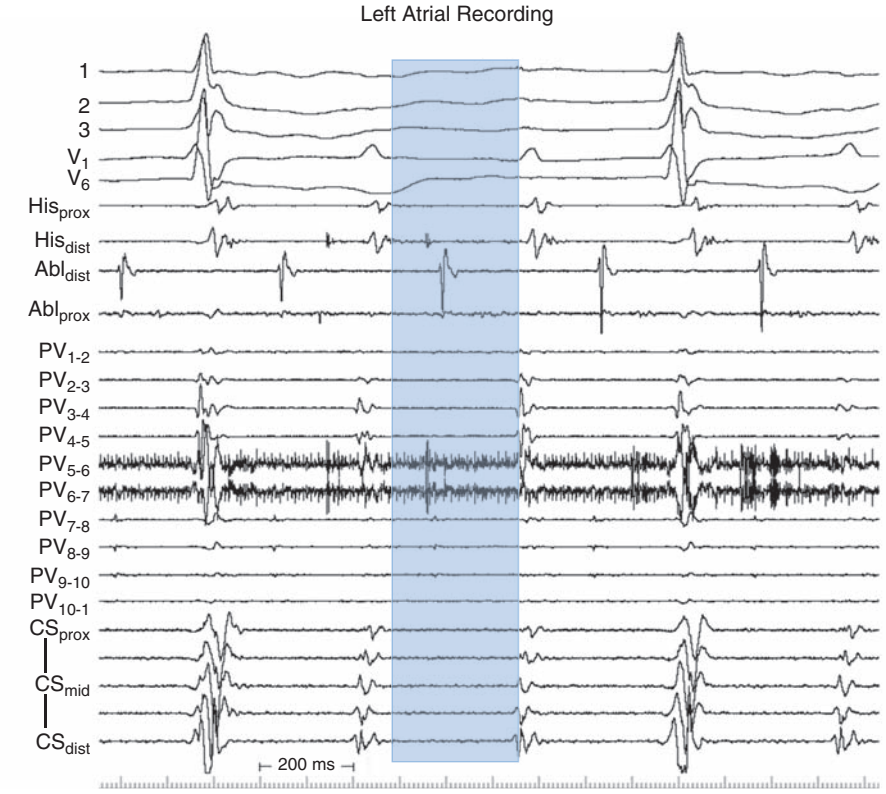


Figure 15-17

Now that a firm diagnosis of macroreentry has been established by a couple of methods, the ablation target becomes a middiastolic potential that can now be sought. Before establishing whether a focal process or macroreentry is present, great caution must be exercised in performing activation mapping because results may be misleading especially in instances in which the focal process is actually present, but substantial slow conduction is also present (such as after a previous ablation procedure). In Fig. 15-17, the ablation catheter records a sharp, isolated potential almost exactly in the middle of diastole (*blue shaded box* from the end of one P wave to the beginning of the next). It appears that we have a good ablation target already.

Electroanatomic Mapping

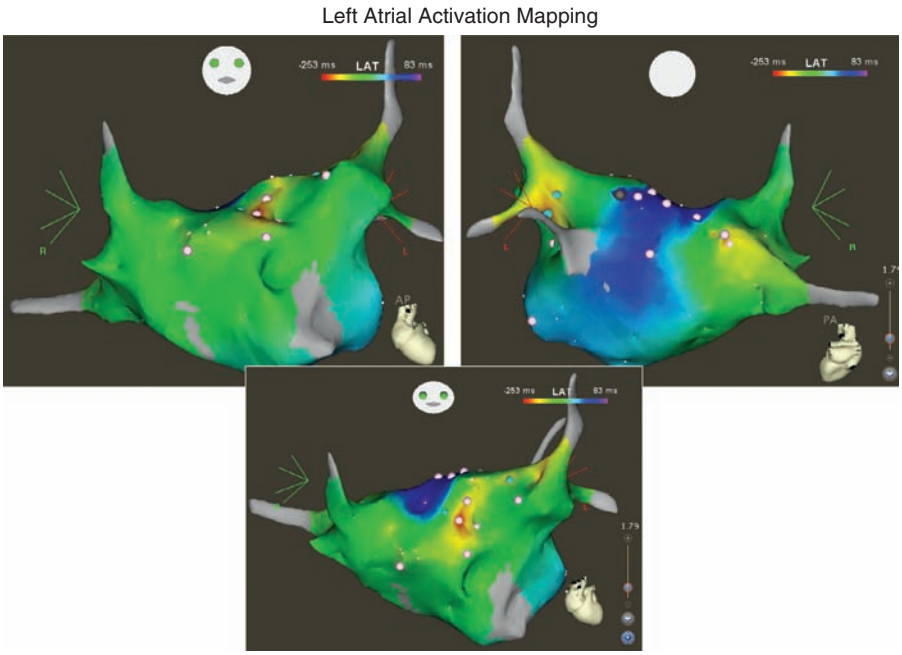

Figure 15-18

Fig. 15-18 is an activation map of the left atrium in several attitudes. This is somewhat disturbing because although a diagnosis of macroreentry has been established, the activation map suggests a focus on the roof of the left atrium *(red area)*, or perhaps a second focus in the region of the left upper pulmonary vein (also *red*). How can this be resolved with the diagnosis of macroreentry?

Mapping and Touch-up Ablation in Pulmonary Veins

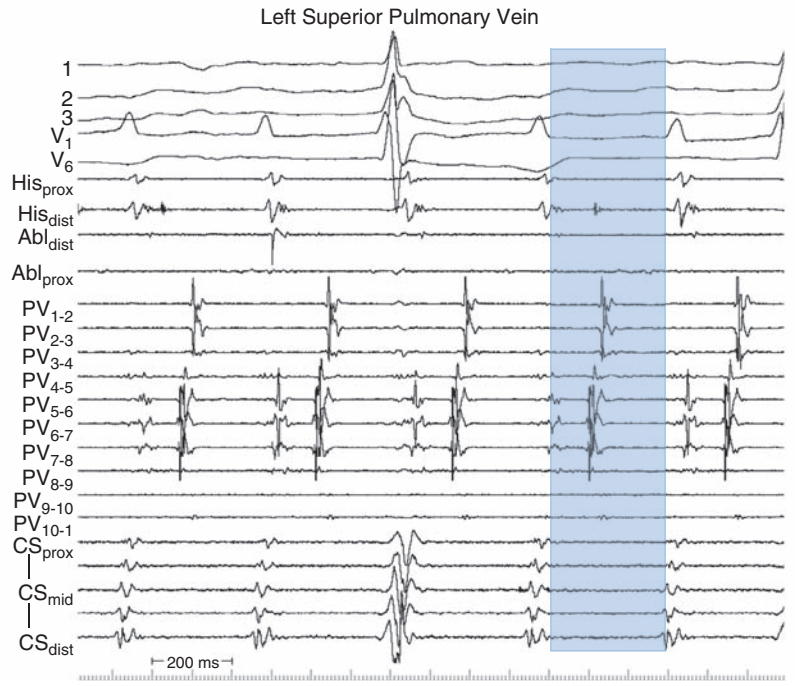

Figure 15-19

The problem with the prior middiastolic potential and the electroanatomic activation map was that pulmonary vein potentials were "contaminating" the activation map, and the middiastolic signal was actually a pulmonary vein recording (Fig. 15-19). Could this be a focus in a pulmonary vein? No, because it has been established as being macroreentry rather than a focus. However, the pulmonary vein potentials are quite large, and it is difficult to know how they should be incorporated into an electroanatomic activation map. One strategy that can be quite useful is to proceed with pulmonary vein isolation at this point; if tachycardia terminates, perhaps pulmonary veins were involved. If tachycardia persists, the PVs were obviously not involved, and the confusing signals they harbored will no longer be problematic.

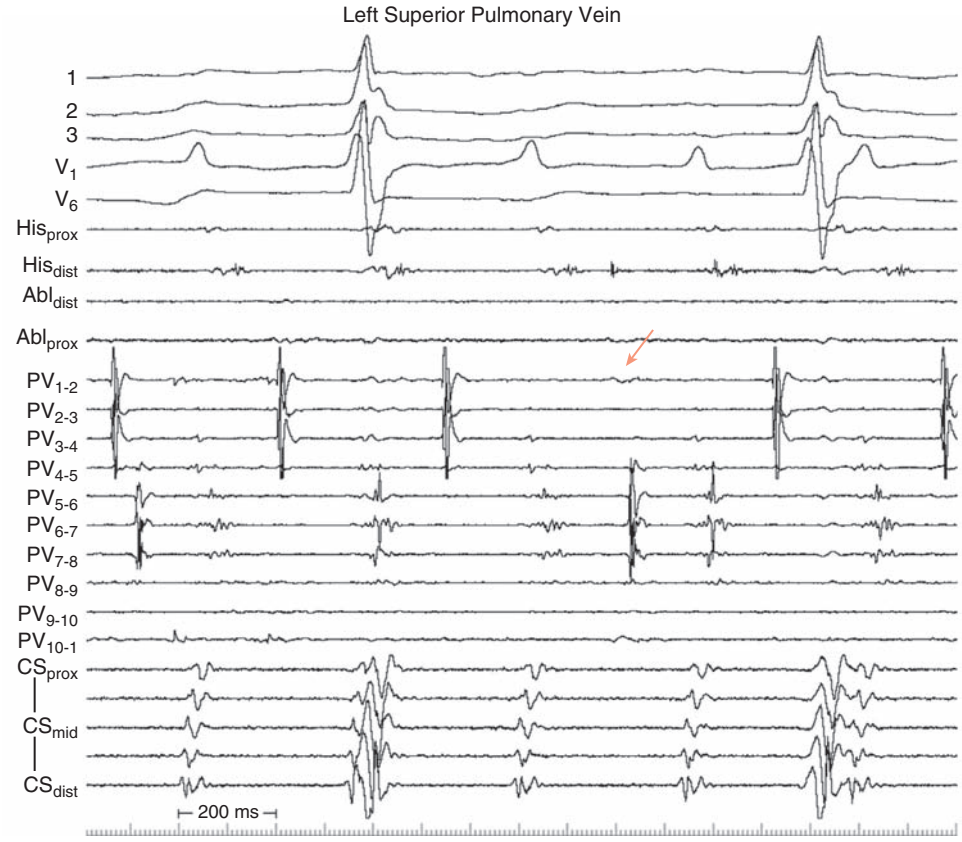

Figure 15-20

Immediately before attempts at isolating the left pulmonary veins, the recordings in Fig. 15-20 were made. Clearly, because the tachycardia persists despite the absence of the signal in PV 1-2 through PV 3-4 on one of the cycles *(orange arrow)*, this pulmonary vein cannot be responsible for the ongoing arrhythmia.

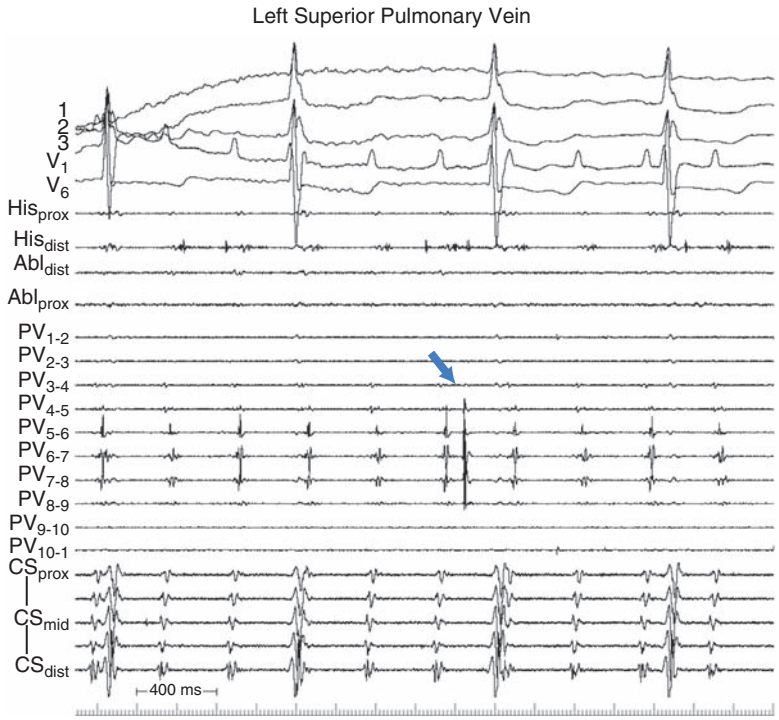

Figure 15-21

After ablation to encircle the left pulmonary veins, they have been isolated (Fig. 15-21). The *blue arrow* points to a random, dissociated potential spontaneously firing from the PV. Other signals noted in PV 5-6 through PV 7-8 were proven to be "far-field" recordings from the adjacent left atrial appendage. Clearly, the left pulmonary veins were not responsible for the ongoing arrhythmia.

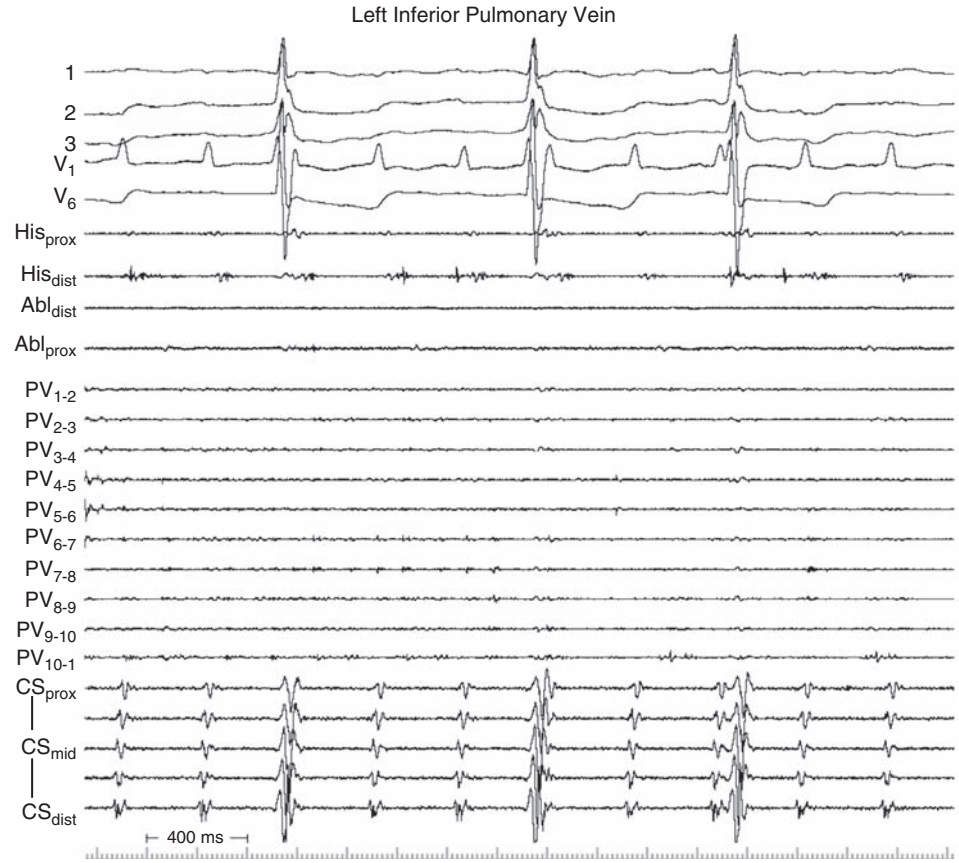

Figure 15-22

Recording from the left inferior pulmonary vein after wide area catheter ablation (Fig. 15-22) reveals no potentials whatsoever.

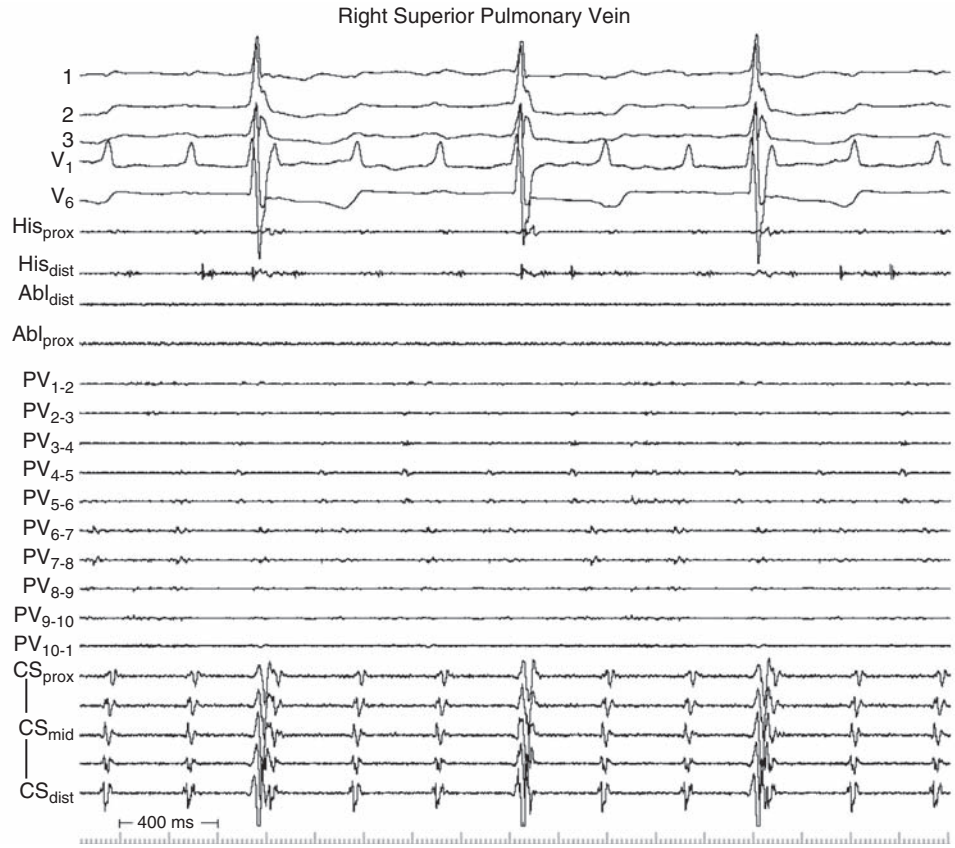

Figure 15-23

Similarly, as shown in Fig. 15-23, the right superior pulmonary vein showed no potentials, having been permanently isolated at the time of the prior procedure.

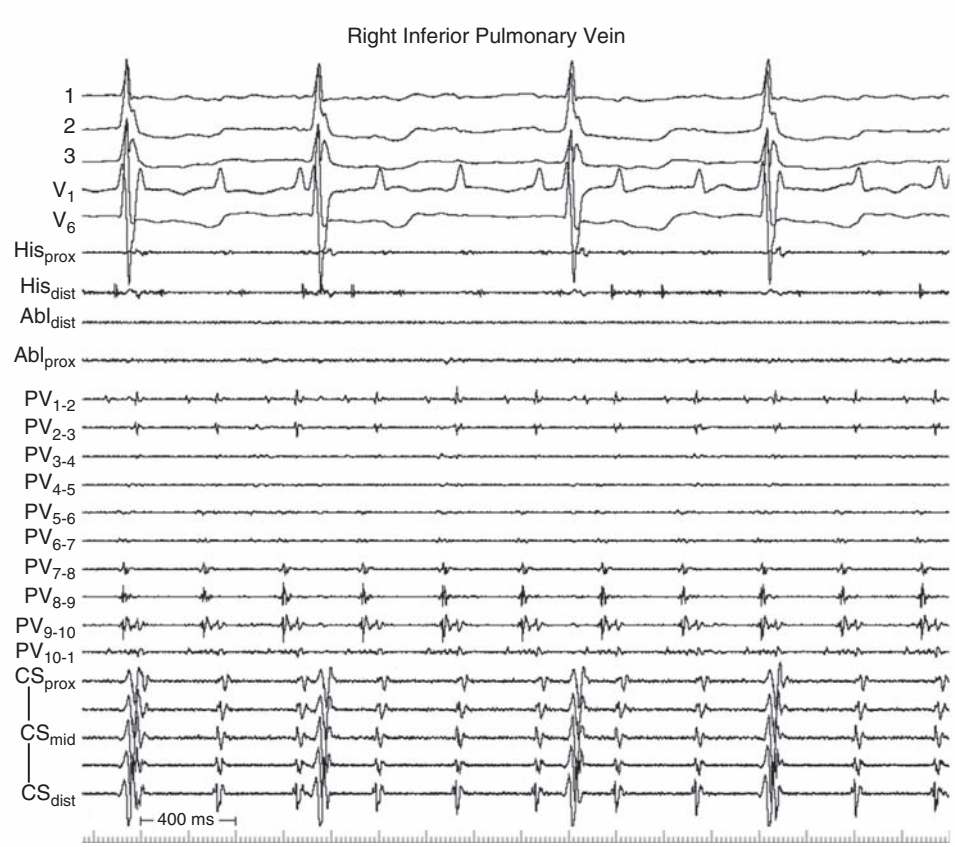

Figure 15-24

The right inferior pulmonary vein showed residual potentials of some interest (Fig. 15-24), because they were quite prolonged.

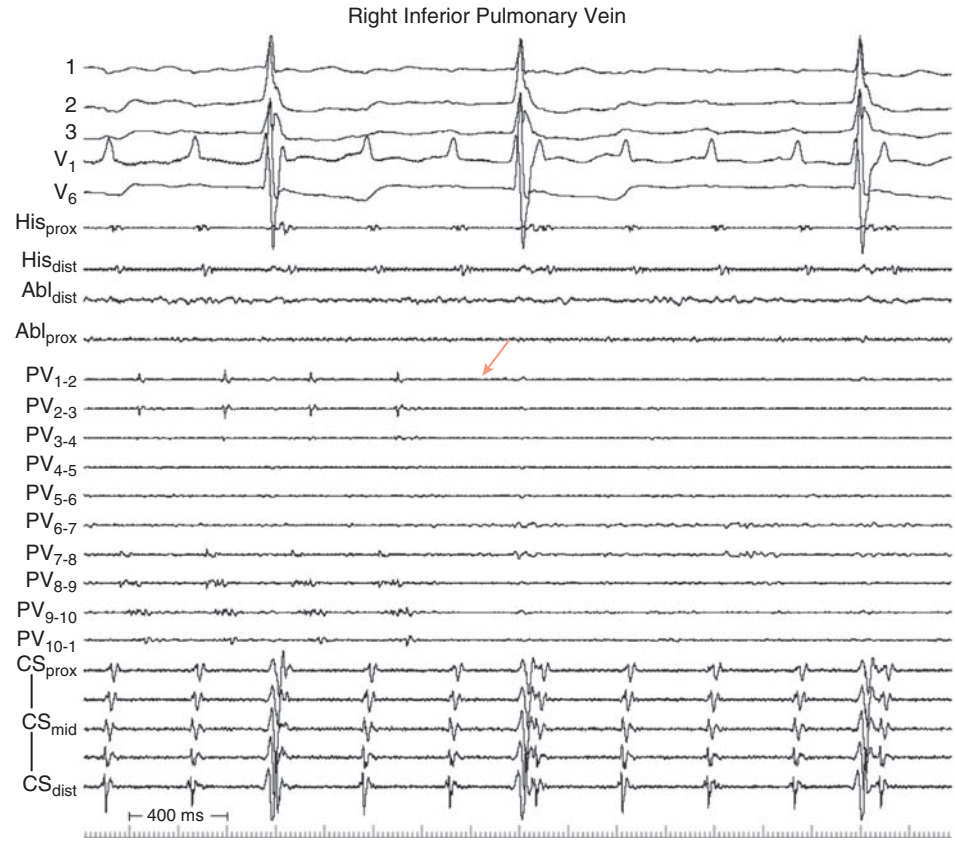

Figure 15-25

Isolation of this pulmonary vein occurs midway through the recordings in Fig. 15-25 *(orange arrow)*, again indicating that it is not responsible for the ongoing arrhythmia.

Electroanatomic Mapping Before and After PV Isolation

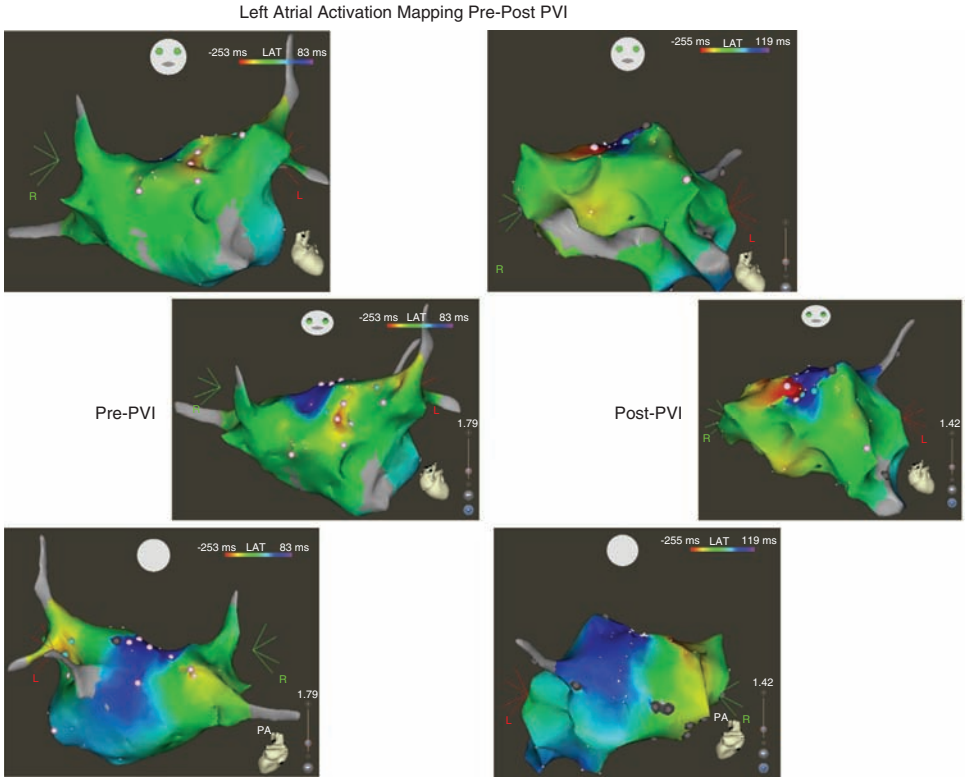

Figure 15-26

The prior electroanatomic map is shown on the left in Fig. 15-26, and on the right when repeated after PV isolation. Now that confusing pulmonary vein potentials have been removed from the activation map, a large reentrant circuit is more readily evident, involving the left atrial roof.

Mapping and Pacing at Left Atrial Roof

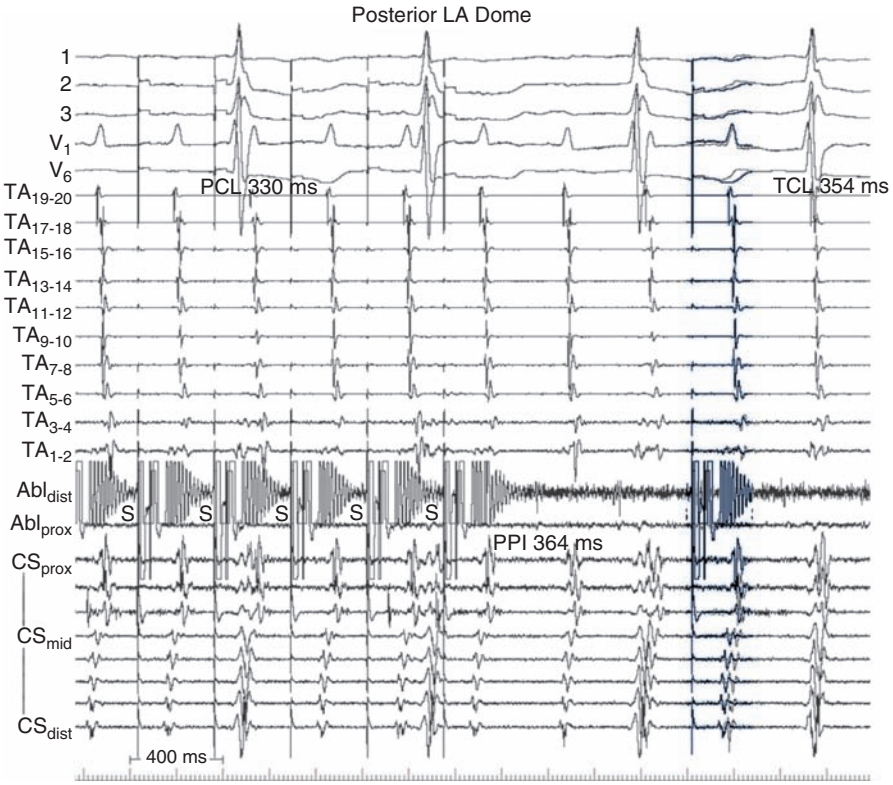

Figure 15-27

Candidate sites for ablation can be tested by overdrive pacing, to ascertain whether they are actually good target sites or not. In Fig. 15-27, pacing from a site on the roof of the left atrium (showing a middiastolic recording during tachycardia, not readily evident here because of distortion after pacing) yields a postpacing interval (PPI) slightly longer than tachycardia cycle length (TCL); a single complex of pacing on the left side has been superimposed on a single beat of tachycardia on the right side, showing strong similarity (though not an exact match). This could be a reasonable site for ablation.

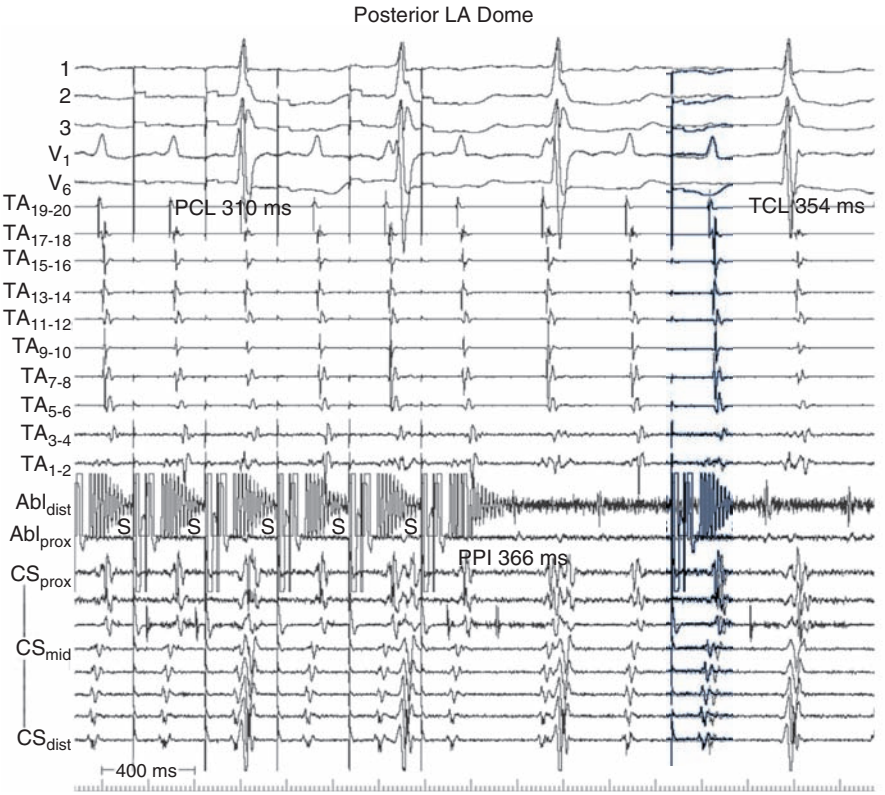

Figure 15-28

Earlier in the procedure, pacing at progressively rapid cycle lengths showed progressive lengthening in the return cycle, leading to suspicion of suppression of an automatic focus. Those data are still valid, and must be explained. In Fig. 15-28, pacing from the same site at a more rapid cycle length yields a similar return cycle to that of the previous figure. This amount of similarity was also seen at relatively slow pacing rates earlier in the procedure.

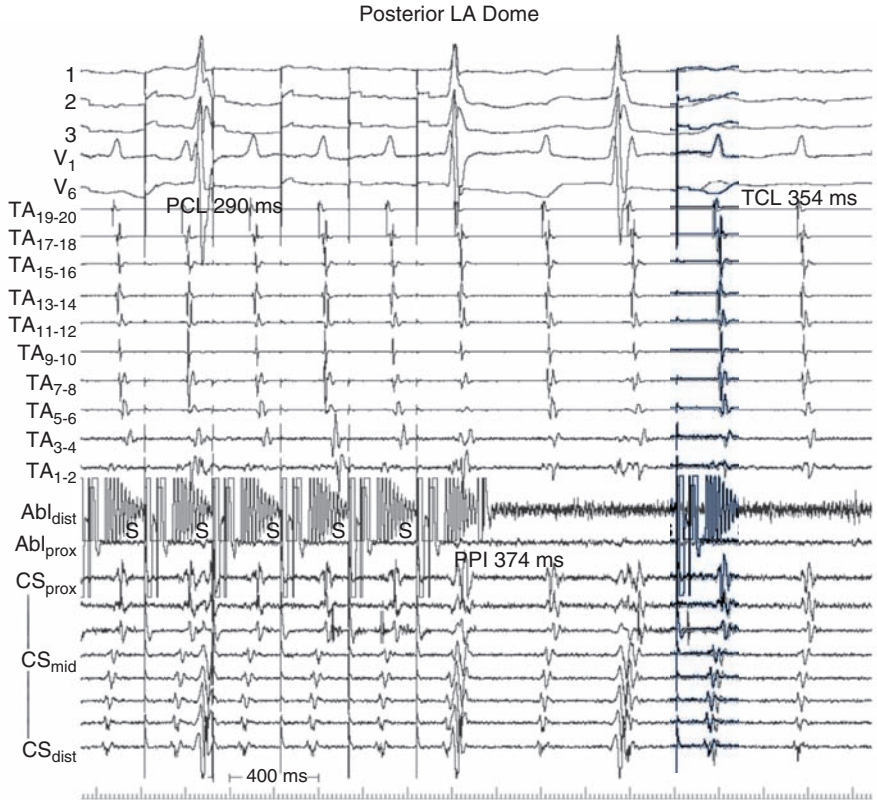

Figure 15-29

Pacing more rapidly from the same site in the left atrium now yields a longer postpacing interval (Fig. 15-29).

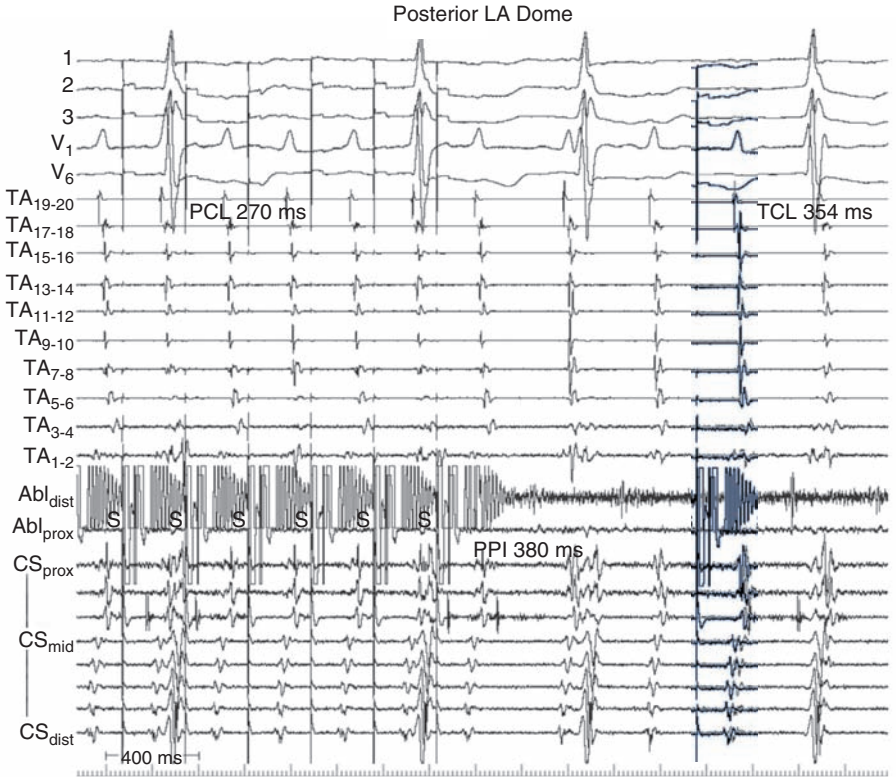

Figure 15-30

Pacing more rapidly still again yields a longer postpacing interval, as shown in Fig. 15-30. This is more than likely because of cycle length–dependent slowing of conduction

("decremental conduction"), not commonly observed in macroreentrant circuits because of their fixed length and conduction properties. However, in the presence of extensive scar, or medications that exhibit use dependence (sodium channel blockers), this phenomenon may be observed. The main significance is that one may never achieve a good "match" between postpacing interval and tachycardia cycle length (the desired result when pacing from the ideal ablation target site), because cycle length–dependent slowing of conduction will always artificially lengthen the postpacing interval.

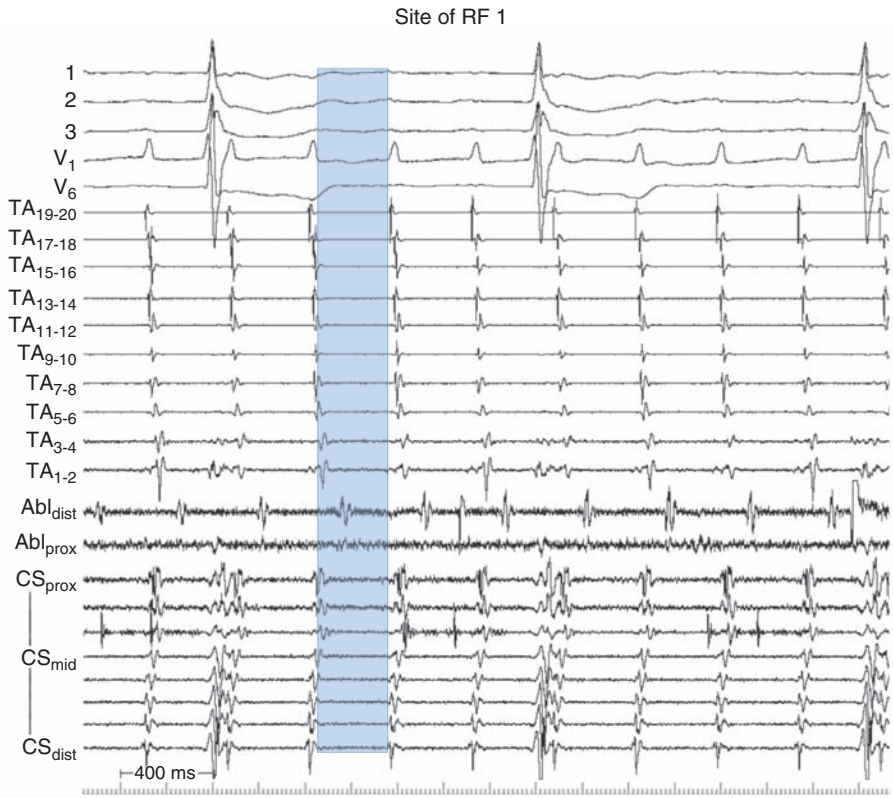

Figure 15-31

A site on the left atrial roof with an early-to-middiastolic recording (Fig. 15-31, diastole shown in *blue shading*) that had good responses to overdrive pacing (PPI similar to TCL, near-perfect pace match with tachycardia activation sequence) was chosen for ablation.

Ablation at Left Atrial Roof

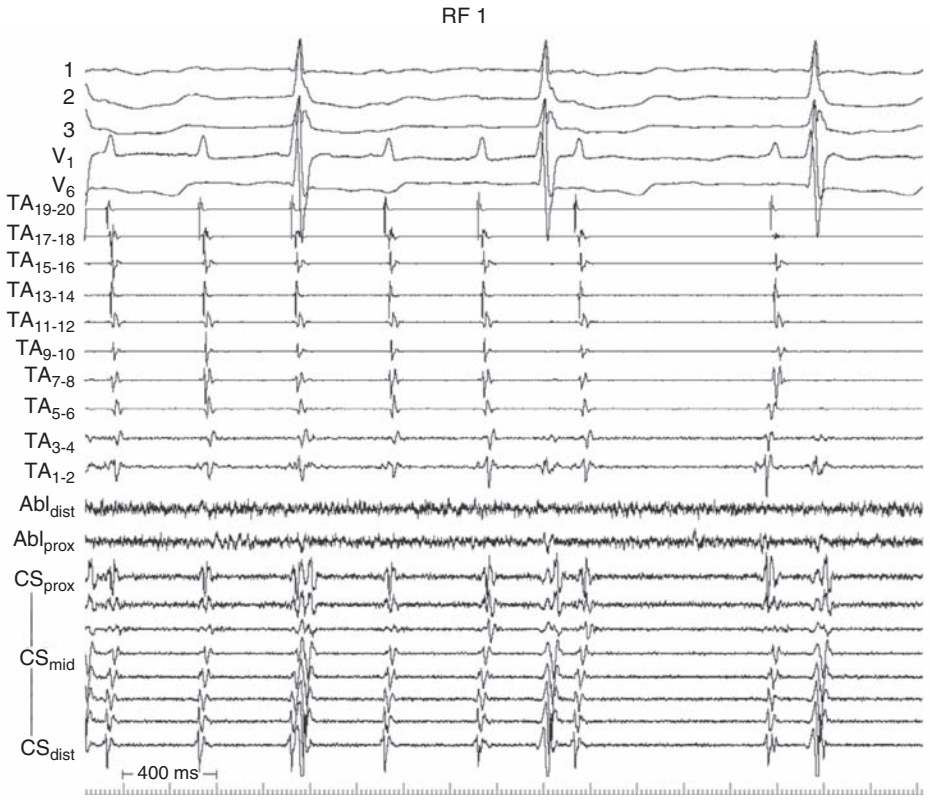

Figure 15-32

After several seconds of the first energy application, tachycardia slows and terminates to sinus rhythm (Fig. 15-32). A line of RF applications on the left atrial roof connecting the two lines encircling the pulmonary veins was made to complete the lesion set. Tachycardia was not inducible thereafter.

Right Atrial Cavotricuspid Isthmus Ablation and Assessment

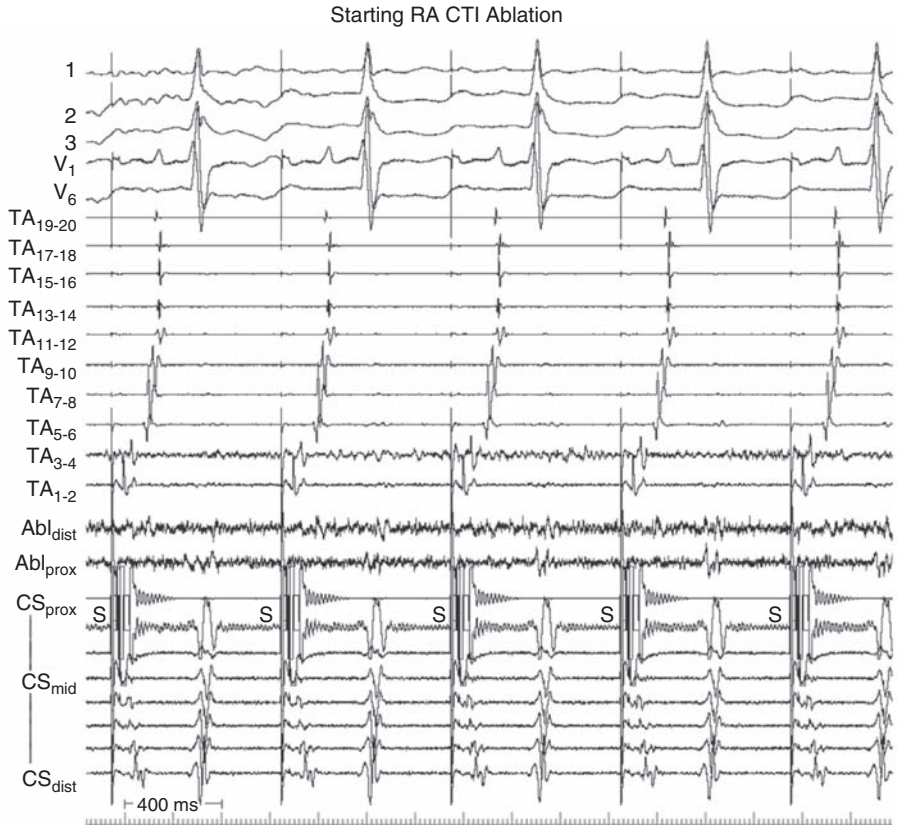

Figure 15-33

Because the patient had some ECGs from 2 yr previously that were compatible with right atrial cavotricuspid isthmus-dependent reentry, this area was also targeted for ablation. In Fig. 15-33, at the beginning of isthmus ablation, pacing from the proximal coronary sinus shows a uniform activation wavefront along the tricuspid annulus (TA).

Figure 15-34

After just one and a half minutes of ablation, electrograms in the cavotricuspid isthmus have already shown substantial delay (Fig. 15-34, *blue arrow*).

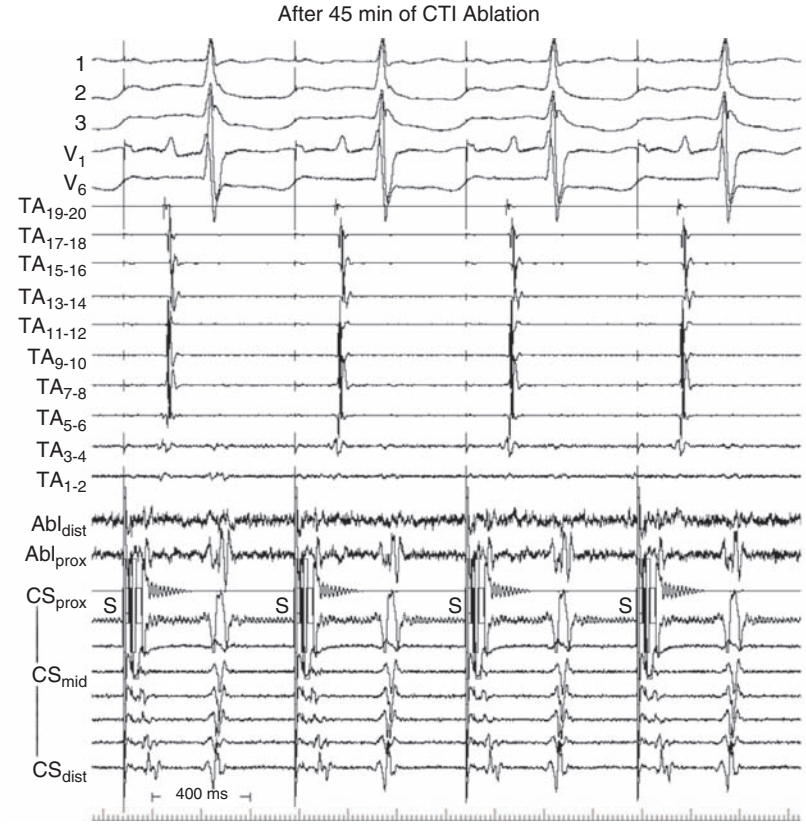

Figure 15-35

Although Fig. 15-35 is actually exactly the same figure as shown previously (Fig. 15-34), it serves to illustrate that after 45 minutes of further ablation in the cavotricuspid isthmus, there has been no substantial change beyond what was seen very early during ablation. This can be because of difficult anatomy ("pouch"), very large bundles of muscle that are difficult to ablate, or incorrect positioning of the tricuspid annulus catheter. Note the absence of any ventricular electrograms on any recording from this catheter, suggesting that it may be too posterior.

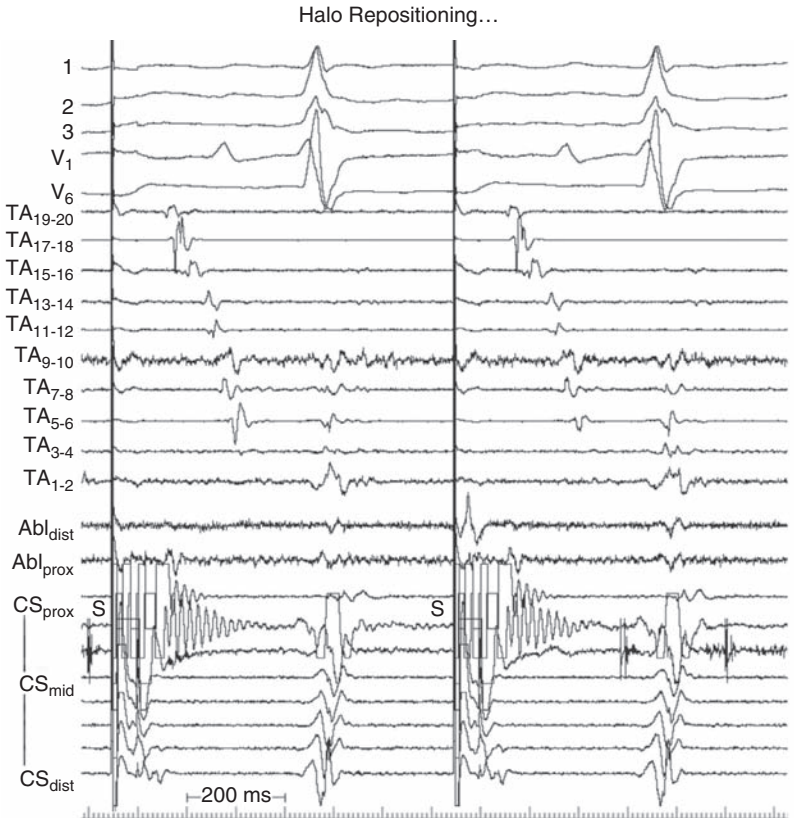

Figure 15-36

After repositioning the tricuspid annulus/"halo" catheter (note at least far-field ventricular signals on electrodes 1 to 10), the paced activation sequence seen in Fig. 15-36 is concordant with what would be expected when block is present in the cavotricuspid isthmus.

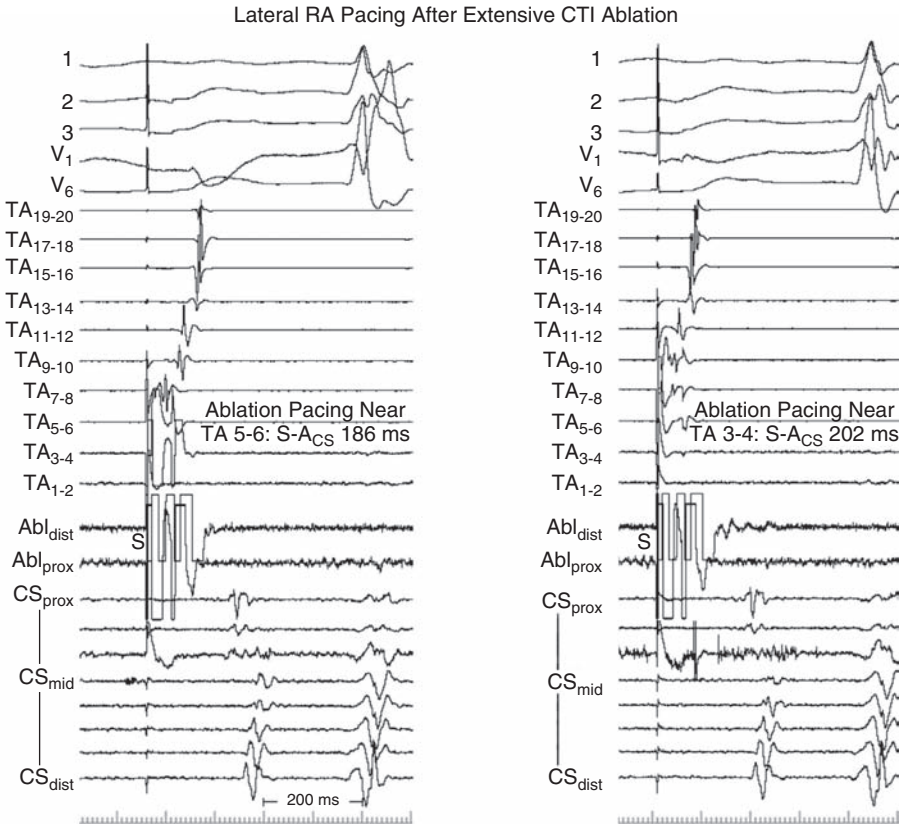

Figure 15-37

Pacing from the tricuspid annulus close to the ablation line (Fig. 15-37) demonstrates block in the lateral-medial direction, because electrodes that are anatomically closer to the ablation line (at right) are electrically further from the opposite side of the ablation line (CS recordings), and sites that are anatomically further away (at left) are electrically closer.

Final ECG

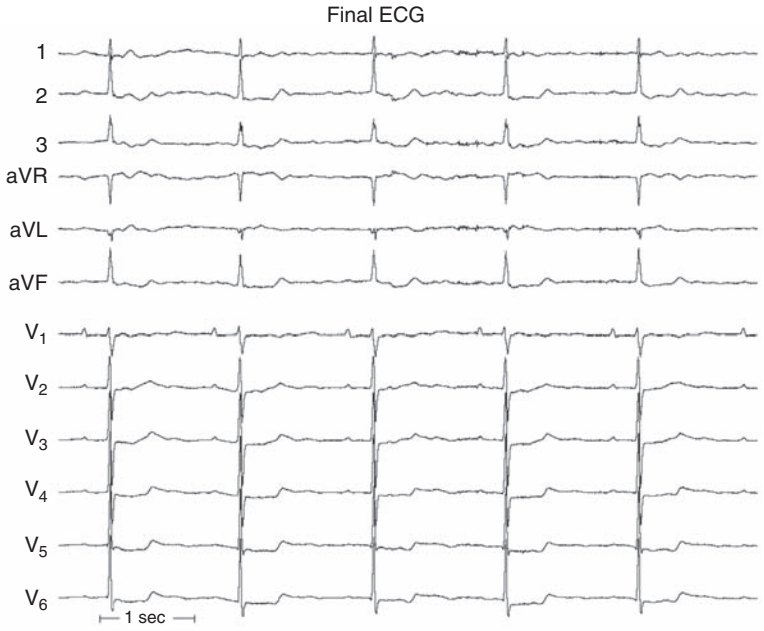

Figure 15-38

At the end of the procedure, sinus rhythm prevailed as shown in Fig. 15-38.

Summary

- Atrial tachycardias in the setting of extensive atrial disease (postsurgical, postablation, postirradiation, etc.) can be focal or reentrant (micro or macro)
- P-wave duration, P-wave duration relative to TCL, and intracardiac activation "envelope" relative to TCL can suggest focality versus macroreentry
- Overdrive pacing techniques are invaluable in diagnosis, revealing:
  - Whether the pattern is focal or macroreentry (and thus the ablation site characteristics)
  - Whether "decremental conduction" is present
- Maintaining correct catheter position (halo) may be critical
- PV potentials can cause confusion during activation mapping

16 Pulmonary Vein Isolation for Atrial Fibrillation

Case Presentation

The patient was a 57-year-old man with paroxysmal atrial fibrillation (AF) present for 3 years. Symptoms were palpitations, lightheadedness, and marked exertional fatigue during episodes 1 to 2 times weekly. His AF was refractory to antiarrhythmic drugs (sotalol, dronedarone), and atrial flutter was observed on some ECGs. Noninvasive evaluation findings were left atrial size 4.1 cm; normal left ventricular systolic function; and no valvular disease. He was referred for electrophysiology (EP) study and possible ablation because of drug-refractory symptomatic AF.

Baseline ECG

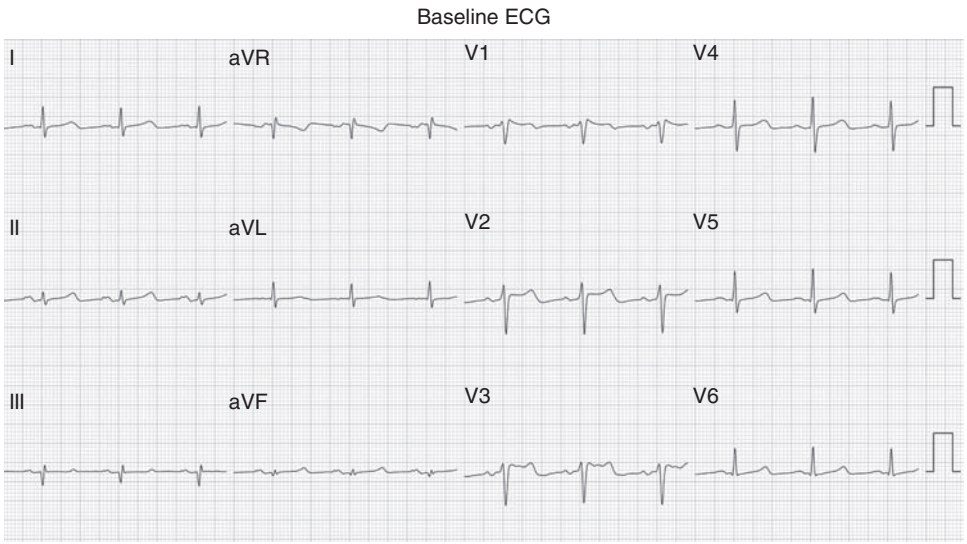

Figure 16-1

Baseline ECG (Fig. 16-1) is pretty normal; the P wave is slightly broad in lead 2.

Recordings from Right Inferior Pulmonary Vein

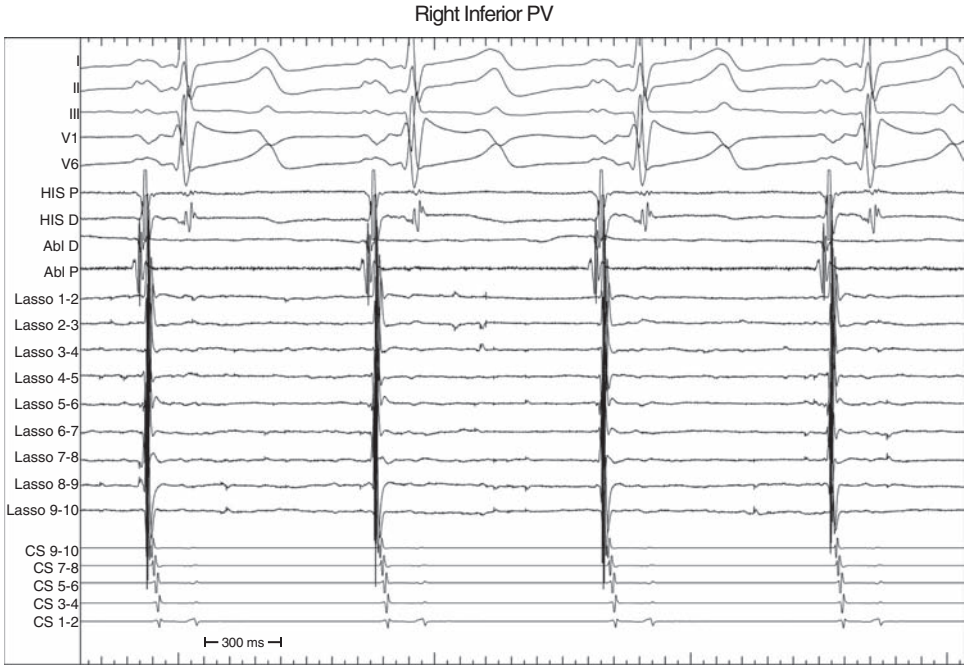

Figure 16-2

After obtaining left atrial access with transseptal catheterization, the left atrial anatomy is delineated by moving a catheter around the chamber. In addition, pulmonary veins (PVs) are interrogated using a ring catheter ("Lasso"). In Fig. 16-2, the catheter is in the right inferior PV and shows very large-amplitude PV recordings. They appear to be atrial recordings, and only by knowing where the catheter was when the recordings were made can we know their nature.

Recording and Pacing from Left Superior PV

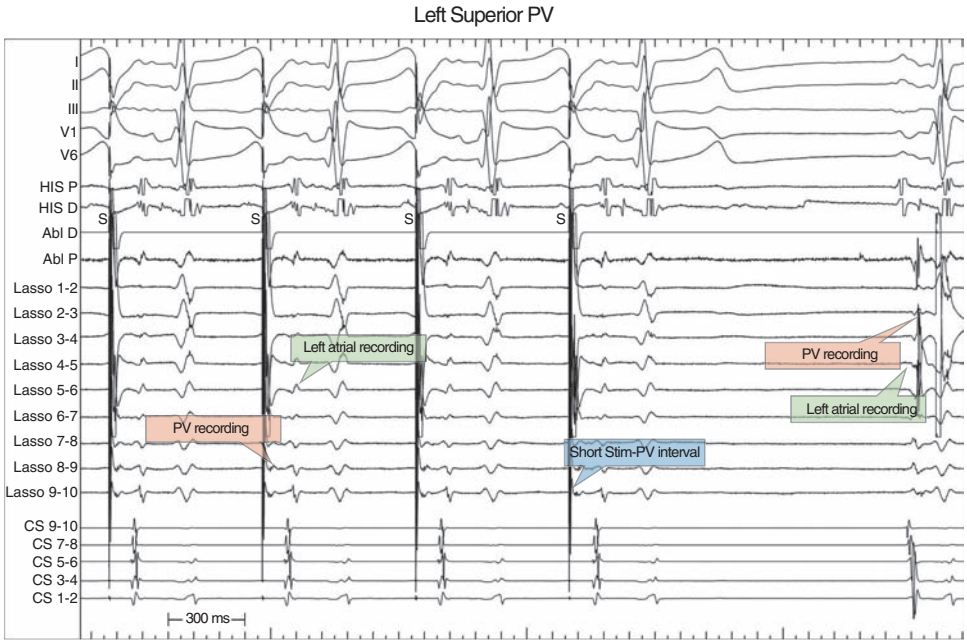

Figure 16-3

With the ring catheter in the left superior PV, pacing from a site more distally in the vein is performed (Fig. 16-3); this location is "tagged" on the electroanatomic mapping system. This will provide a means for checking exit block from the vein after isolation: if pacing from this site captured the PV reliably before isolation, and pacing from the same site does not conduct to the atrium after attempted isolation, one can be assured that exit block is present (even if the ring catheter is no longer recording in the vein). There is a very short interval from stimulus to captured PV potentials, after which conduction to the left atrium occurs (as indicated by *blue arrow*).

Recording from Left Superior PV, Pacing from Left Inferior PV

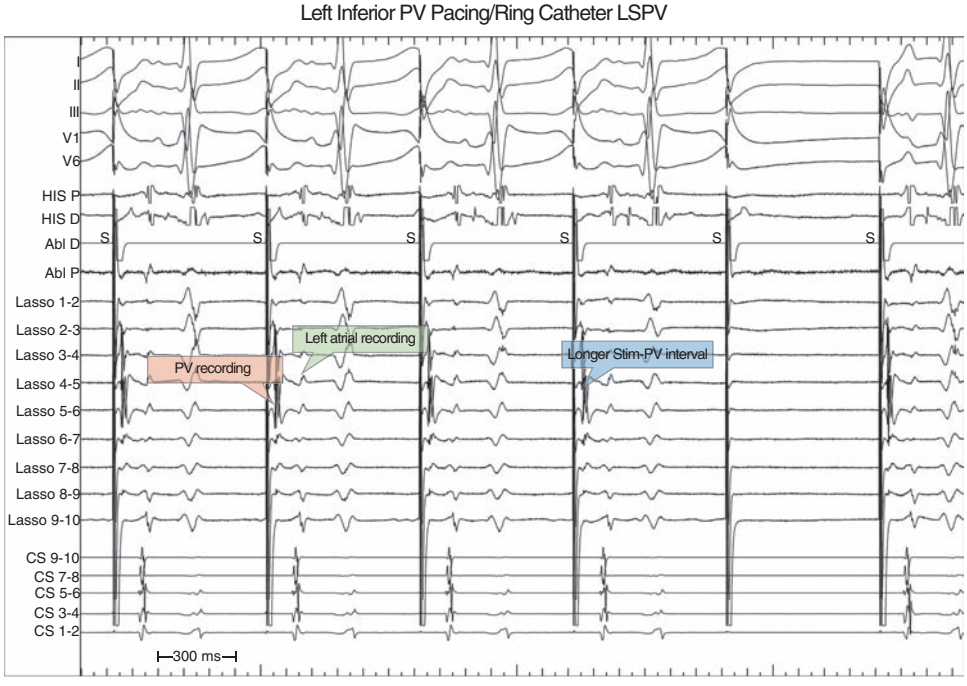

Figure 16-4

In Fig. 16-4, the ring catheter remains in the left superior PV but the ablation catheter has been moved to the inferior vein. Note the slight increase in stimulus-PV potential interval because the impulse must travel from inferior to superior vein before activating these cells.

Recording and Pacing from Right Superior PV

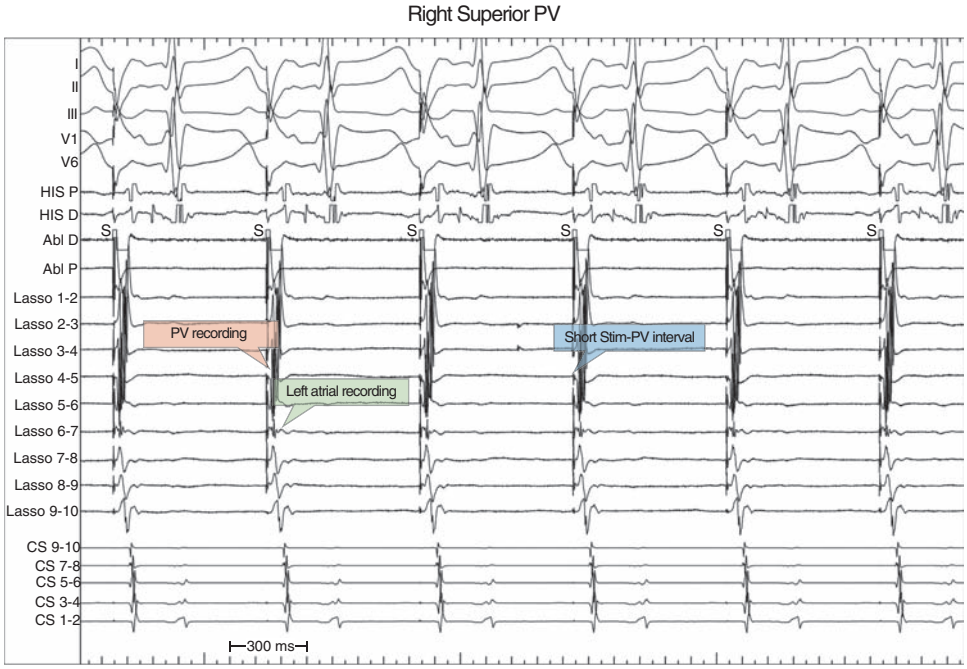

Figure 16-5

Similarly, with the ring catheter in the right superior PV, pacing from a site more distally in the vein is performed (Fig. 16-5); this location is "tagged" on the electroanatomic mapping system. This will provide a means for checking exit block from the vein after isolation.

Recording from Right Superior PV, Pacing from Right Inferior PV

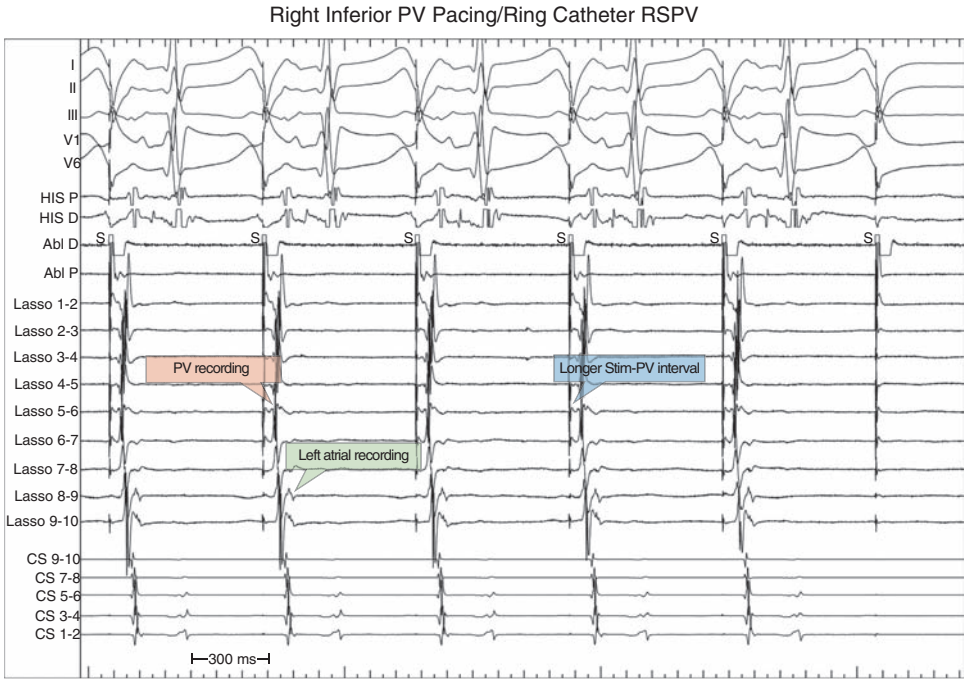

Figure 16-6

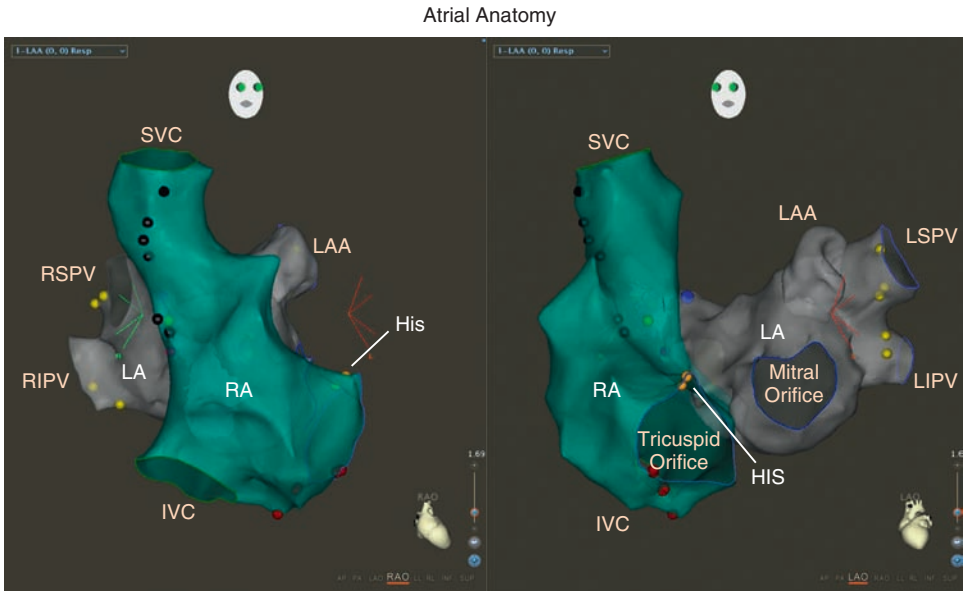
In Fig. 16-6, the ring catheter remains in the right superior PV but the ablation catheter has been moved to the inferior vein. Note the slight increase in stimulus-PV potential interval because the impulse must travel from inferior to superior vein before activating these cells.

Atrial Anatomy on Electroanatomic Maps

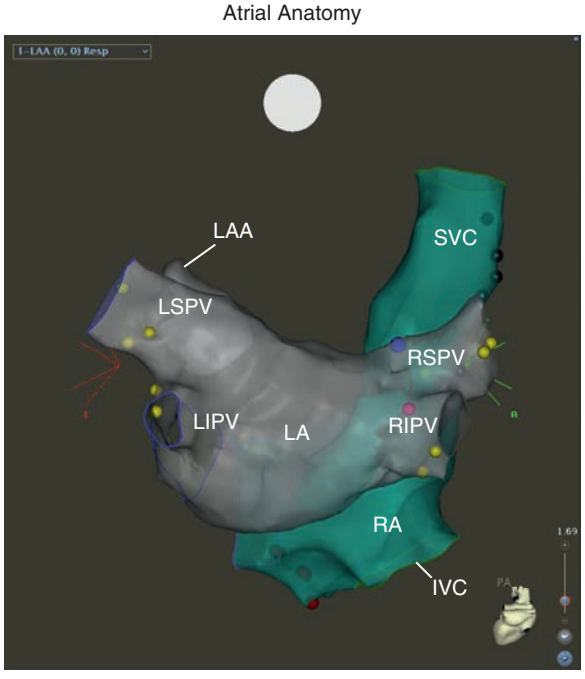
Figure 16-7



Right Anterior Oblique
Black dots: phrenic nerve capture

Left Anterior Oblique
Yellow dots: pulmonary vein capture

Figure 16-8



Figs. 16-7 and 16-8 display the posterior views of fast anatomic map (FAM) generated by manipulating catheters in the atria. *His*, His bundle location; *IVC*, inferior vena cava; *LA*, left atrium; *LAA*, left atrial appendage; *LIPV*, left inferior pulmonary vein; *LSPV*, left superior pulmonary vein; *RA*, right atrium; *RIPV*, right inferior pulmonary vein; *RSPV*, right superior pulmonary vein; *SVC*, superior vena cava. *Black dots* denote locations at which pacing resulted in phrenic nerve capture; *yellow dots* indicate sites at which pacing captured PV sleeves.

Progressive Left PV Isolation

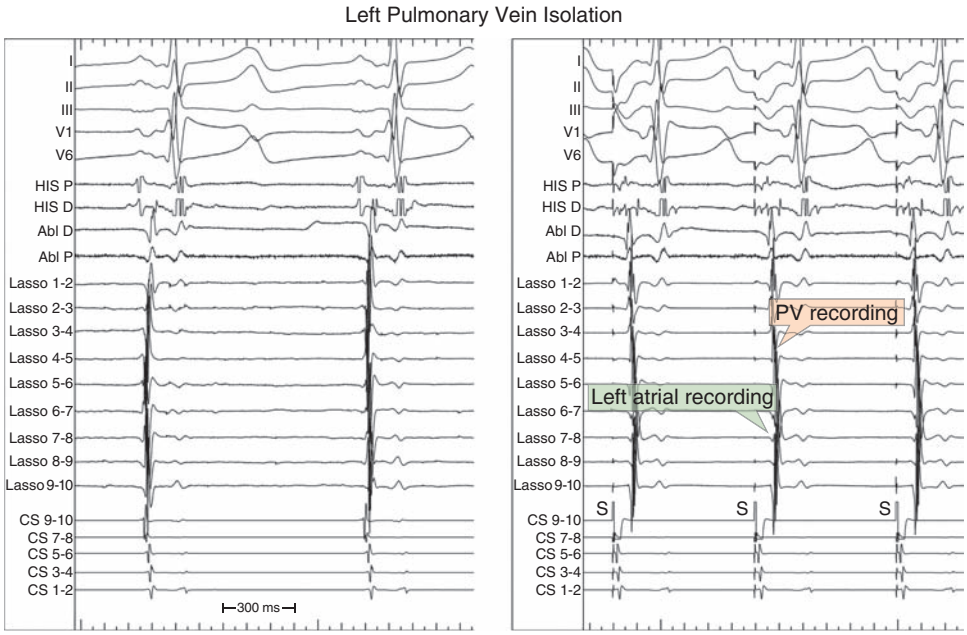


Figure 16-9

The left PVs were isolated as a unit with wide-area catheter ablation (WACA). At left of Fig. 16-9, during sinus rhythm, it is difficult to distinguish PV potentials from nearby left atrial signals; at right, during coronary sinus pacing, high-amplitude, high-frequency PV potentials are slightly more readily distinguished from lower-amplitude, lower-frequency left atrial recordings.

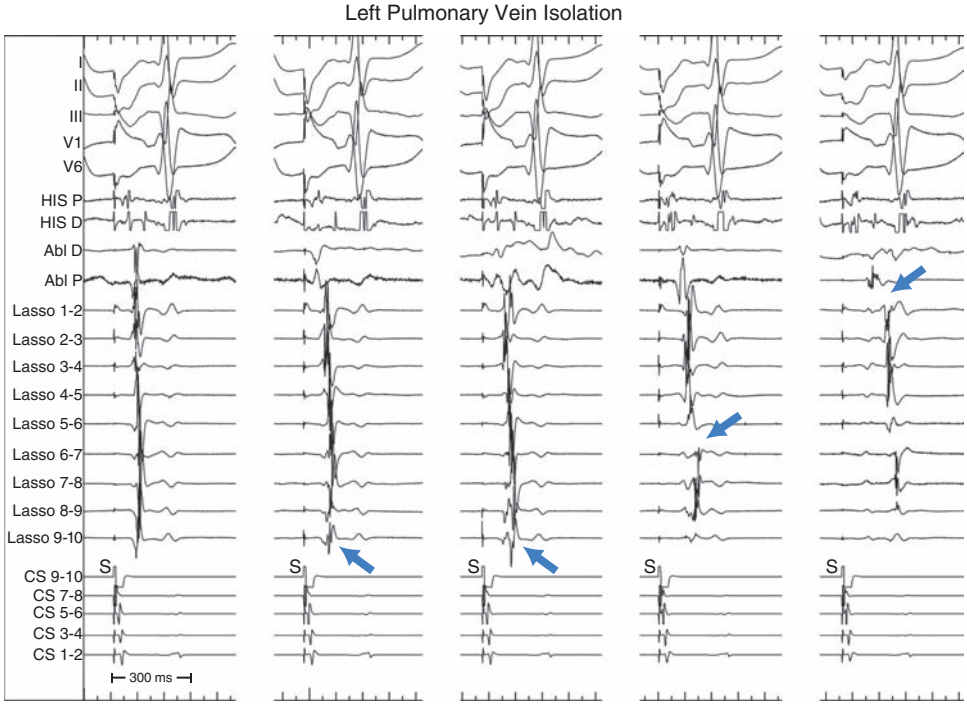

Figure 16-10

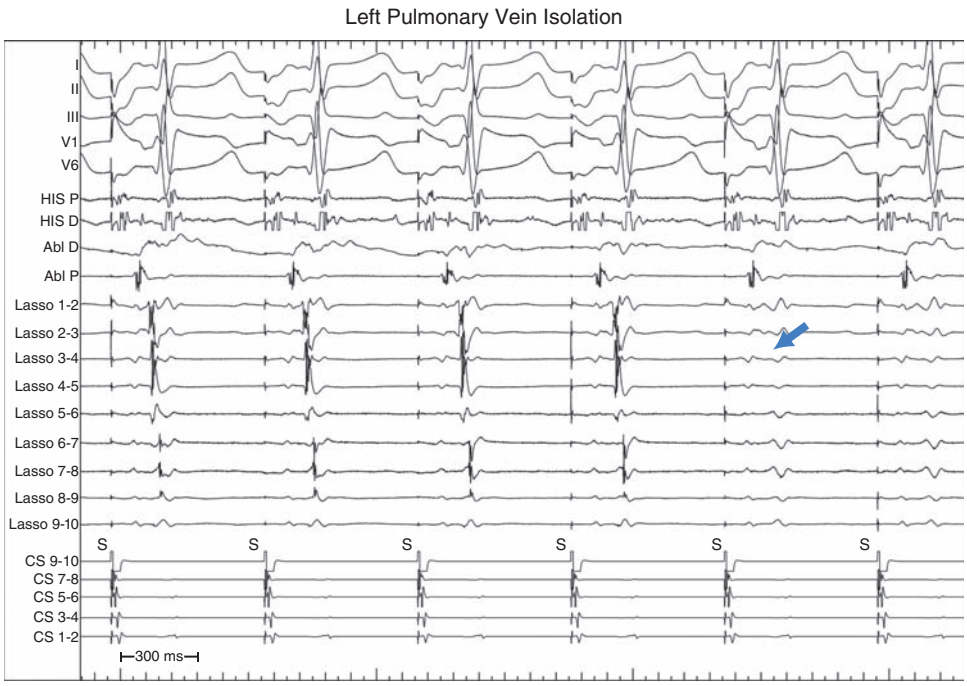
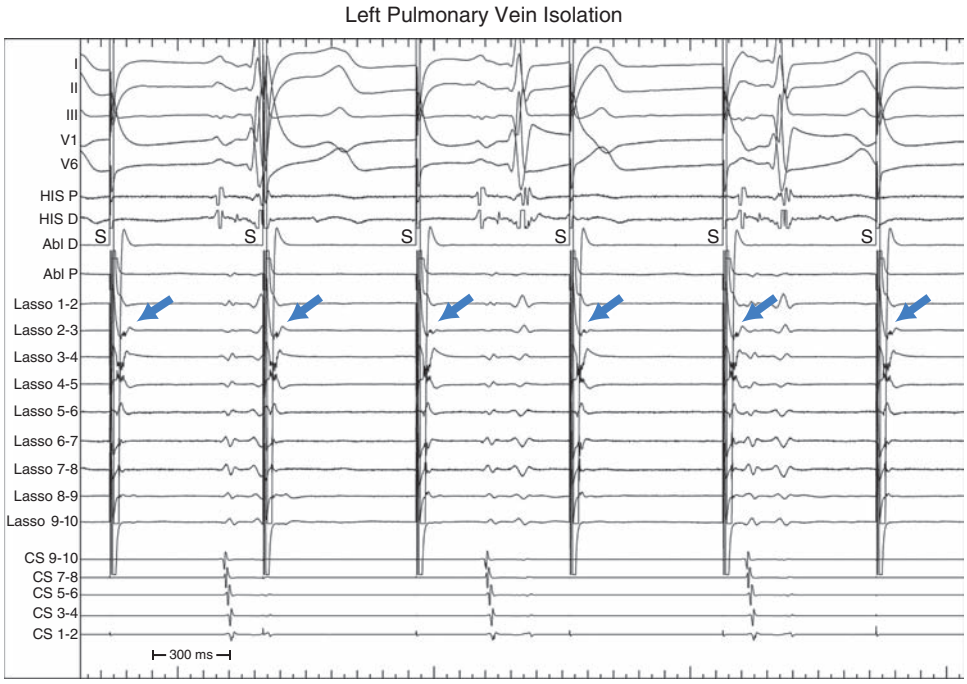
Over the span of several minutes, ablation around the left PV antrum results in progressive delay of PV potentials (Fig. 16-10, *arrows*).

Figure 16-11



Finally, after nearly completely circumscribing the left PV antrum with RF applications, progressive delay of PV potentials is followed by complete loss of PV potentials (Fig. 16-11, *arrow*). Entrance block is now present in the left superior PV.

Figure 16-12



After demonstrating entrance block in the left superior PV, the ablation catheter is moved into the PV to a location tagged before ablation as a site at which pacing captured the PV. Pacing at this site (Fig. 16-12, *arrows*) now shows capture of potentials but no conduction to the adjacent left atrium, which remains in sinus rhythm. Exit block has now been demonstrated in the left superior PV. The same maneuver was performed in the left inferior PV with the same findings.

Progressive Right PV Isolation

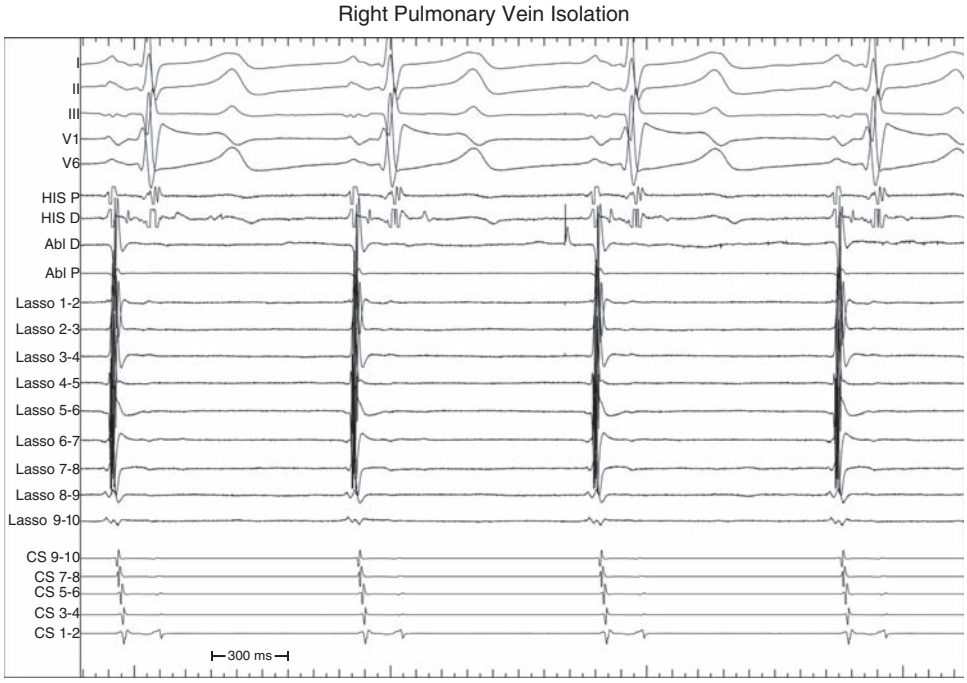


Figure 16-13

Attention is now turned to the right PVs. In Fig. 16-13, the ring catheter is in the right superior PV. Pacing rarely separates PV potentials (large, sharp signals in Lasso recordings) from nearby left atrium, so ablation is performed during sinus rhythm.

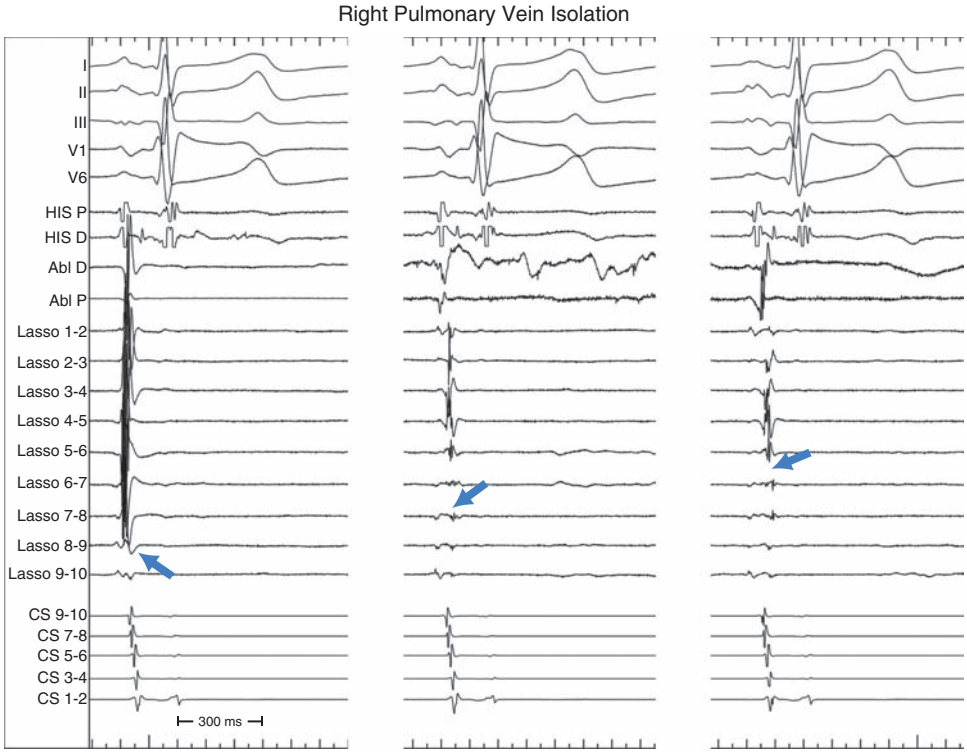

Figure 16-14

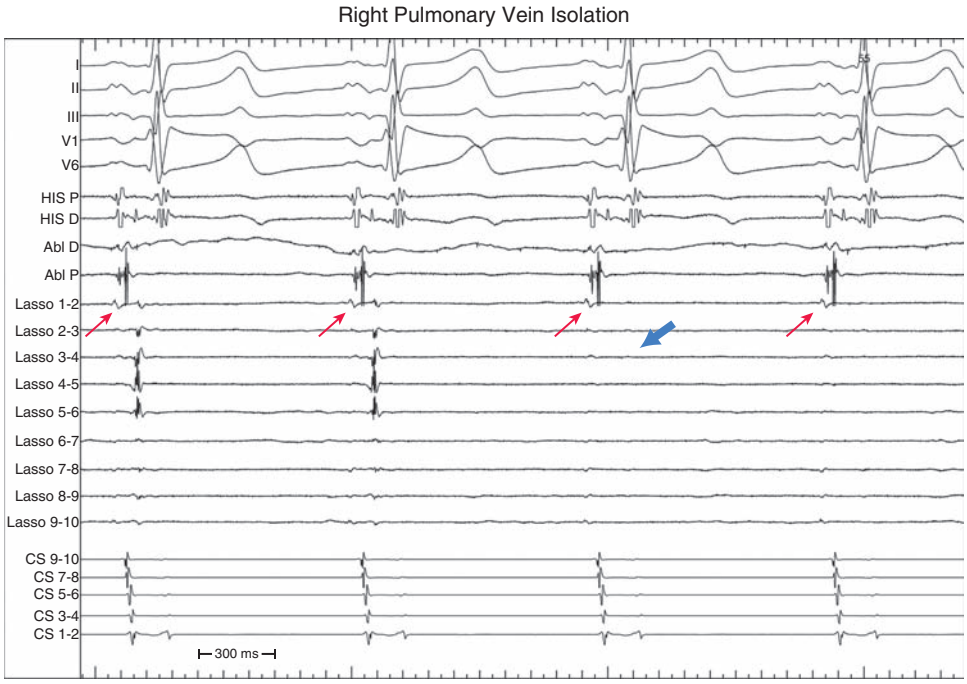
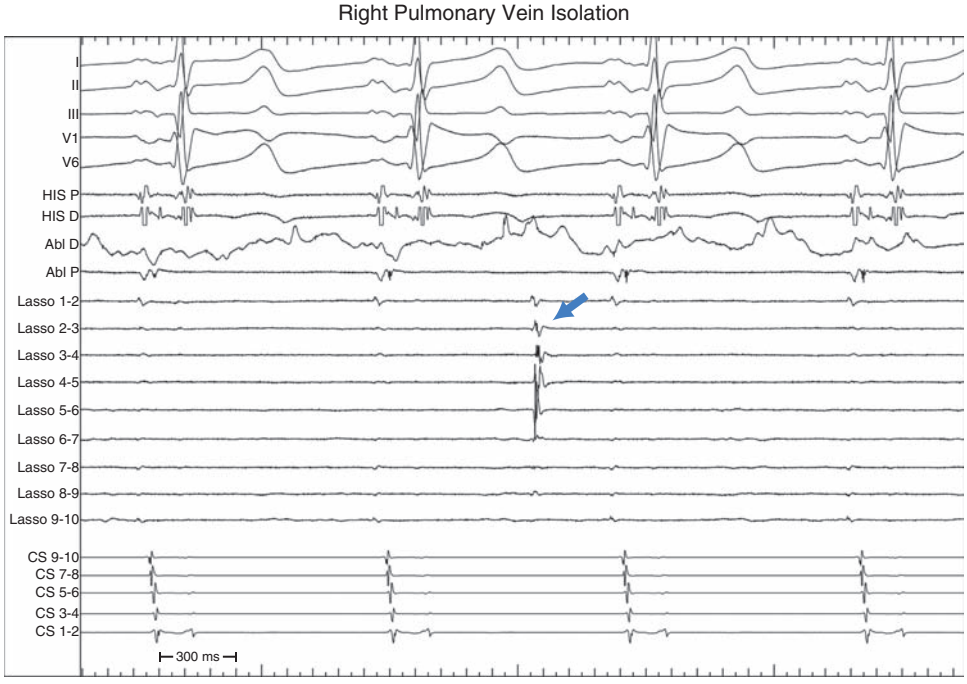
With progressive encirclement around the right PVs, PV potentials become more delayed in Fig. 16-14; the ring catheter has shifted slightly in the PV over the course of ablation, and thus the recordings are not identical in morphology.

Figure 16-15



With still further encirclement around the right PVs, PV potentials cease (Fig. 16-15, *blue arrow*); this could be because the ring catheter had suddenly become displaced deeper in the PV or into the left atrial cavity, but far-field left atrial potentials are unchanged *(red arrows)*; thus the catheter has not moved and the loss of PV potentials means that this PV has entrance block.

Figure 16-16



After encirclement and establishing entrance block into the right superior PV, a dissociated potential is observed in Fig. 16-16 (unaffected by the prevailing atrial rhythm, nor affecting the atrial rhythm).

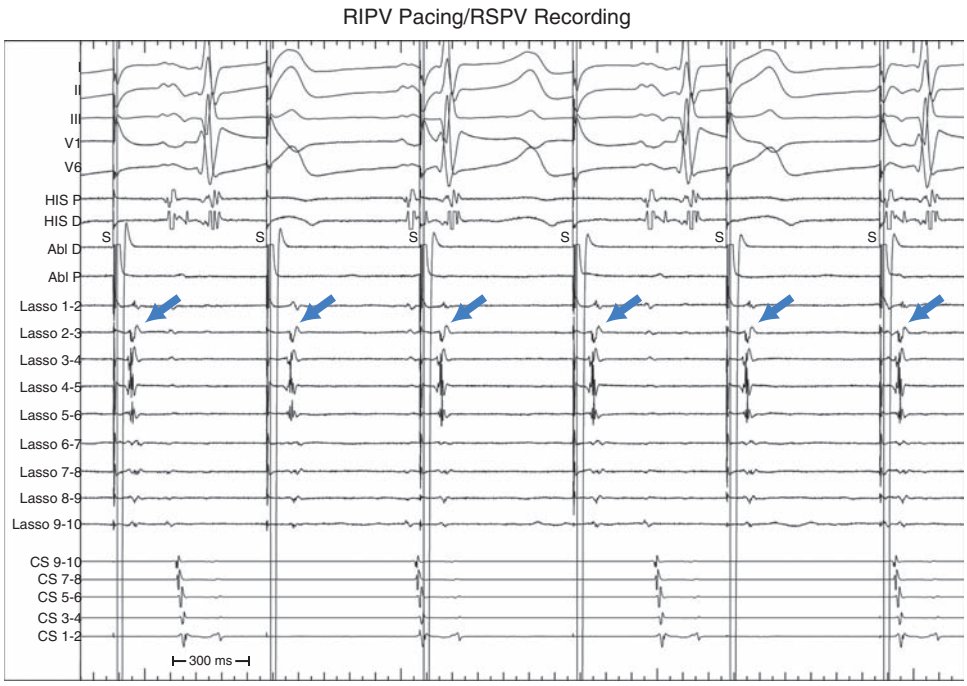


Figure 16-17

Pacing is performed in the right inferior PV with the ring catheter in the right superior PV; this shows PV potentials after each stimulus artifact without conduction to the atrium (Fig. 16-17). Capture of the right inferior PV is inferred, because it conducts to the right superior PV. This shows exit block of *both* PVs.

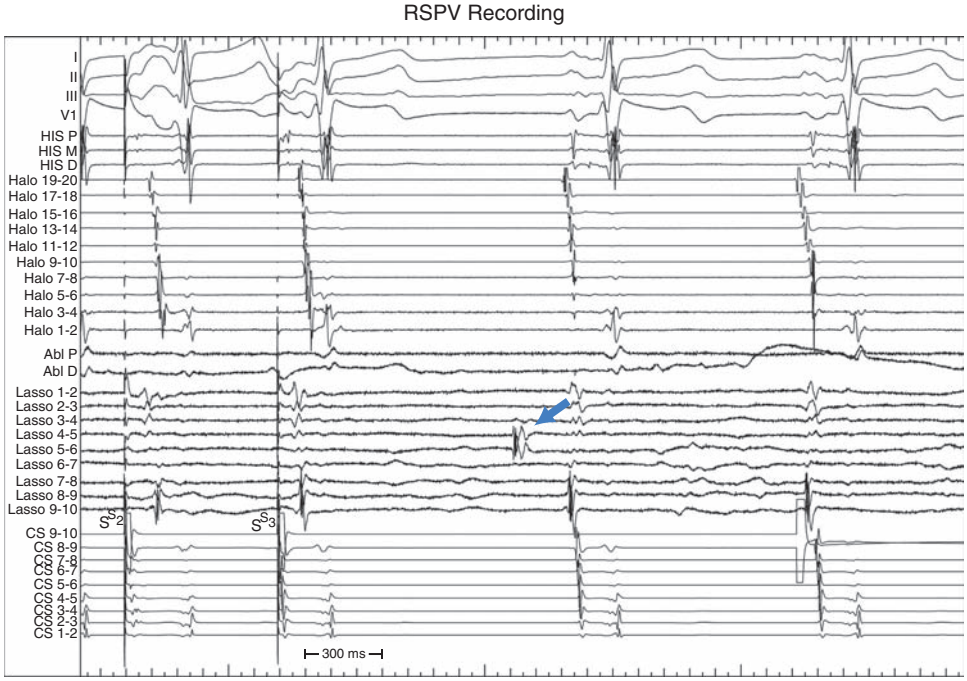

Figure 16-18

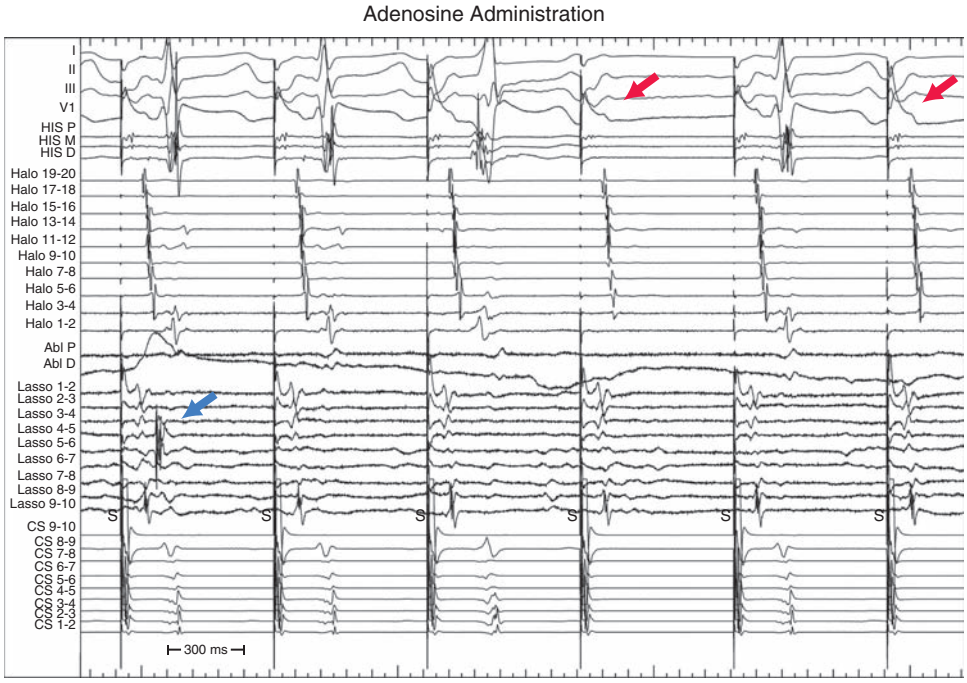
A dissociated PV potential is recorded with the ring catheter in the right superior PV (Fig. 16-18, *arrow*). A "halo" catheter has been placed around the tricuspid annulus in preparation for flutter ablation (because of his history of this arrhythmia). Cavotricuspid isthmus ablation was performed resulting in bidirectional conduction block (not shown).

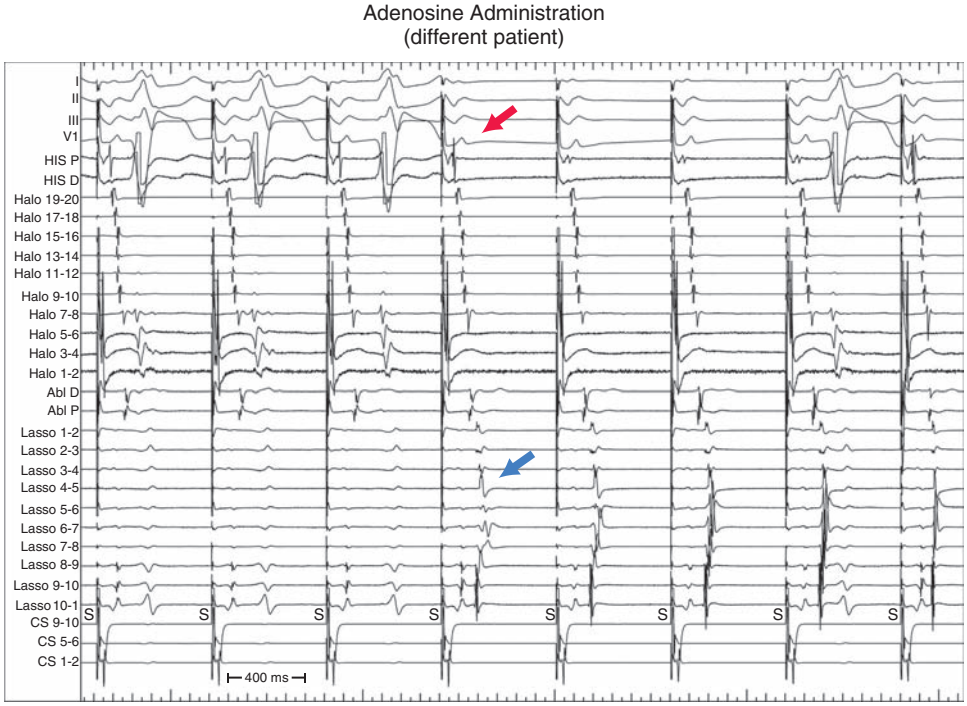
Adenosine Administration

Figure 16-19



After cavotricuspid isthmus ablation, adenosine is administered (12 mg IV bolus). Its effect on the AV node is manifest by heart block (Fig. 16-19, *red arrows*) but cavotricuspid isthmus block persists as does right superior PV isolation; a dissociated PV potential is seen in the ring catheter recordings from this PV *(blue arrow)*.

Figure 16-20



Adenosine administration is a different case (12 mg IV bolus). Its effect on the AV node is again manifest by heart block (Fig. 16-20, *red arrow*), and though cavotricuspid isthmus block persists, potentials are seen again in the left superior PV *(blue arrow)*. Additional ablation around this PV eliminated this response.

Electroanatomic Maps with RF Sites

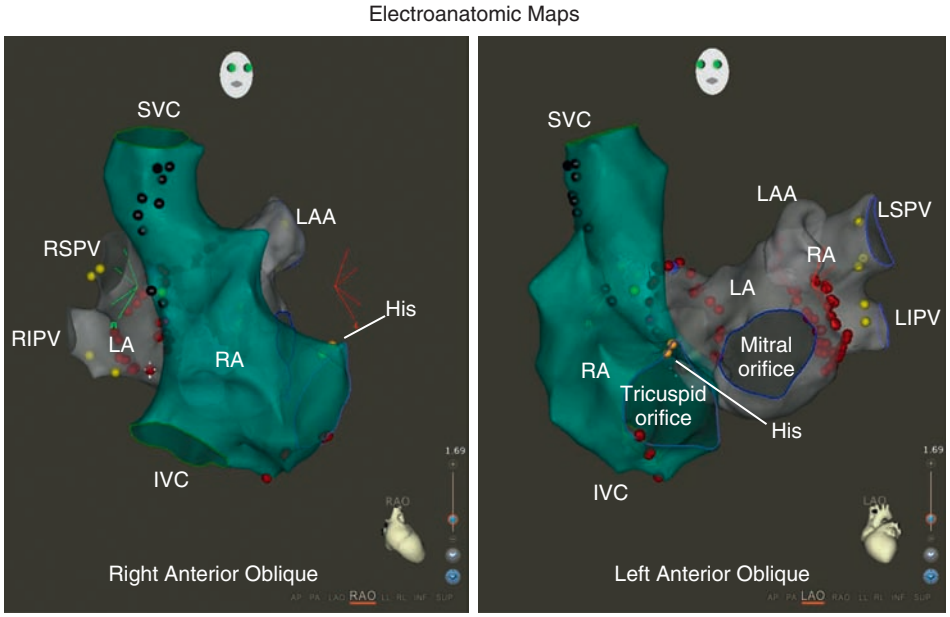


Figure 16-21

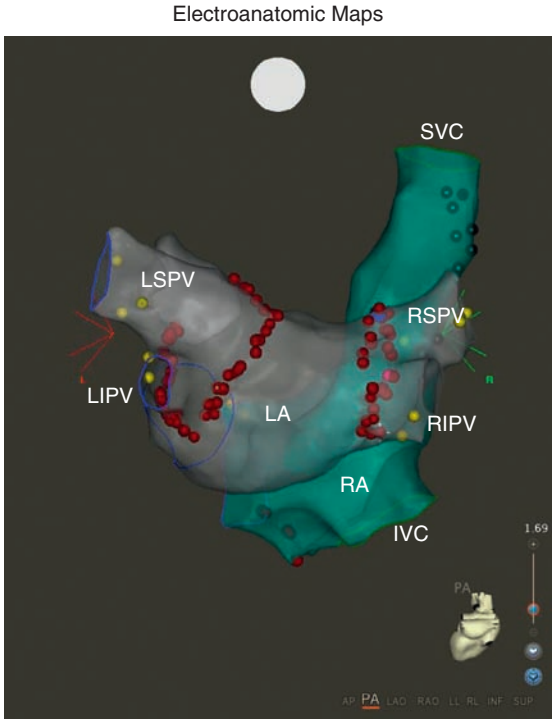

Figure 16-22

In Figs. 16-21 and 16-22, *red dots* show points at which radiofrequency energy was delivered (around PVs).

Summary

- PV isolation remains the standard for catheter-based therapy of atrial fibrillation
- Entrance and exit block should be demonstrated
- Additional means of assuring durable PV isolation may be used, including
  - Voltage mapping (not very sensitive or specific)
  - Adenosine (showing lack of resurgence of conduction)
  - Pacing along ablation line (showing inexcitability)

17 Pulmonary Vein Isolation, Rotor Mapping and Ablation, and Flutter Ablation for AF/Flutter

Case Presentation

The patient was a 67-year-old man with atrial fibrillation (AF) for the past 4 years or more; episodes were paroxysmal but arrhythmia is now persistent. His symptoms included lightheadedness, fatigue, and palpitations. Medical therapy with Metoprolol and then with diltiazem had no effect on his symptoms. Cardioversion without and with amiodarone failed to maintain sinus rhythm. He was referred for electrophysiology (EP) study and possible ablation; amiodarone was discontinued 1 month before the procedure. He was anticoagulated with dabigatran until 1 day before the procedure.

Baseline ECGs and Intracardiac Recordings

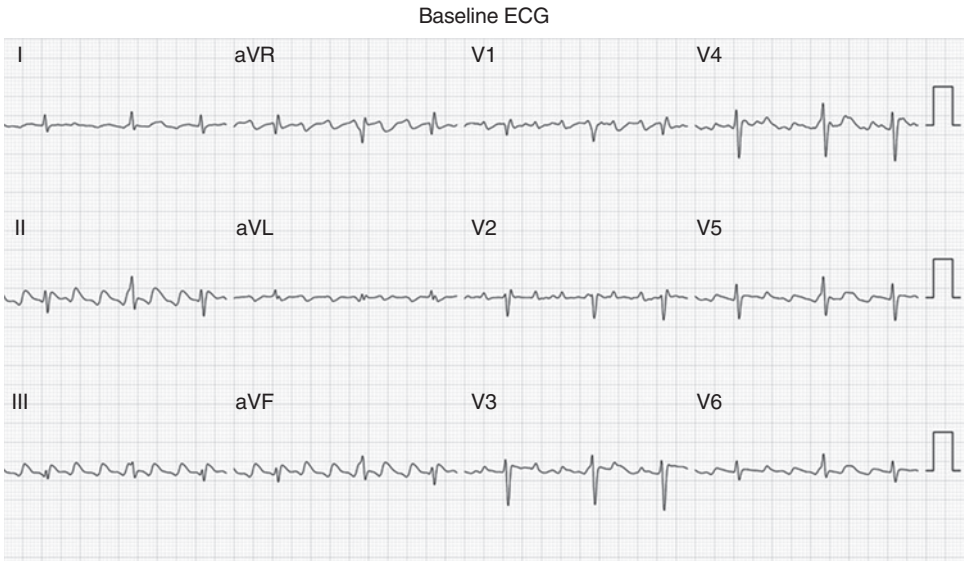

Figure 17-1

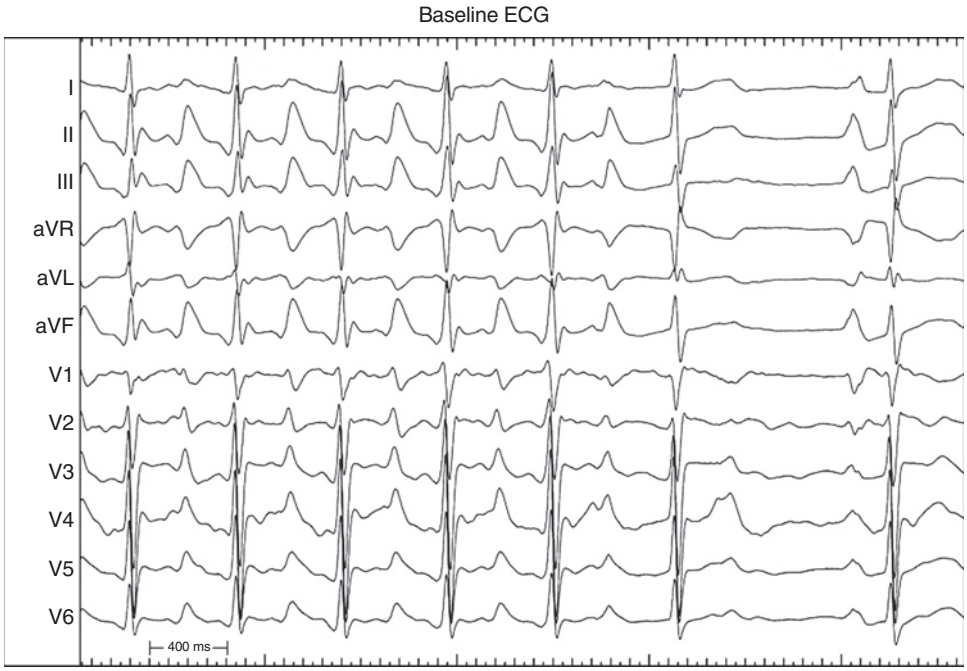
Fig. 17-1 was the baseline ECG at the start of the procedure. It is consistent with clockwise right atrial flutter, though slower than usual (300 ms atrial cycle length), and is the first recorded ECG of this arrhythmia (all others had been fibrillation). This may be an effect of residual amiodarone, or just another manifestation of his atrial arrhythmias independent of drug effect.



What Does This Mean? [Fig. 17-2]

Figure 17-2

Shortly after obtaining the baseline ECG, the presenting arrhythmia terminated spontaneously to sinus as shown in Fig. 17-2. This occurred shortly after placement of the coronary sinus catheter and did not appear to result from catheter-mediated trauma or ectopy. This would be very unusual behavior for typical right atrial flutter and is perhaps more suggestive of a focal process. In addition, the morphology of the P wave in the inferior leads is less consistent with typical right atrial flutter.

What Does This Mean? [Fig. 17-3]

Figure 17-3

Fig. 17-3 are surface ECG and intracardiac recordings from the coronary sinus (CS) catheter (the only catheter in the heart then) at the time of termination of the presenting arrhythmia. It is clear that there was no catheter-induced ectopy or cycle length change before termination. It also appears that the CS catheter electrodes are activated before the apparent onset of the surface P wave *(dashed line)*, as well as in a proximal-distal direction.

Figure 17-4

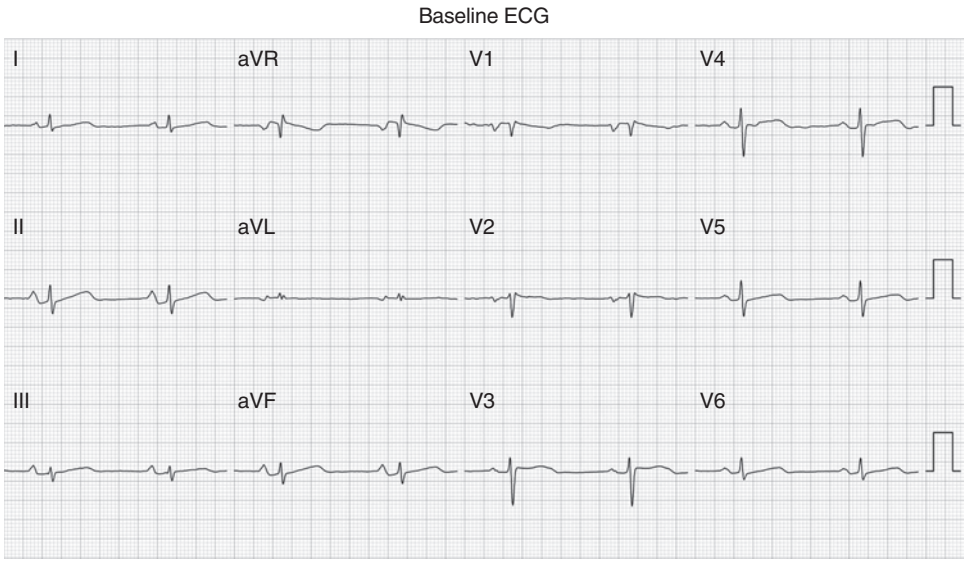


Fig. 17-4 shows sinus rhythm immediately after termination of the presenting arrhythmia. Terminal negativity of the P wave in V1 is consistent with left atrial hypertrophy but there are no other abnormalities.

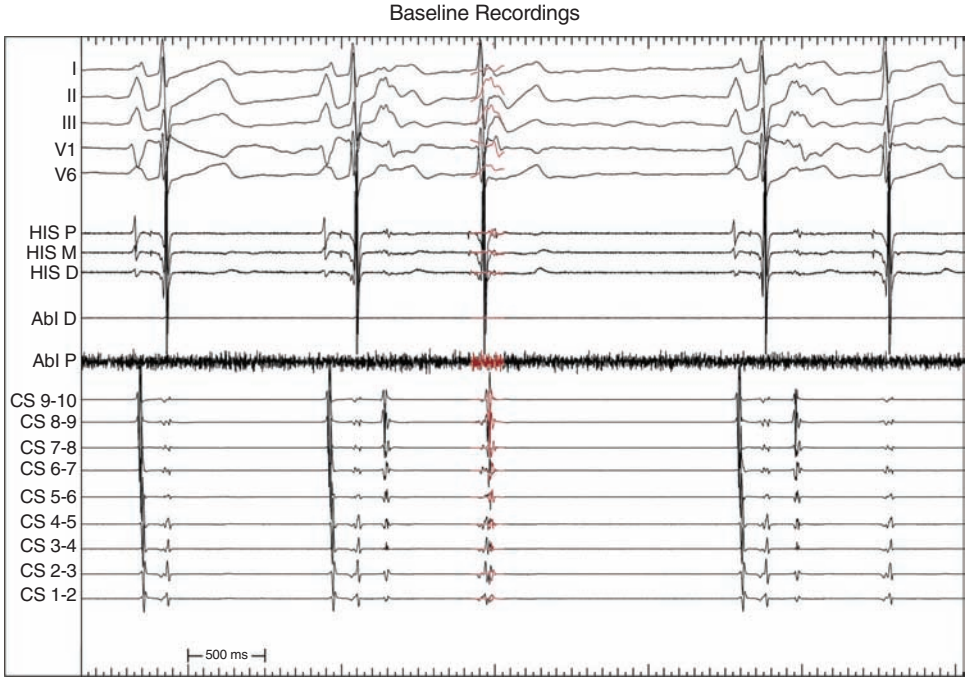
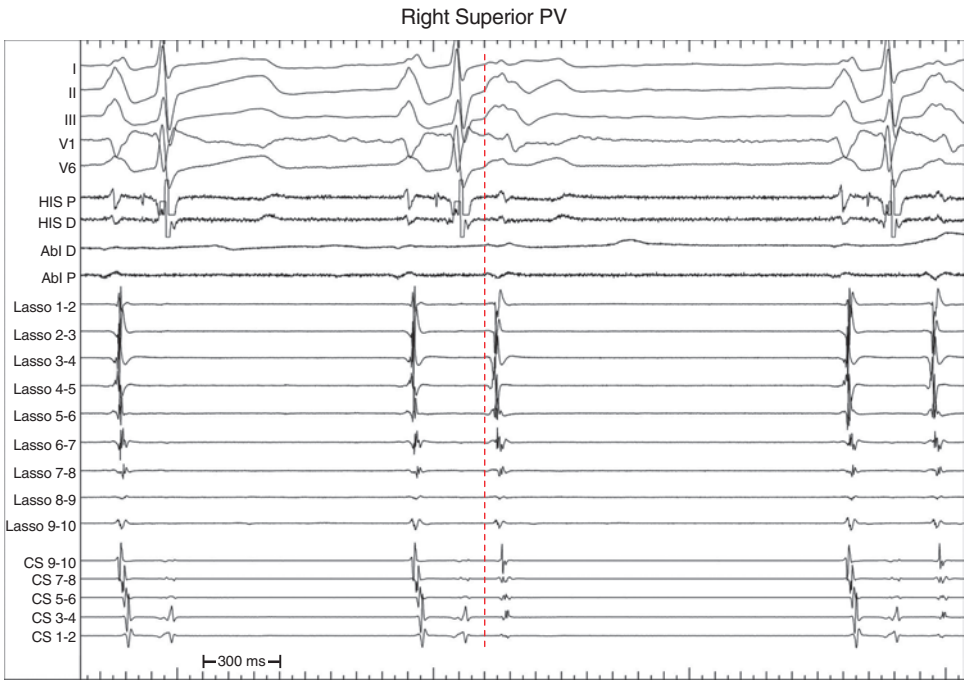
What Does This Mean? [Fig. 17-5]

Figure 17-5



Seen in Fig. 17-5, premature atrial complexes (PACs) can certainly initiate AF episodes; in addition, PACs can emanate from the "culprit pulmonary vein (PV)," the one that is responsible for AF (either as a trigger or driver). Thus targeting consistent, repetitive PACs may be a useful adjunctive strategy in treating AF. The middle QRS complex has an atrial activation associated with it, the timing of which suggests a typical atrioventricular (AV) nodal echo; however, the P wave appears to be positive in the inferior leads (unlike AV nodal echoes) and has a configuration similar to the PAC when that complex is superimposed on it *(red)*.

Right Superior Pulmonary Vein Recordings

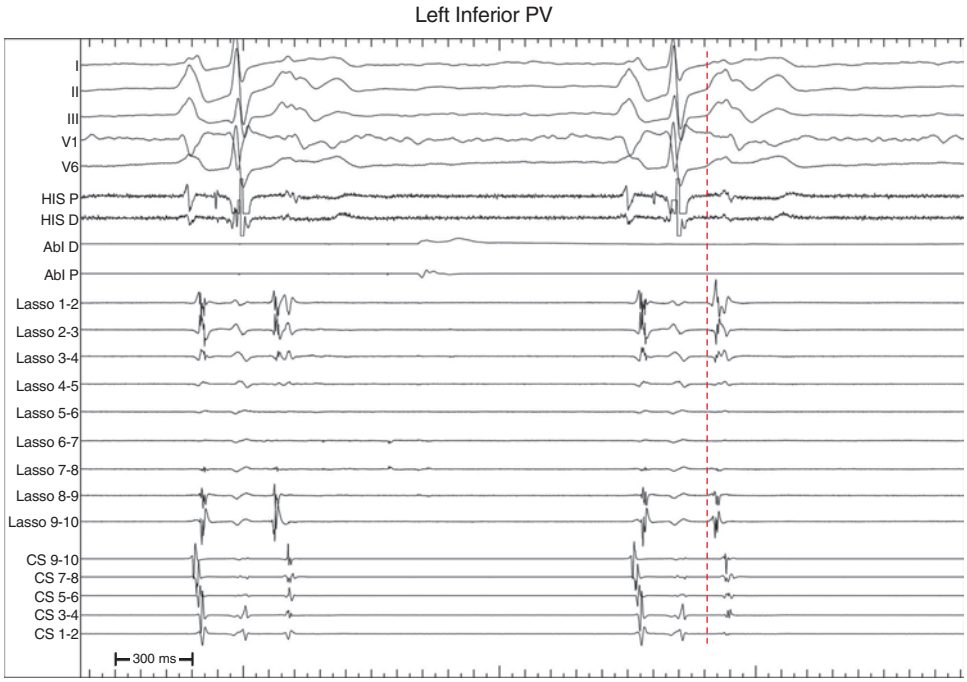


Is the PAC Coming from Here? [Fig. 17-6]

Figure 17-6

Left atrial access was obtained with transseptal catheterization, and a ring catheter ("Lasso") was used to record within PVs. When recording from the PV of origin of PACs (Fig. 17-6), the PV potentials always occur >50 ms before the P-wave origin because of slow conduction when exiting the PV. In this case because the PV potentials in the right superior PV occur after the P-wave onset *(red dotted line)*, the PAC cannot be originating here.

Left Inferior PV Recordings



Is the PAC Coming from Here? [Fig. 17-7]

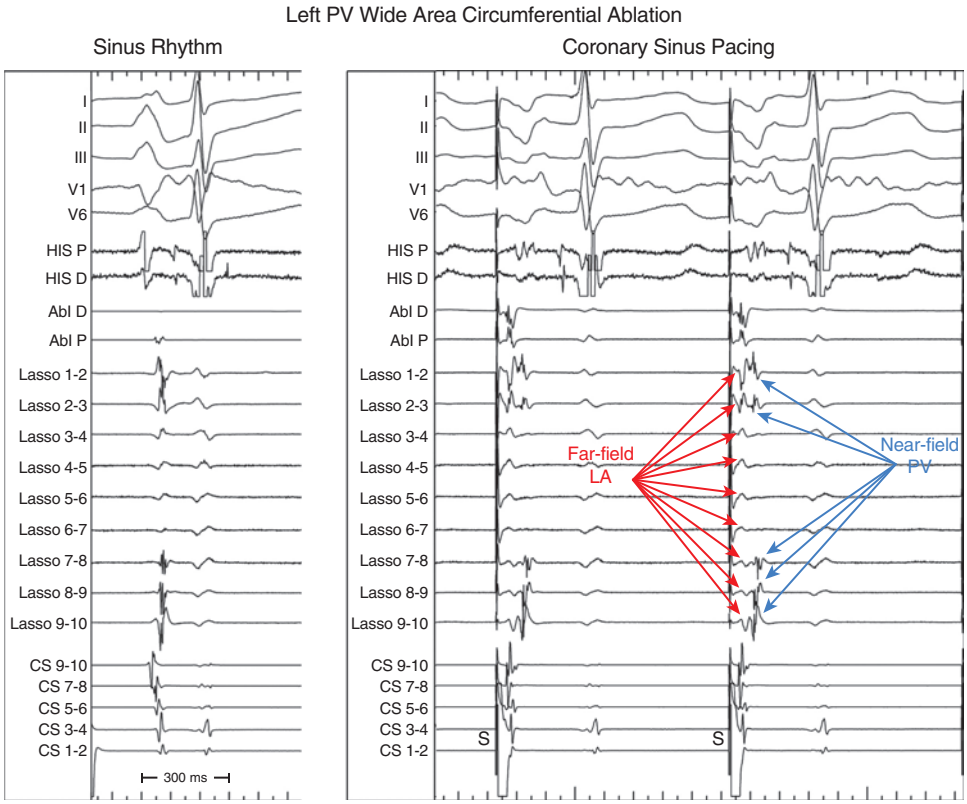
Figure 17-7

Using the same reasoning as in the prior figure, because the P wave of the PAC starts before the electrograms in the left inferior PV occur *(red dotted line)*, the PAC cannot be originating from this PV (Fig. 17-7).

Left Pulmonary Vein Wide-Area Circumferential Ablation

Baseline Pacing

Figure 17-8



In Fig. 17-8, the left superior PV could not be easily engaged with the ring catheter but was the suspected source of the PACs. Circumferential wide-area catheter ablation was begun around the left PVs while the ring catheter was in the left inferior PV. During sinus rhythm, it is not clear which of the recordings represents atrial versus PV potentials; with coronary sinus pacing as shown, PV potentials *(blue arrows)* are clearly separated from far-field left atrial recordings *(red arrows)*.

Start of Ablation

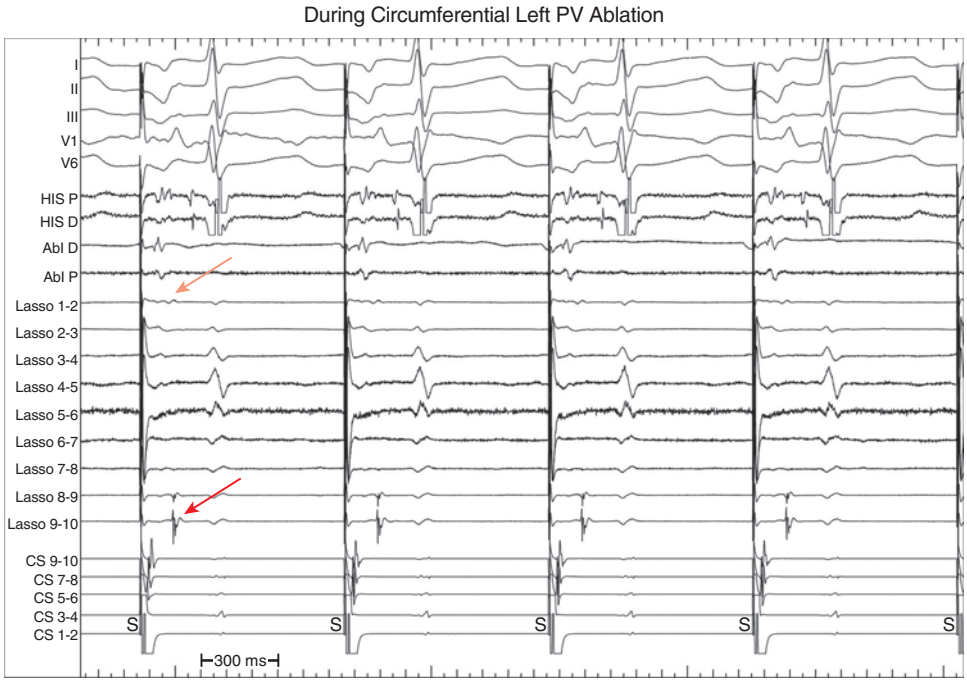


Figure 17-9

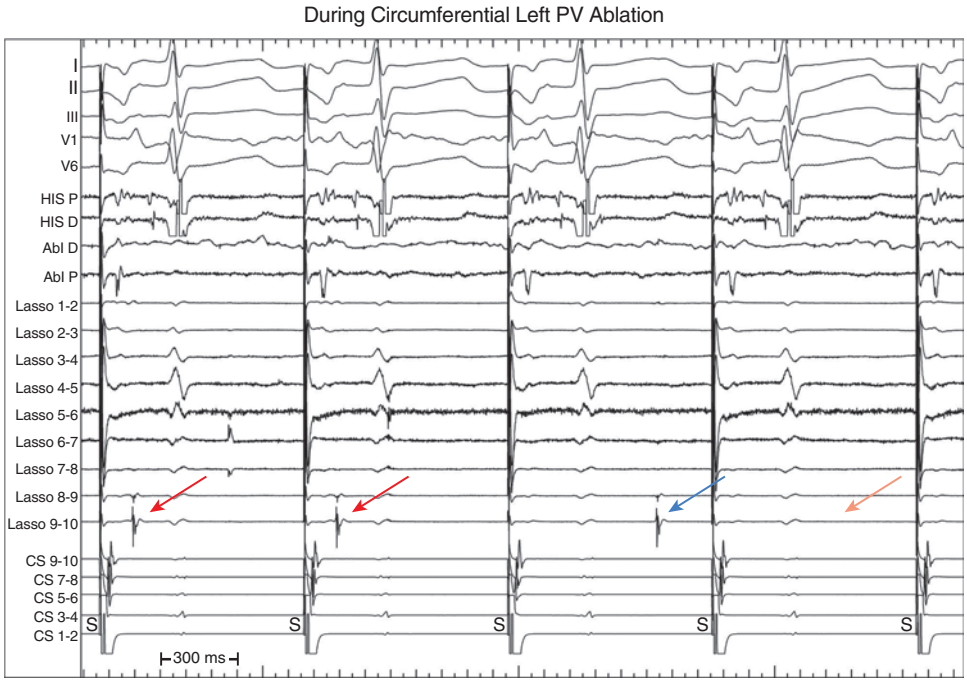
In Fig. 17-9, as circumferential ablation around the left PVs continues, some of the PV potentials have been eliminated *(pink arrow)*, whereas others are substantially delayed from their prior timing *(red arrow)*. Of note, the ring catheter has moved slightly within the PV (judging by the appearance of the far-field LA potentials compared with the prior figure), but the fact remains that PV potentials have been dramatically delayed from some, as well as eliminated from other recordings. Additionally, the PACs (which had occurred several per minute before) ceased at this time, signifying that their source was likely along the line of ablation, rather than in a PV; if it had been in a PV, most likely isolated, dissociated firing of PV potentials from the PAC focus would persist (but did not).

Isolation Occurs

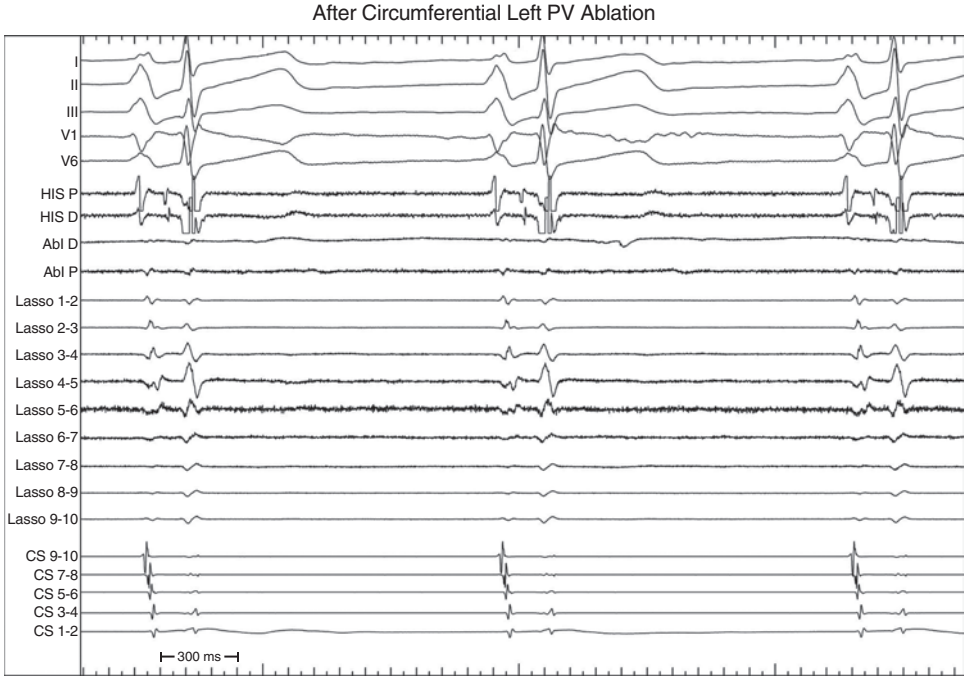
Figure 17-10



As circumferential ablation around the left PVs nears completion in Fig. 17-10, PV potentials *(red arrows)* show further delay after the third stimulus *(blue arrow)*, and then are finally eliminated *(pink arrow)*.

Sinus Rhythm After Isolation

Figure 17-11



After circumferential ablation around the left PVs (Fig. 17-11), no PV potentials are seen during sinus rhythm; PACs are also absent at this time.

Exit Block After Isolation

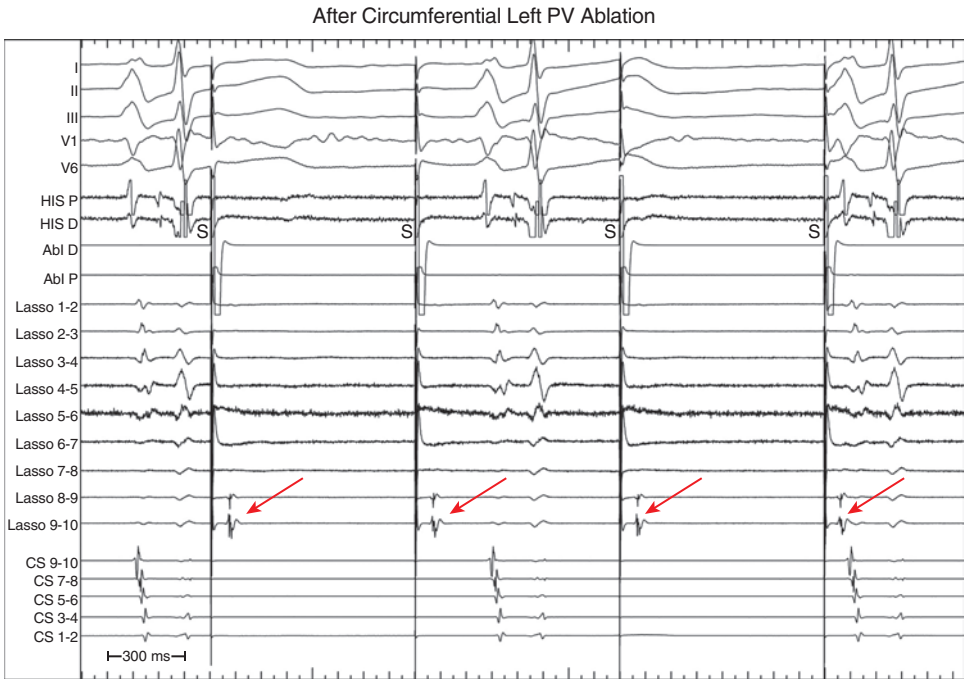


Figure 17-12

Entrance block (propagation into the PV) has been demonstrated, but it is important to show exit block (from PV to atrium) after circumferential ablation around the left PVs. Pacing from the left superior PV, while recording from a ring catheter in the left inferior PV (Fig. 17-12), shows inferred capture of PV potentials in the left superior PV, with conduction to the left inferior PV where potentials are recorded *(red arrows)*, but no conduction to the left atrium (which remains in sinus rhythm, unaffected by PV pacing). Thus both left PVs have been isolated (both entrance and exit block) as a unit.

Right PV Wide-Area Circumferential Ablation

Start of Ablation

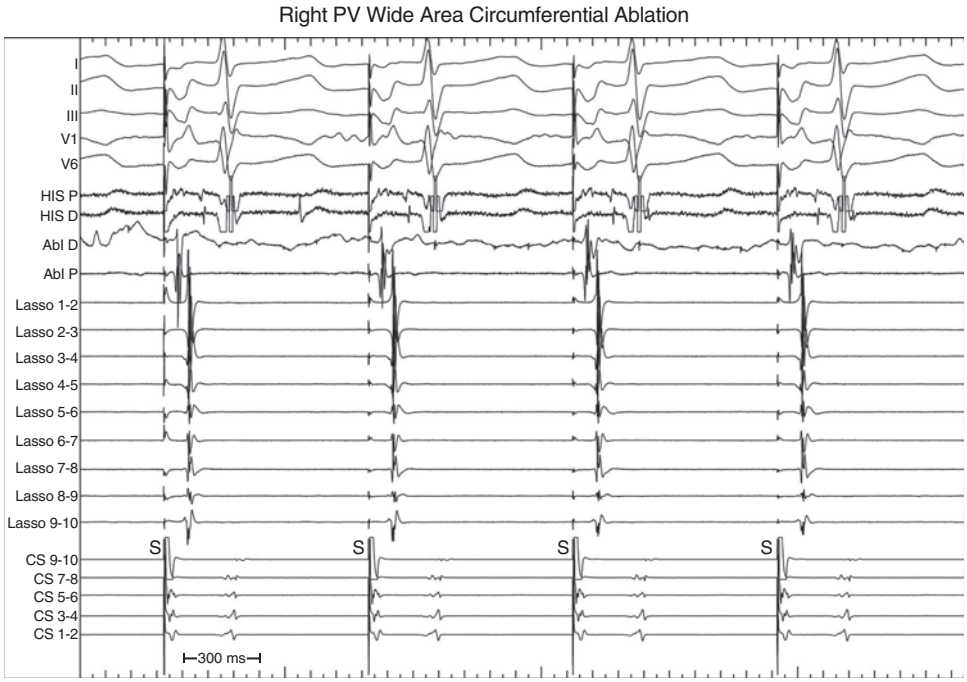

Figure 17-13

After completion of left PV isolation, attention is turned to the right PVs (Fig. 17-13). Here, the ring catheter is in the right superior PV, again during coronary sinus pacing. With right PVs, coronary sinus pacing usually does not separate left atrial and PV potentials nearly as well as it does with left PVs; pacing was done in this instance because of bradycardia.

Flutter Initiates

Figure 17-14

During attempted right PV isolation (Fig. 17-14), a PAC *(blue arrow)* occurs (perhaps due to irritation from the ablation catheter) that initiates what appears to be atrial flutter, with

upright flutter waves in the inferior leads. This is reminiscent of the arrhythmia that was present at the beginning of the procedure when catheters were first being placed.

Flutter Terminates in Right Atrium

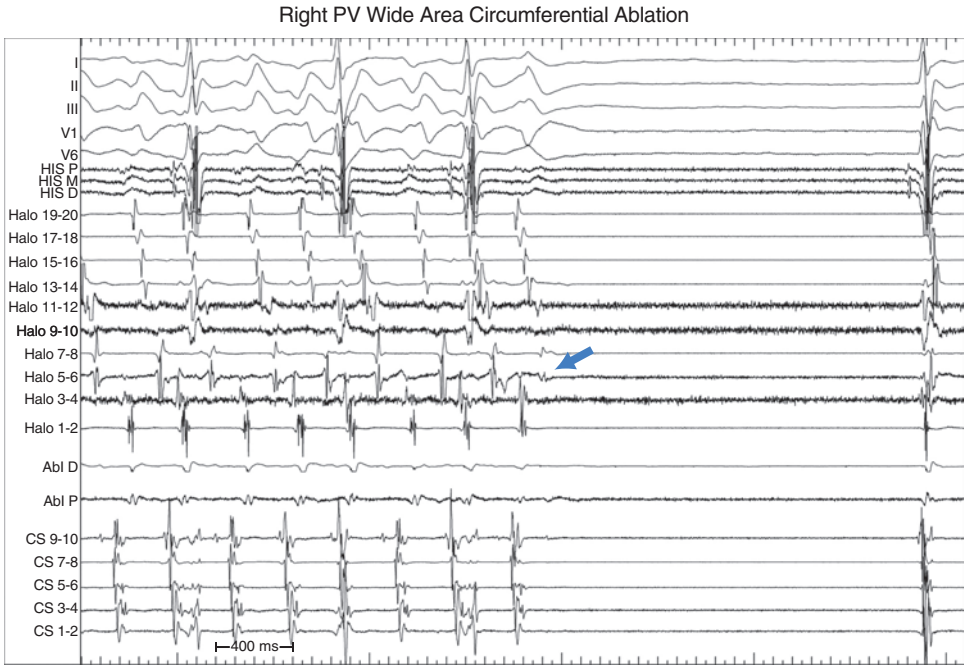

Figure 17-15

Since the last figure, a 20-pole catheter ("Halo") has been placed in the right atrium to record around the tricuspid annulus (Fig. 17-15). Here, a spontaneous termination of the arrhythmia is shown. The last electrograms that are seen are from the tricuspid annulus *(arrow)*, suggesting that the rhythm originates in the left atrium (because, when the arrhythmia ceased, the last cycle was transmitted to the right atrium and no further activity is seen until a junctional escape complex at the far right). It is also possible that the arrhythmia is actual right-atrial, peritricuspid reentry that terminated because of tenuous conduction properties in the tissue between electrodes 5-6 and 3-4 on the tricuspid annular catheter; there is clearly poor conduction in this area, indicated by the prolonged interval between these adjacent electrode pairs compared with others.

Partial Isolation

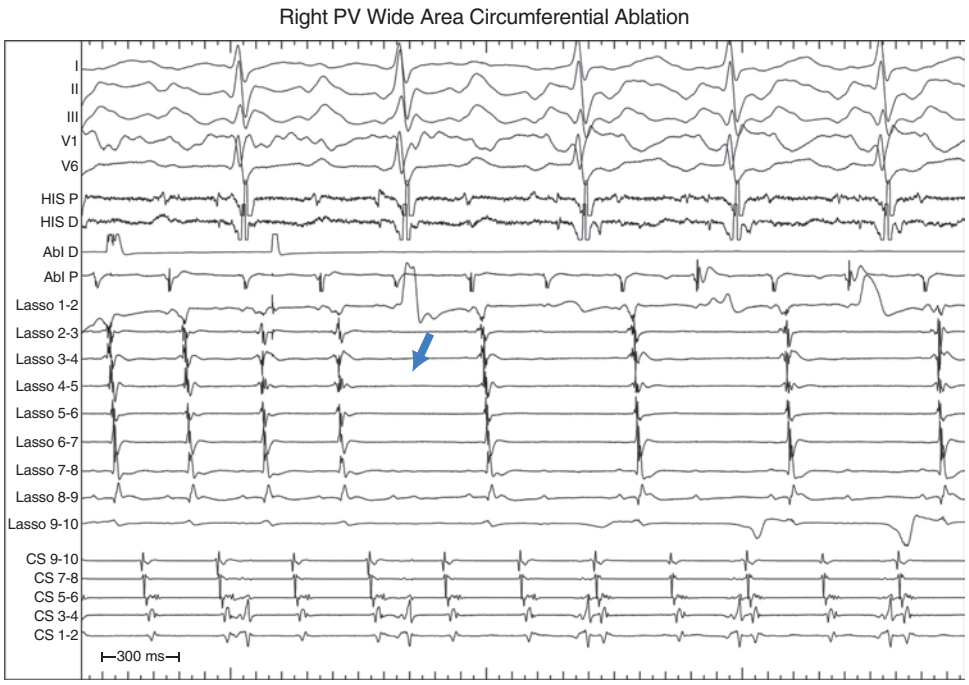

Figure 17-16

In Fig. 17-16, ablation around the right pulmonary veins was continued; in a similar way as previously (PAC; not shown here), the flutter-like arrhythmia began again. Here, PV potentials from the right superior PV go from 1:1 with the arrhythmia to every other cycle *(arrow)*, indicating that this PV is not responsible for the ongoing arrhythmia. PV isolation can be performed during sinus rhythm, atrial pacing, or atrial flutter/fibrillation equally well.

Full Isolation

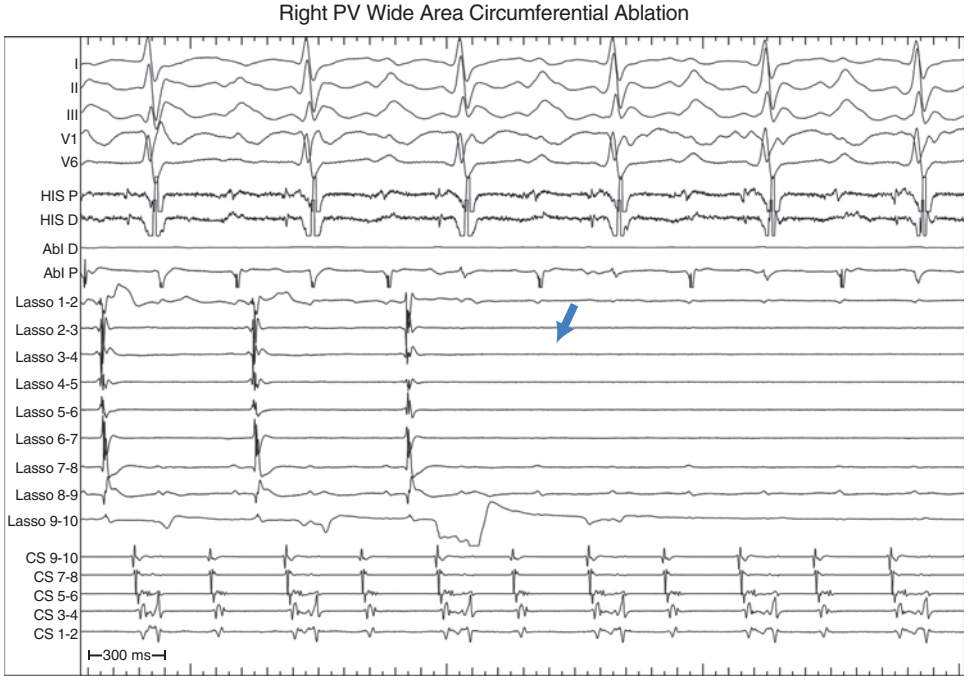

Figure 17-17

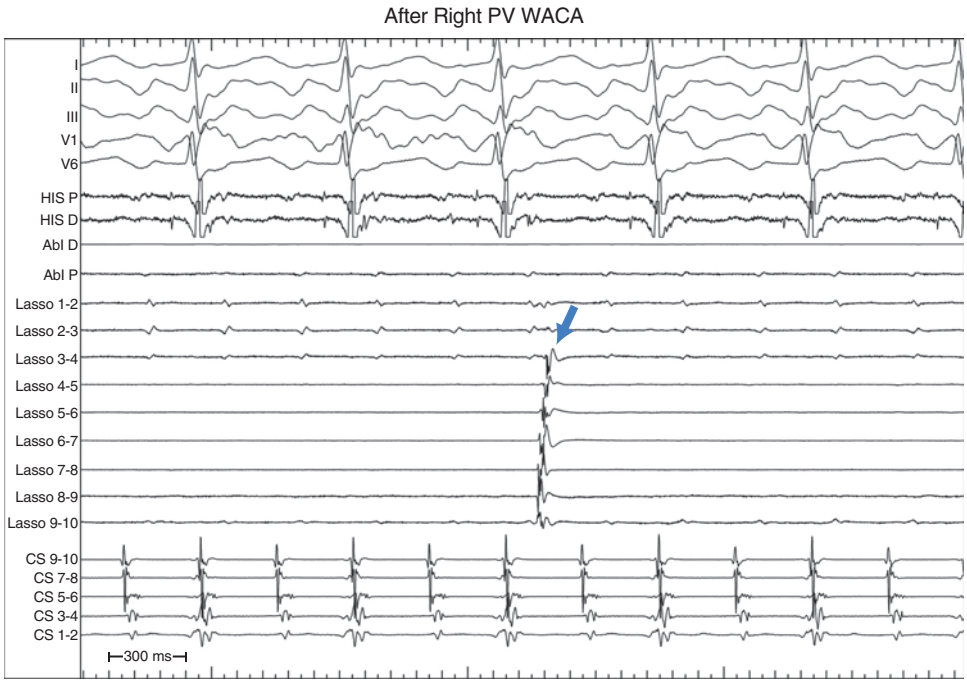
Ablation around the right pulmonary veins continues. In Fig. 17-17, PV potentials from the right superior PV are suddenly eliminated *(arrow)*. Obviously, this PV is not responsible for the flutter-like arrhythmia that continues (already known from the prior figure).

Dissociated Potential Seen After Right WACA



What Is Demonstrated? [Fig. 17-18]

A. Entrance block
B. Exit block
C. Both
D. Neither

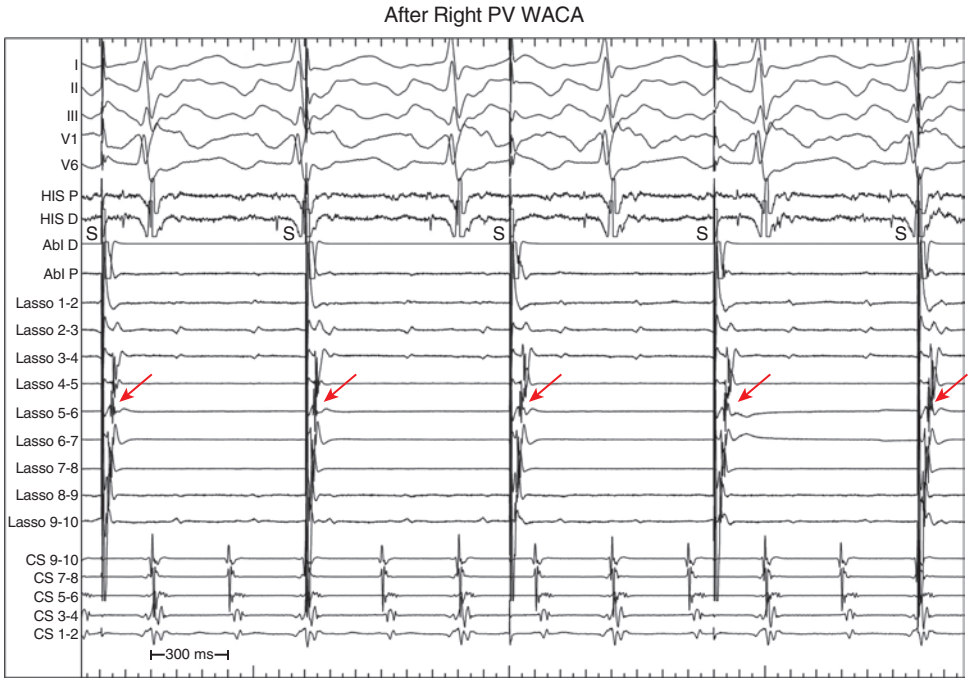
Figure 17-18

The flutter-like arrhythmia continues after the right superior PV has been isolated; a single spontaneous discharge (dissociated potential, *arrow* in Fig. 17-18) occurs during a short waiting period to ensure that the PV does not reconnect to the left atrium. This shows entrance block to the PV, but not exit block (which cannot be demonstrated until the rate in the PV is faster than the rate in the atrium).

Exit Block Can't Be Demonstrated When Pacing in Vein After Right WACA During Flutter. What Is Demonstrated? [Fig. 17-19]

A. Entrance block
B. Exit block
C. Both
D. Neither

Figure 17-19

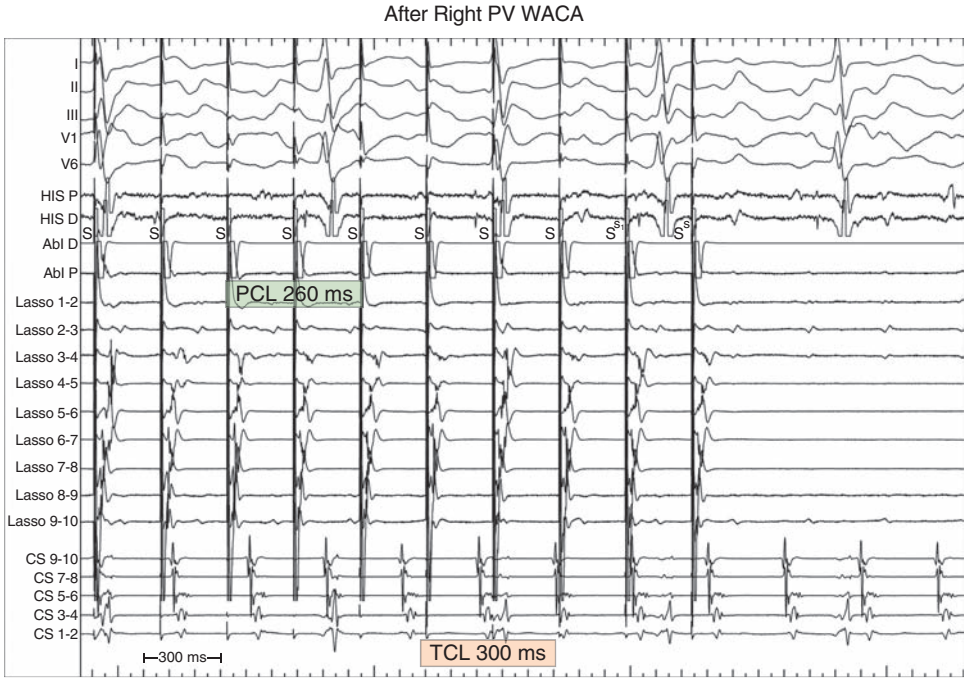


Here, pacing the right *inferior* PV inferentially captures that PV and conducts to the right *superior* PV (where the ring catheter remains; controlled PV potentials are shown by *arrows*) (Fig. 17-19). This again shows entrance block to the PV, because if there were *not* entrance block, the PV potentials would be related to the ongoing flutter-like arrhythmia rather than the stimulus artifacts (as here). This again does not demonstrate *exit* block, which requires dissociation between PV and LA in the presence of a more rapid input from the PV. Although exit block cannot be shown at this time, there is still value in finding a location at which PV capture is possible: after sinus rhythm is restored, the catheter can be maneuvered back to that spot to easily determine whether exit block is present (even without a separate catheter recording from the PV, as here).

Exit Block Testing When Pacing in Vein After Right WACA During Flutter. Which Is Demonstrated? [Fig. 17-20]

A. Entrance block
B. Exit block
C. Both
D. Neither

Figure 17-20



Now, pacing the right inferior PV captures that PV and conducts consistently to the right superior PV at 260 ms, whereas the flutter-like arrhythmia's cycle length is 300 ms and

quite regular (Fig. 17-20). Because there is no influence of the pacing on the ongoing arrhythmia, exit block—from both right PVs, because the inferior PV is paced and the superior PV is recorded—has now been reasonably demonstrated.

Pacing During Flutter

From Midcoronary Sinus

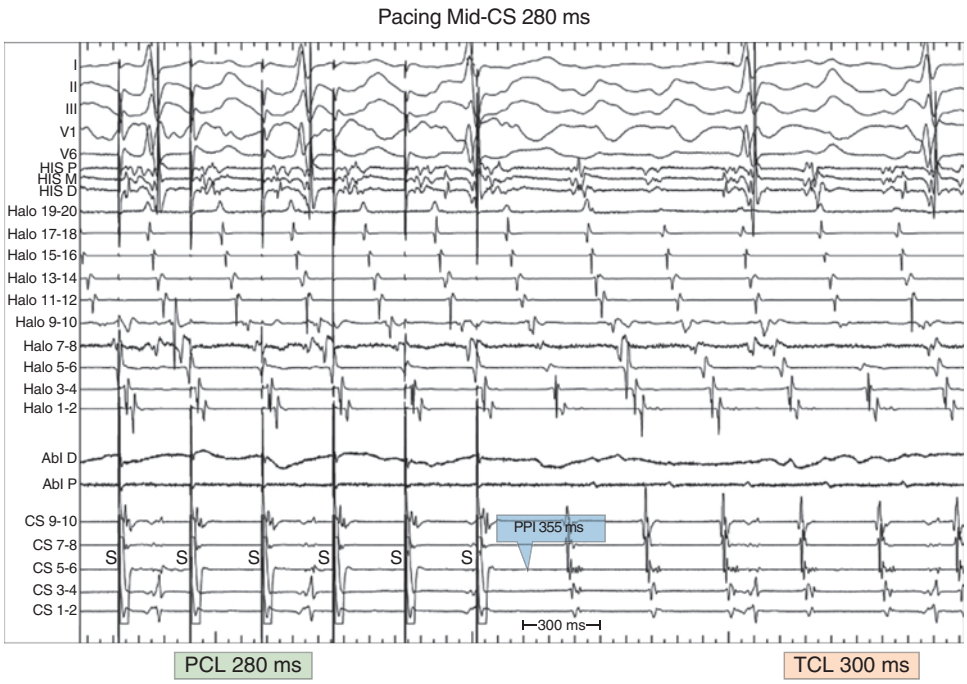


Figure 17-21

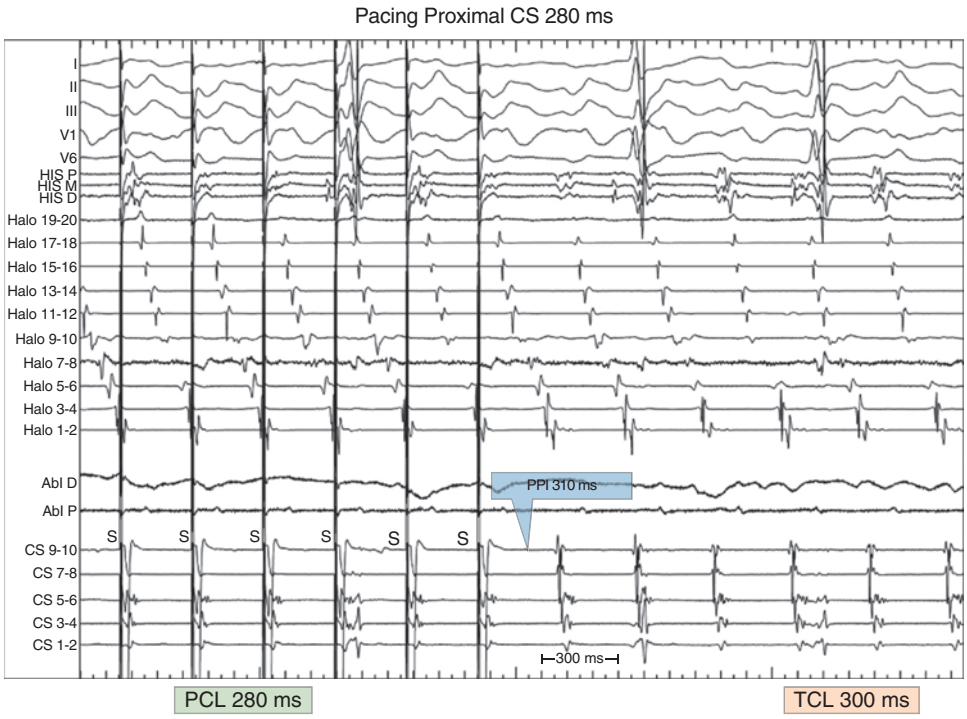
Now that all four PVs have been fully isolated with entrance and exit block demonstrated, attention is turned to the flutter-like arrhythmia. In Fig. 17-21, the last several cycles of overdrive pacing from the midcoronary sinus are shown. Because there has been no prior ablation within the right atrium that could alter the expected activation sequence along the tricuspid annulus, the fact that the atrial activation sequence during CS pacing has the configuration shown rather than the expected "chevron" sequence (equivalently early at Halo 1-2 and Halo 19-20, latest at Halo 11-12) is a demonstration of fusion and is diagnostic of macroreentry. Further, the postpacing interval (PPI) at the mid-CS is 355 ms, substantially longer than the tachycardia cycle length (TCL) and suggests that this portion of the CS is not part of the circuit. This is curious, because the prior spontaneous termination event (Fig. 17-15) suggested a left atrial source.

From Proximal Coronary Sinus

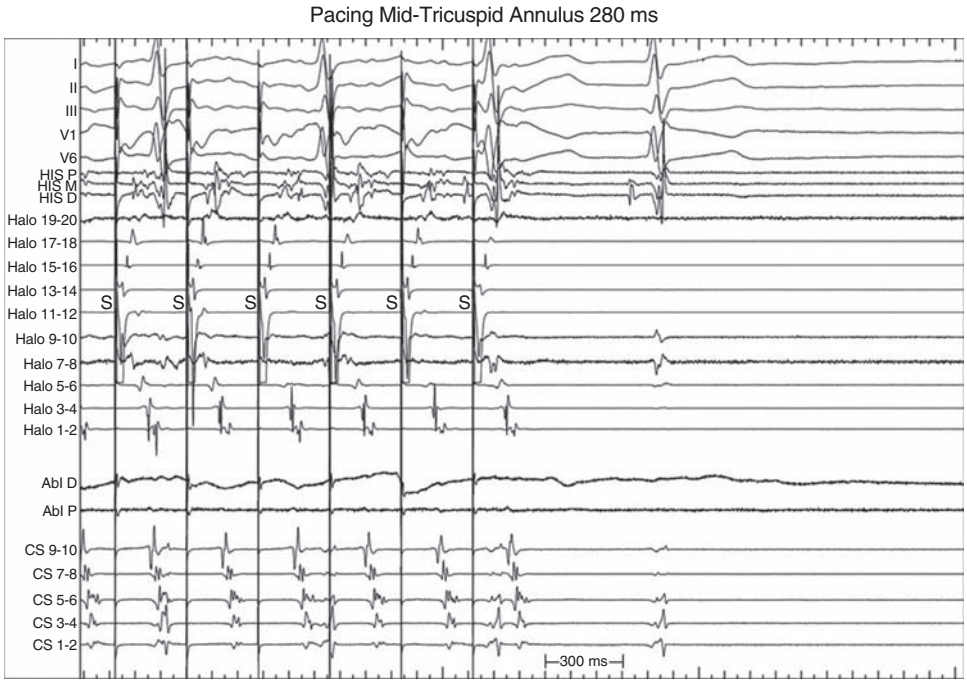
Figure 17-22



In Fig. 17-22, the last several cycles of overdrive pacing from the proximal coronary sinus electrodes (at the ostium) are shown. The atrial activation sequence along the tricuspid annulus is the same as in the prior figure, but the PPI from this site is now 310 ms, nearly the same as the TCL, suggesting that this portion of the CS is very near or part of the circuit.

From Midtricuspid Annulus

Figure 17-23



In Fig. 17-23, the last several cycles of overdrive pacing from the midtricuspid annulus electrodes are shown. Whereas multiple attempts at overdrive pacing from the coronary sinus (some not shown) did not terminate tachycardia, it was nonetheless terminated by

the first attempt at pacing from the tricuspid annulus. When this unexpected result occurs, it is always worth looking back earlier during the episode of stimulation to see if something unusual happened.

Earlier in That Episode of Tricuspid Annulus Pacing

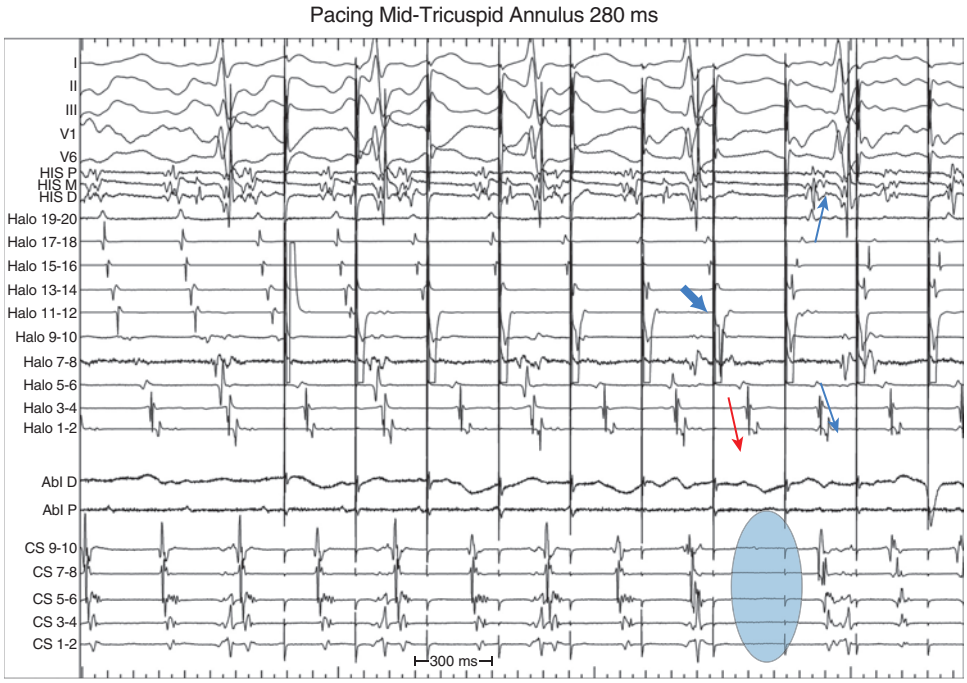


Figure 17-24

In Fig. 17-24, the first several cycles of overdrive pacing from the midtricuspid annulus electrodes are shown. The stimulus indicated by the *large blue arrow* captures the tricuspid annulus tissue and sends the impulse forward *(red arrow)*; however, it does not arrive at the CS *(translucent oval)*. The subsequent stimulus artifact conducts in both directions from the stimulation site *(blue arrows)*, because there is no wavefront from the prior cycle proceeding around the tricuspid annulus. This indicates that tissue close to the proximal CS recordings was essential for perpetuation of the tachycardia (because, in the absence of activation of this site, tachycardia terminates), and that the arrhythmia is most likely right atrial macroreentry (typical, counterclockwise atrial flutter). This is despite the unusual ECG appearance of the flutter waves. Why, then, did a previous figure show this arrhythmia spontaneously terminating in a fashion suggesting a left atrial source (Fig. 17-15)? The answer is in the figure shown here, demonstrating (as noted earlier) that there is a portion of the medial cavotricuspid isthmus where conduction is not robust, and subject to termination when input arrives before full recovery from refractoriness at that site.

Single Extrastimulus from Lateral Tricuspid Annulus

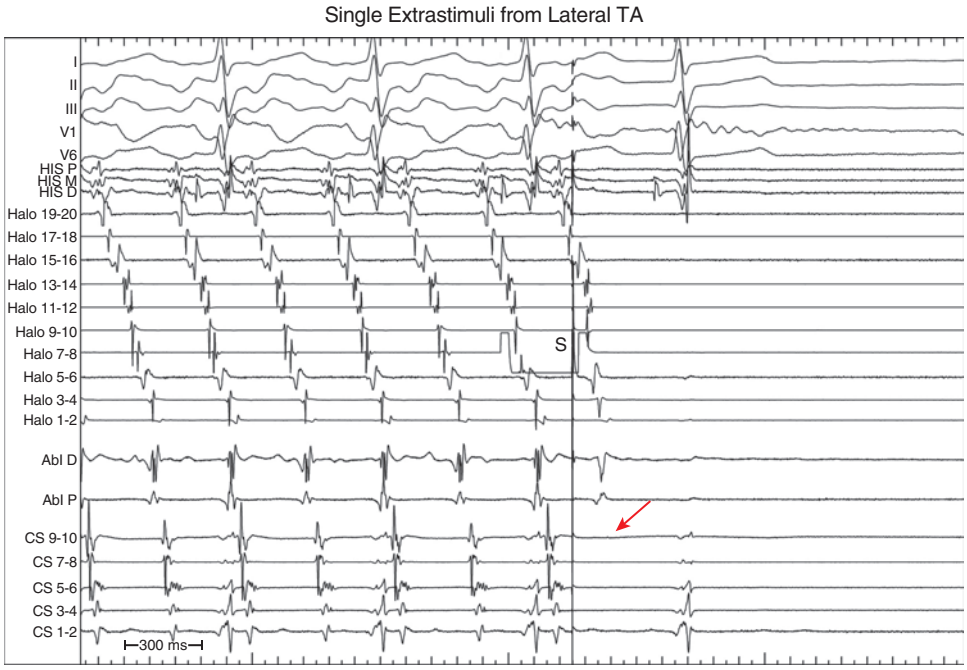

Figure 17-25

To further prove the point, the arrhythmia was reinitiated and a single extrastimulus was given during flutter from another site on the tricuspid annulus (Fig. 17-25); this too propagates distally along the tricuspid annulus toward the CS but fails to reach the CS *(arrow)* because of local refractoriness of that portion of the cavotricuspid isthmus (CTI). This once again shows that the right atrium, not the left, is responsible for this arrhythmia. This phenomenon was reproduced several times after easy reinitiation of flutter. Because of the same phenomenon, overdrive pacing from the CTI (not shown) repeatedly resulted in tachycardia termination rather than entrainment.

Ablation from Cavotricuspid Isthmus

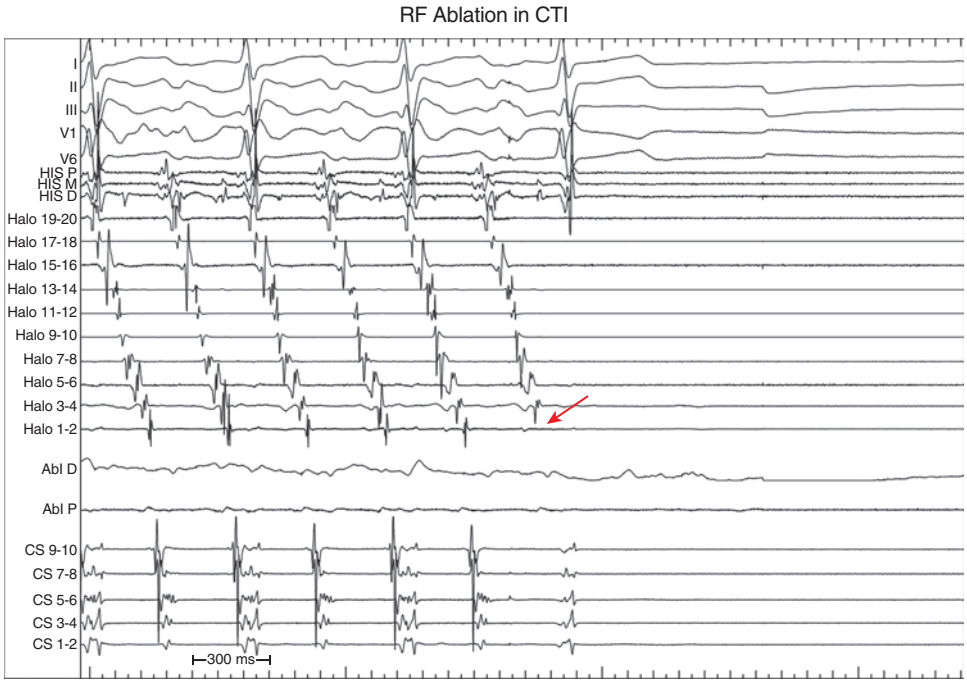

Figure 17-26

Based on the prior findings, ablation in the CTI was begun. This readily terminated flutter, as predicted (Fig. 17-26). Block occurs between electrodes near the tip of the tricuspid annulus catheter (*arrow*, at the medial aspect of the CTI), and proximal CS recordings (at the ostium). This is where spontaneous termination had occurred previously.

Completion of Cavotricuspid Isthmus Ablation

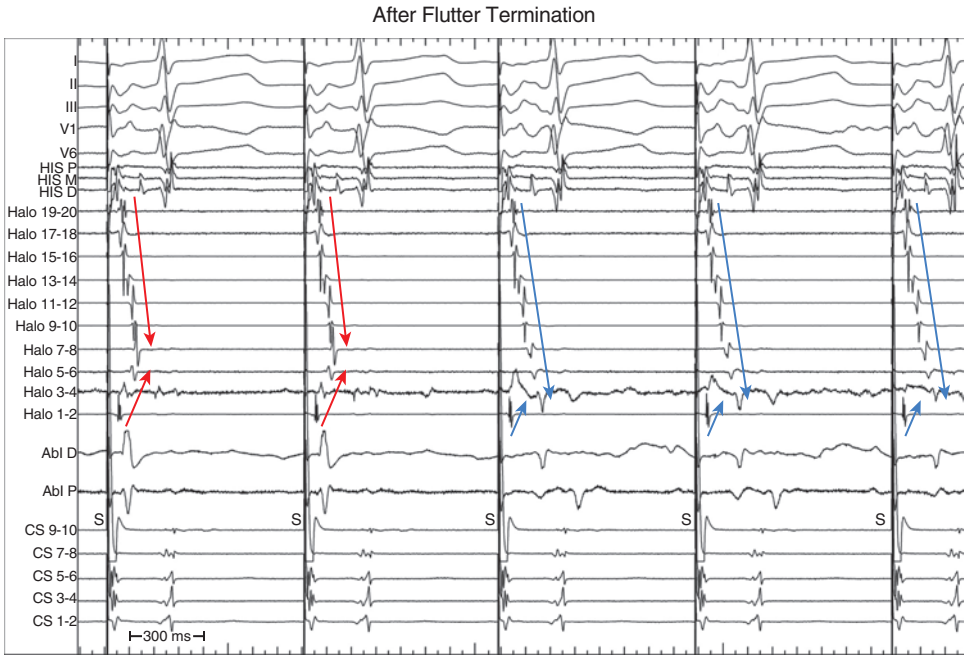

Figure 17-27

As is so often the case, termination of flutter is not equivalent to having bidirectional CTI block. In Fig. 17-27, immediately after termination of flutter, CS pacing shows persistence of conduction in the CTI *(red arrows)*. Additional RF energy is delivered, resulting in medial-lateral block, as shown here *(blue arrows)*. Pacing from the lateral TA (not shown) showed block in the lateral-medial direction as well.

Burst Pacing Initiates Atrial Fibrillation

Figure 17-28

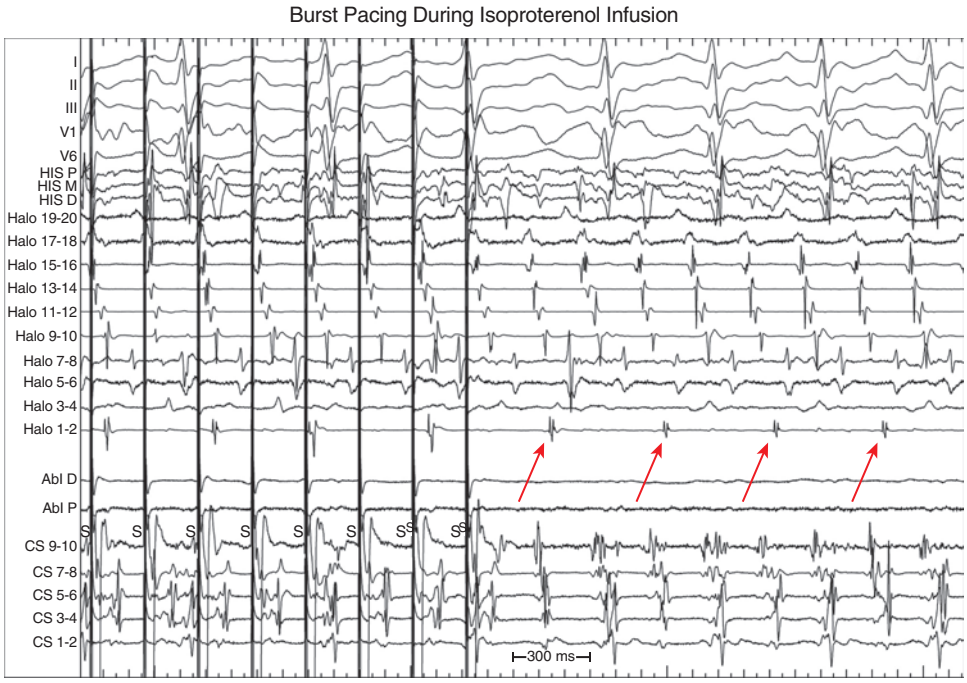

Figure 17-29

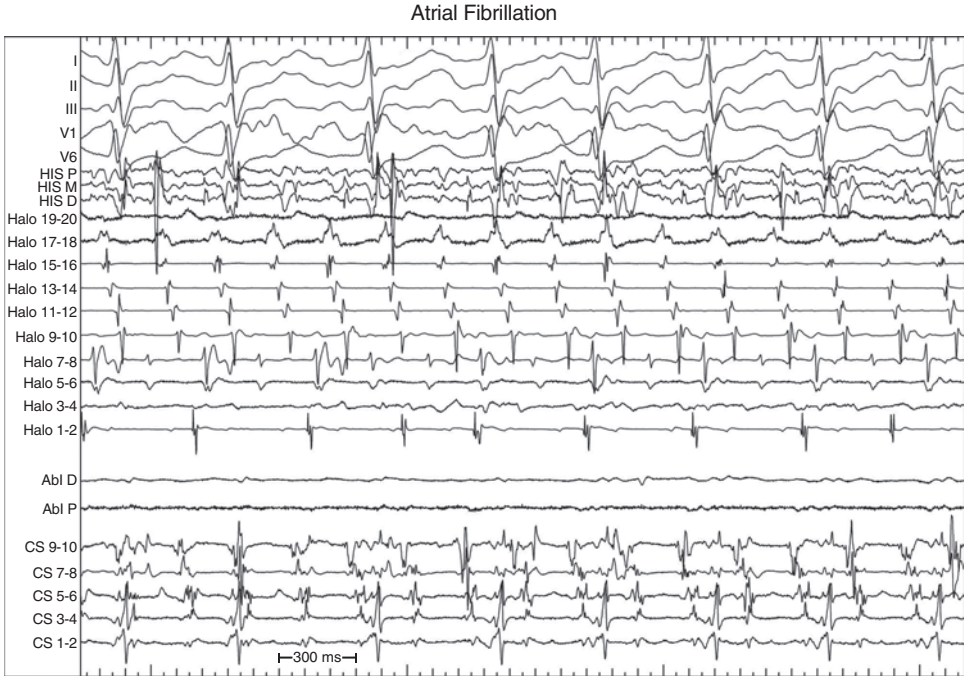

Because the patient had a history of only atrial fibrillation by ECG, despite the elimination of atrial flutter, the operators deemed it important to investigate for fibrillation. No arrhythmia was initiated with stimulation in the baseline state, but after isoproterenol infusion at 5 mcg/min, burst pacing initiated the arrhythmia shown in Fig. 17-28. Of note, electrodes at the medial tricuspid annulus (Halo 1-2) are not activated with every atrial cycle *(red arrows)*. At first glance it appears organized, but quickly degenerated to fibrillation (shown in Fig. 17-29), as shown especially in the CS and His recordings.

Standard Intracardiac Recordings and Basket Catheter Recordings in AF

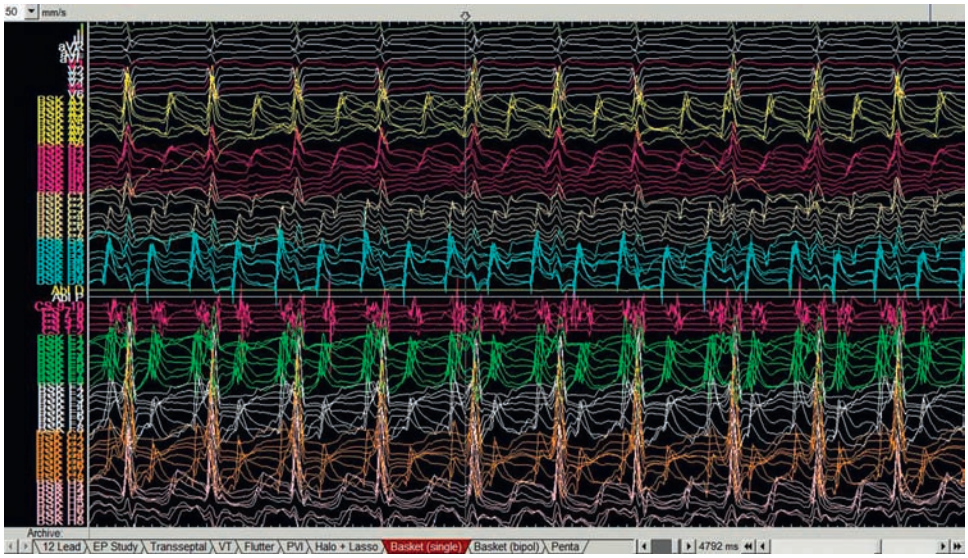

Figure 17-30

Based on the greater degree of disorganization in the CS recordings than those on the tricuspid annulus (right atrium), a 64-pole basket catheter was deployed in the left atrium and recordings were made during fibrillation (Fig. 17-30). Note that, while the CS recordings (*maroon*, at center) are still quite disorganized, the unipolar recordings from the basket catheter appear to be much more uniform from cycle to cycle. One minute of these recordings was acquired and analyzed by a proprietary mapping system looking for rotors or focal sources of atrial fibrillation.

Fluoroscopy of Catheters Including Basket in Left Atrium

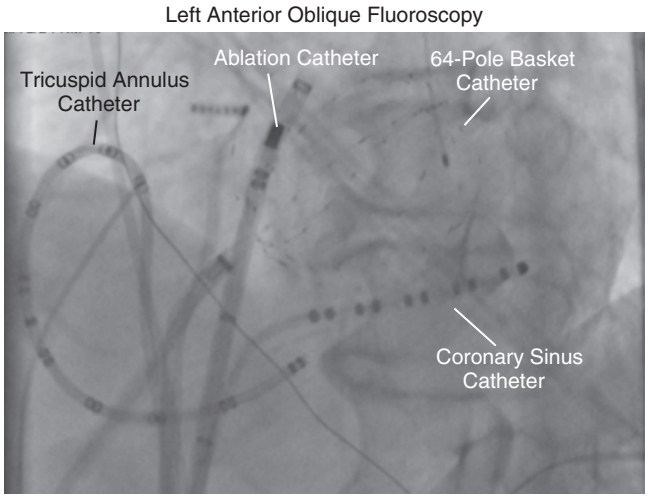

Figure 17-31

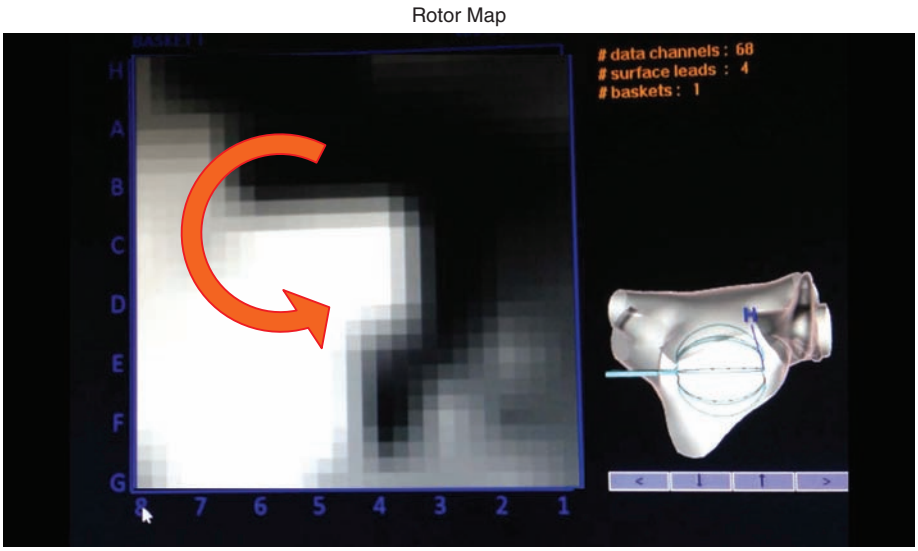
Fig. 17-31 shows a fluoroscopic view of catheter locations, including the 64-pole basket catheter in the left atrium; the ablation catheter is still inside a sheath, the tip of which is also in the left atrium. Note the location of the tip of the tricuspid annular catheter in relation to the coronary sinus proximal electrodes (positions the same as during flutter ablation).

Rotor Movie/Still

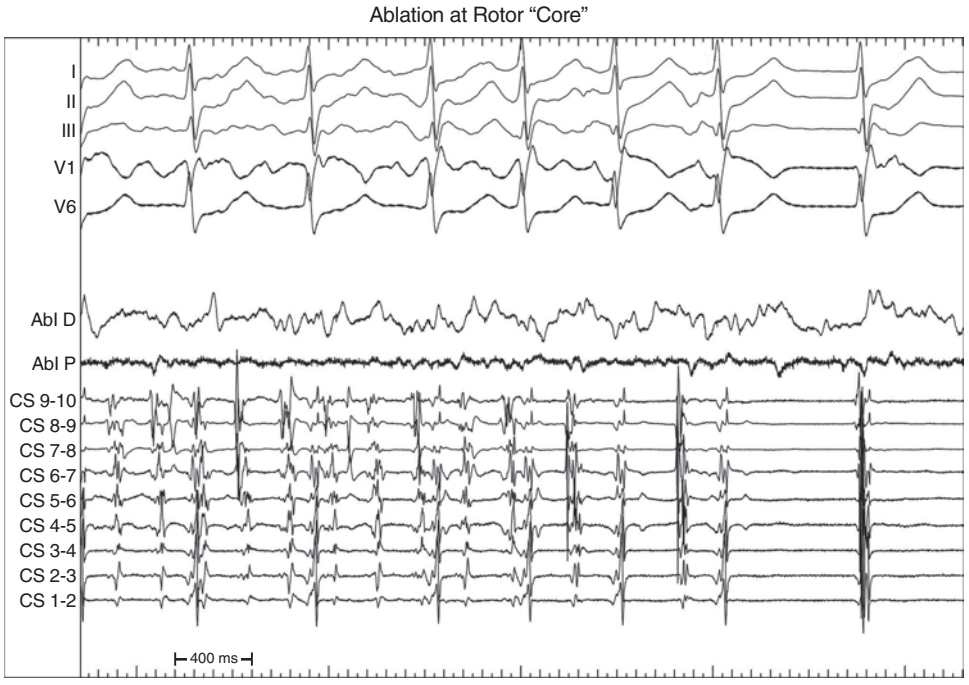
Figure 17-32



In this 4-second movie (Video 17-1 and Fig. 17-32), a counterclockwise left atrial rotor is seen with a center of rotation at about B-6 on the axial coordinates. This area, corresponding to the inferomedial free wall/floor of the left atrium, was targeted for ablation.

Ablation at Rotor "Core" Terminates AF

Figure 17-33



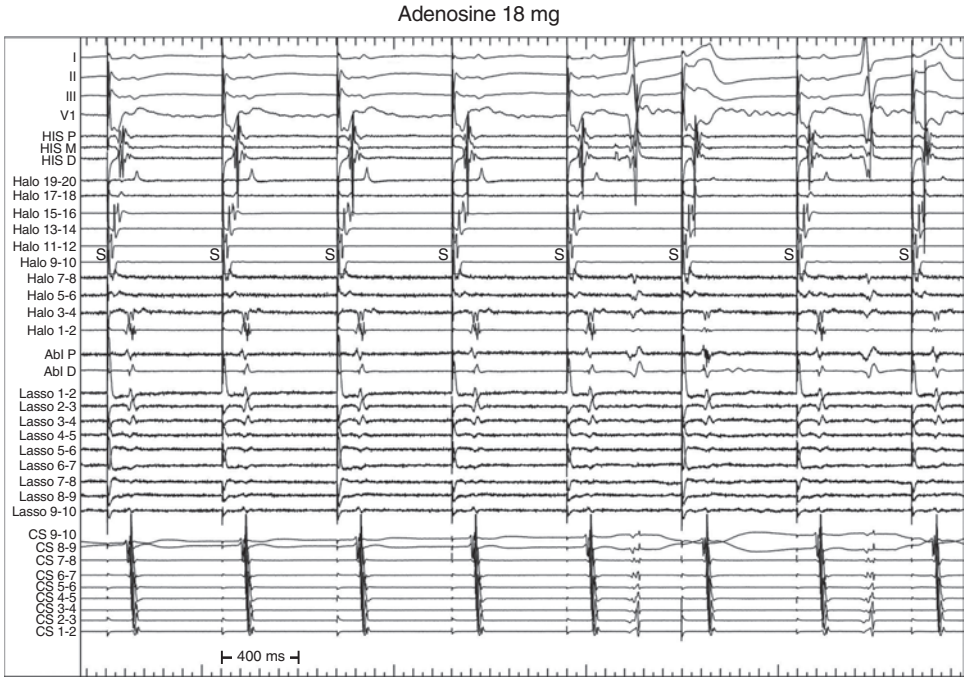
RF ablation near the center of rotation of the previously shown rotor (located on the inferomedial left atrial free wall) resulted in termination of the arrhythmia to junctional rhythm (Fig. 17-33). Fibrillation was reinitiated (with some difficulty) during continued isoproterenol infusion; a second left atrial rotor (located on the inferior portion of the septal aspect of the left atrium) was identified, and during RF ablation at the center of rotation of this rotor, fibrillation terminated to sinus rhythm (not shown). Thereafter, despite higher dose isoproterenol infusion, no arrhythmias could be initiated; the pacing protocol consisted of single- and double-atrial extrastimuli as well as burst pacing for >30 repeated attempts at cycle length 190 ms (shortest cycle length with 1:1 capture at high output).

Adenosine Administration

Figure 17-34

After completion of stimulation and checking for bidirectional block in the CTI as well as four PVs in the resting state before and after discontinuation of isoproterenol, adenosine (18 mg) was administered by intravenous bolus while recording from tricuspid annulus as well as right superior PV ("Lasso") and left superior PV (Abl) (Fig. 17-34). Adenosine-mediated hyperpolarization of atrial cells can transiently restore dormant conduction and show that additional ablation is needed. Here, at the time of atrioventricular block *(center)*, pacing from the proximal CS shows persistence of medial-lateral CTI block; there are no PV potentials recorded from either left or right superior PVs.

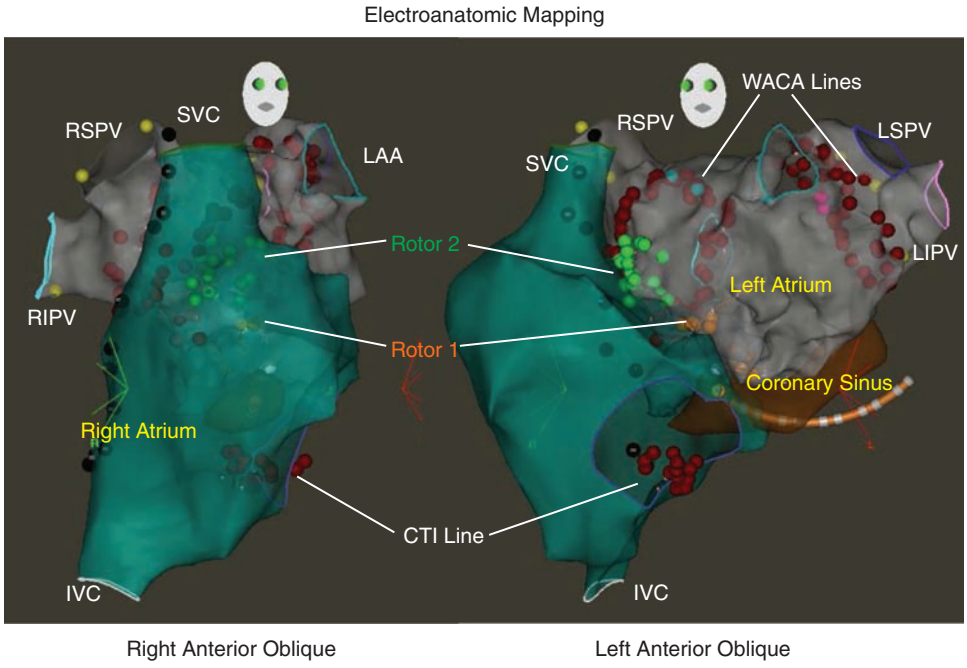
Figure 17-35



Seconds later, the site of simulation is changed to the lateral aspect of the CTI, showing persistence of block in the lateral-medial direction (Fig. 17-35). Again, no PV potentials are recorded from either left or right superior PVs. Not shown is attempted stimulation from the left superior PV, at a site in which capture had been demonstrated previously, without conduction to left atrium. The patient has had no recurrent atrial arrhythmias in long-term follow-up.

Electroanatomic Mapping Showing Ablation Regions

Figure 17-36



In this electroanatomic mapping diagram in Fig. 17-36, the right atrium is *green*, left atrium *gray*, and coronary sinus *brown*. Wide-area circumferential ablation (WACA) lines encircling the PVs are shown as well as sites of rotor mapping (#1 *[orange dots]*, inferomedial left atrial

free wall; #2 *[green dots]*, inferior portion of the septal aspect of the left atrium). It is clear that both of these rotor locations are well outside the standard WACA lines and were "missed" by PV isolation. *CTI,* cavotricuspid isthmus; *IVC,* inferior vena cava; *LAA,* left atrial appendage orifice; *LIPV,* left inferior PV; *LSPV,* left superior PV; *RIPV,* right inferior PV; *RSPV,* right superior PV; *SVC,* superior vena cava.

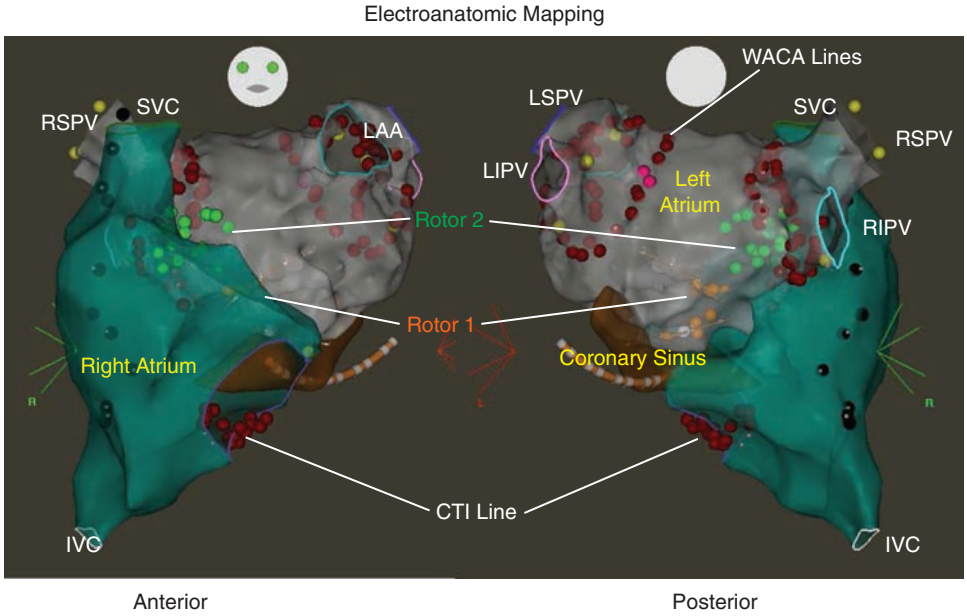


Figure 17-37

The same maps as in the prior figure are displayed in Fig. 17-37 in different orientations. *CTI,* cavotricuspid isthmus; *IVC,* inferior vena cava; *LAA,* left atrial appendage orifice; *LIPV,* left inferior PV; *LSPV,* left superior PV; *RIPV,* right inferior PV; *RSPV,* right superior PV; *SVC,* superior vena cava.

Summary

- Atrial fibrillation can be transformed to atrial flutter by sodium-channel–blocking agents such as amiodarone (which also slows the flutter cycle length)
- Spontaneous termination of atrial flutter is rare but can occur at the narrowest part of the circuit (CTI)
- Careful use of overdrive pacing during tachycardia—analyzing events both at the end and at the beginning of pacing—can be very useful diagnostically
- In patients with predominant atrial fibrillation clinically who are in flutter at the time of the procedure, fibrillation should usually still be treated
- Rotors that maintain fibrillation may reside near typical ablation lines for PV isolation, or outside these zones

Idiopathic Focal Right Ventricular Outflow Tract Ectopy

18

Case Presentation

The patient was a 39-year-old woman referred for management of palpitations for the last 2 years. Episodes began after birth of the eighth child and often worsened when she was upset. Ambulatory recorder showed premature ventricular complexes (PVCs) comprising about 25% of all complexes. Baseline ECG showed sinus rhythm with PVCs having a left bundle branch block (LBBB) and right-inferior axis with a precordial R-wave transition at V3 and smooth R-wave contours in inferior leads. Metoprolol was ineffective at controlling her symptoms (palpitations and fatigue), which were increasingly bothersome. Physical examination finding was normal aside from skipped beats. Echocardiogram showed mild global hypokinesis (ejection fraction 45%). She underwent an EP study elsewhere; the right ventricular outflow tract (RVOT) was thoroughly mapped, and multiple sites were ablated without altering the PVC frequency. She was referred for a repeat EP study and ablation.

Baseline ECGs and Intracardiac Recordings

Where Is the Likely Origin? [Fig. 18-1]

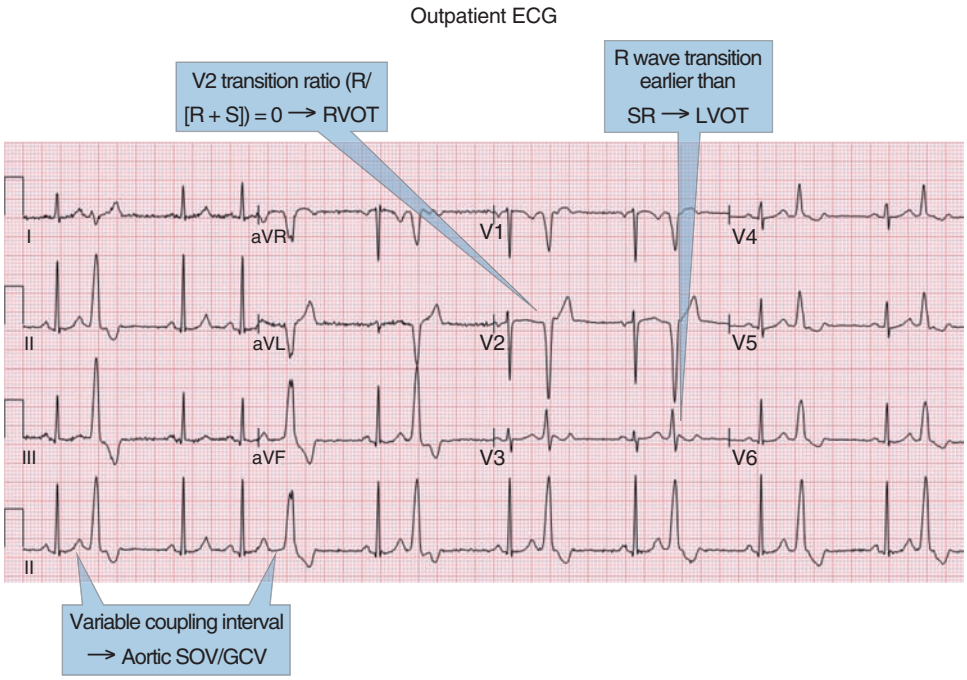

Figure 18-1

A 12-lead ECG of the patient's sinus rhythm with ventricular ectopy is shown in Fig. 18-1. As indicated, several morphologic criteria of the PVCs yield disparate indicators of its origin. For instance, in lead V2, the ratio $R/(R + S)$ of 0 suggests RVOT origin, whereas R-wave transition occurring earlier in the PVC than in sinus rhythm (V3 vs V4) suggests left ventricular outflow origin; finally, the variable coupling interval from the prior sinus complex to the PVC in the rhythm strip suggests aortic sinus of Valsalva (SOV) or great cardiac vein (GCV) origin.

Is This the Same as What We Saw Earlier? [Fig. 18-2]

Figure 18-2

With the patient in the electrophysiology laboratory, PVC coupling intervals appear to be more constant (Fig. 18-2); the V2 ratio still suggests RVOT origin but the precordial transition occurs in V4, the same as in sinus. In many cases, precordial leads positioning in the electrophysiology laboratory is slightly different from that in the clinic because of defibrillation patches and electrode patches for the electroanatomic mapping system, if used.

In general, the ECG leads are the last of these to be applied to the chest, and are placed as close to standard locations as possible, but working around patches that are already in place for other purposes. Thus ECGs taken at this setting may not be identical to those obtained in other settings.

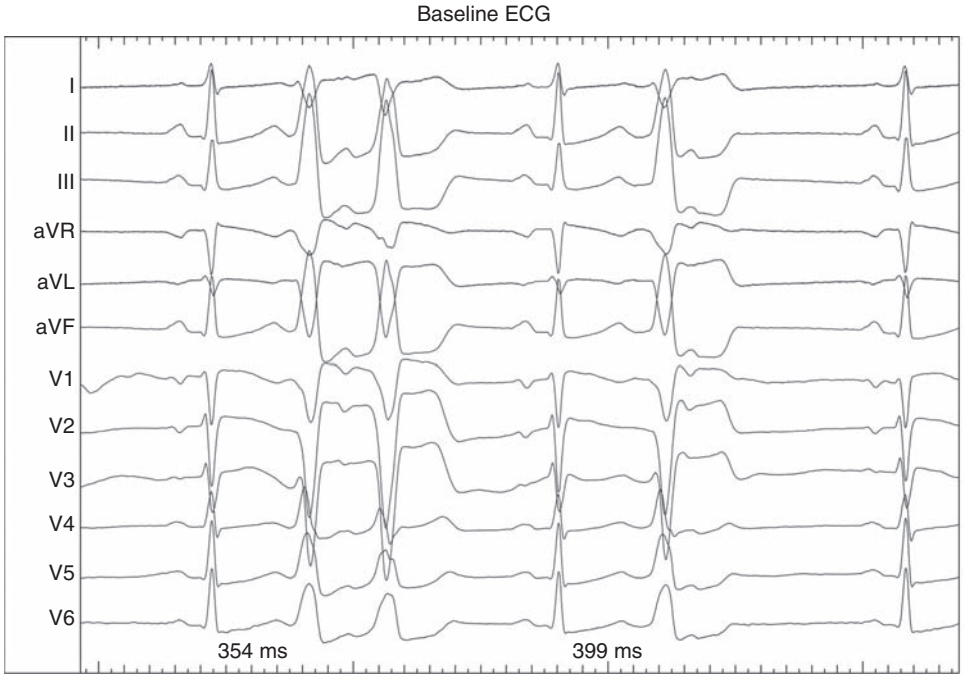

Figure 18-3

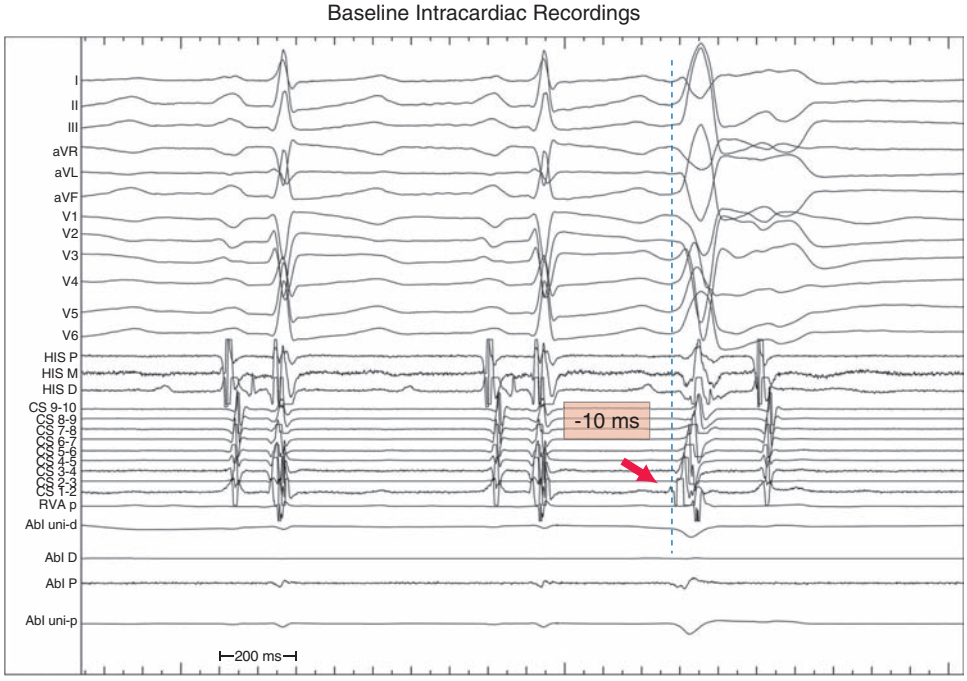
A few minutes later in the procedure, PVC coupling intervals in Fig. 18-3 are less constant. It is important to acquire several examples of spontaneously occurring PVCs, as well as noting their coupling intervals, before placement of any endocardial catheters that could cause catheter-induced ectopy and introduce confusion as to morphology and timing of PVCs. Does this indicate anything about target site location?

Figure 18-4

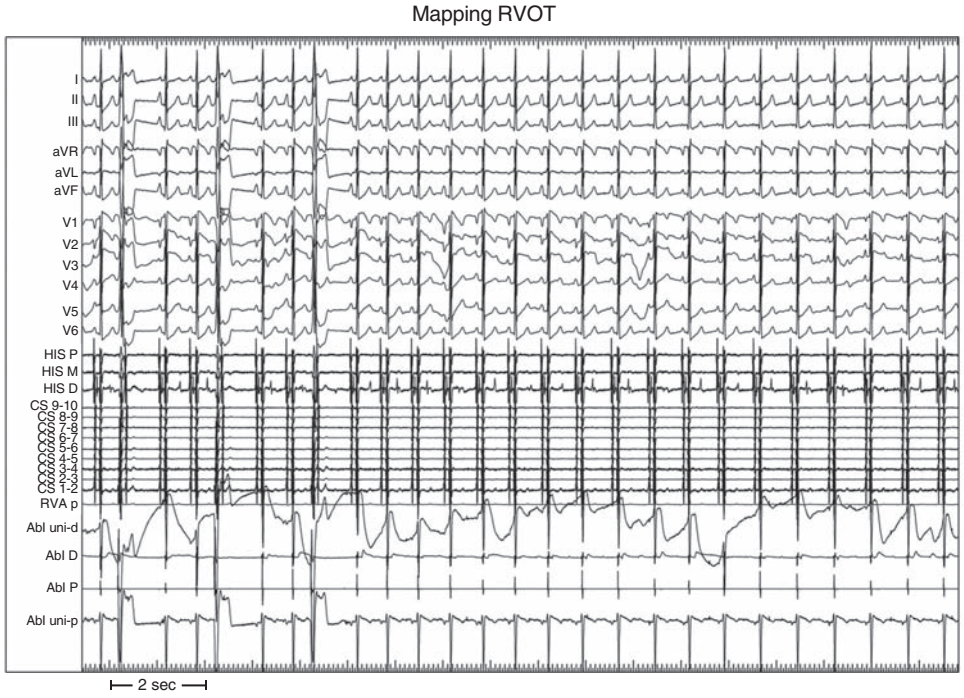


In Fig. 18-4, the coronary sinus (CS) catheter tip has been positioned at the top of the mitral annulus (as distally as possible); the onset of the QRS complex is denoted by a *dashed line*. A far-field component of the distal CS ventricular recording precedes the QRS onset by 10 ms. This suggests that the actual focus is nearby, but probably not exactly at this location (timing at the actual source should be 20 to 40 ms before PVC's QRS onset).

Mapping Different Sites

Does This Mean Anything? [Fig. 18-5]

Figure 18-5



Manipulation of the mapping catheter in the right ventricular outflow tract, where mapping was started, resulted in sudden cessation of ventricular ectopy whereas it previously had occurred every 4 or 5 complexes (seen at left in Fig. 18-5). This probably means that the catheter has "bumped" into the tissue at the source, rendering it transiently depolarized

and unable to discharge again until recovery has occurred. If this is a correct interpretation, it is reasonable evidence that the origin is nearby—endocardial RVOT, and not in the great cardiac vein, left ventricle, epicardial surface, or sinus of Valsalva.

Is This a Good Ablation Site?

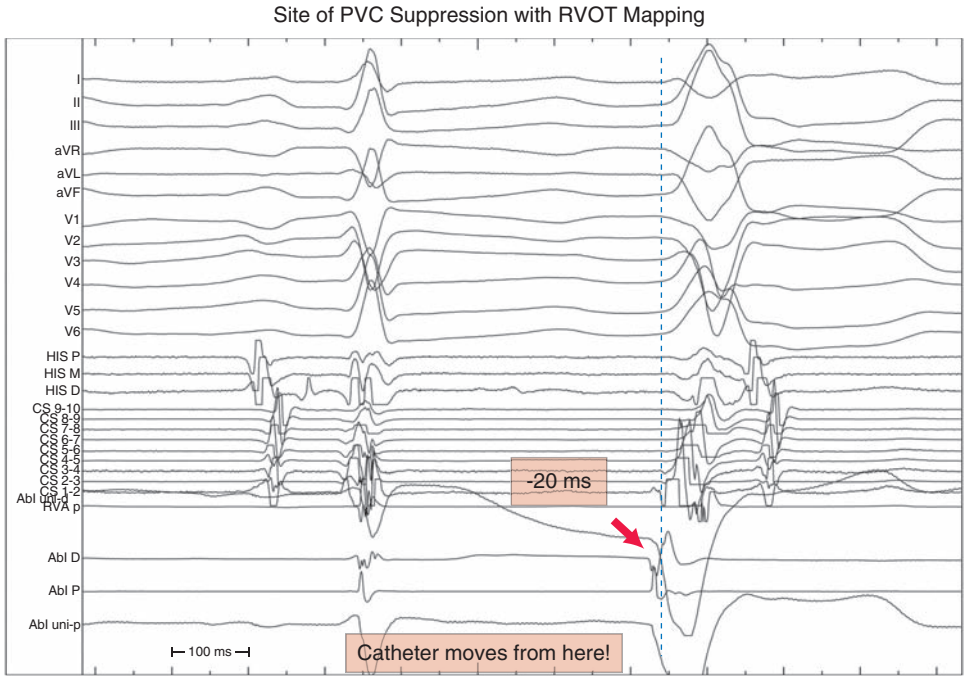


Figure 18-6

Recordings displayed in Fig. 18-6 were made just before inadvertant catheter dislodgement from the site, after which ectopy transiently ceased. Catheter-mediated trauma that eliminates pathway conduction or focal firing suggests proximity to an important site for the arrhythmia. Often, however, trauma has occurred during somewhat vigorous catheter movement (not just gentle "bumping"), so the effect may not be very localizing, and (more important) the catheter tip has often moved on from where the contact actually affected the rhythm—such that the location where it is first observed after the event may not be where the effect occurred. However, the electrogram at this site just before catheter movement had a timing 20 ms before QRS onset and suggests it was, in fact, close to the origin.

Is This a Good Site?

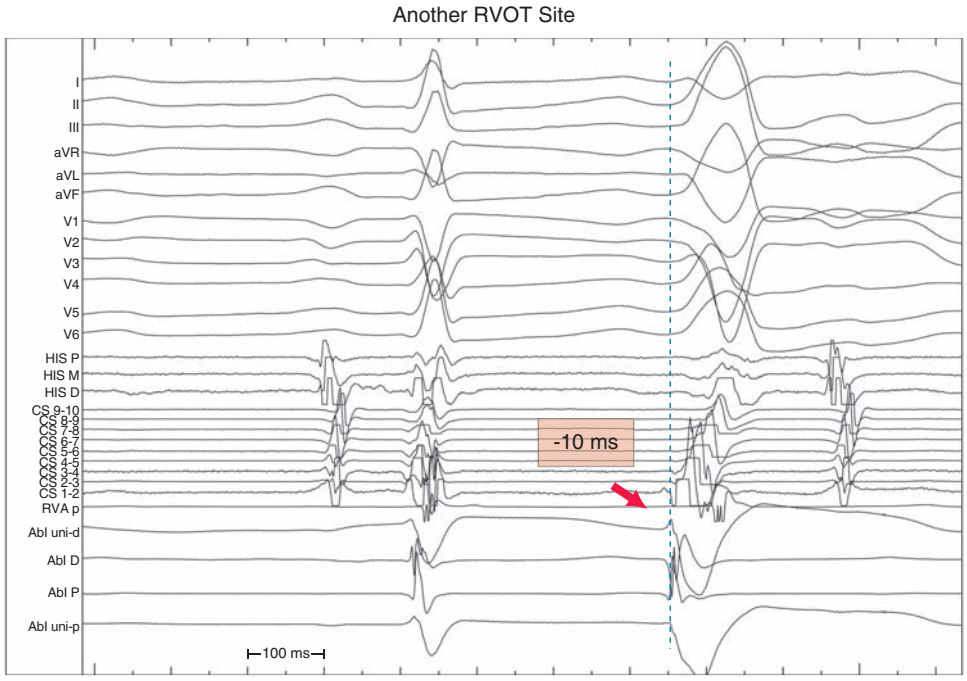

Figure 18-7

Mapping was continued after resumption of PVCs (Fig. 18-7). This is not such a good site; the distal unipolar recording has an R wave, and the proximal bipolar recording is almost as early as the distal, neither of which are as good as the prior site.

Algorithm Says 94% Match. Ablate Here?

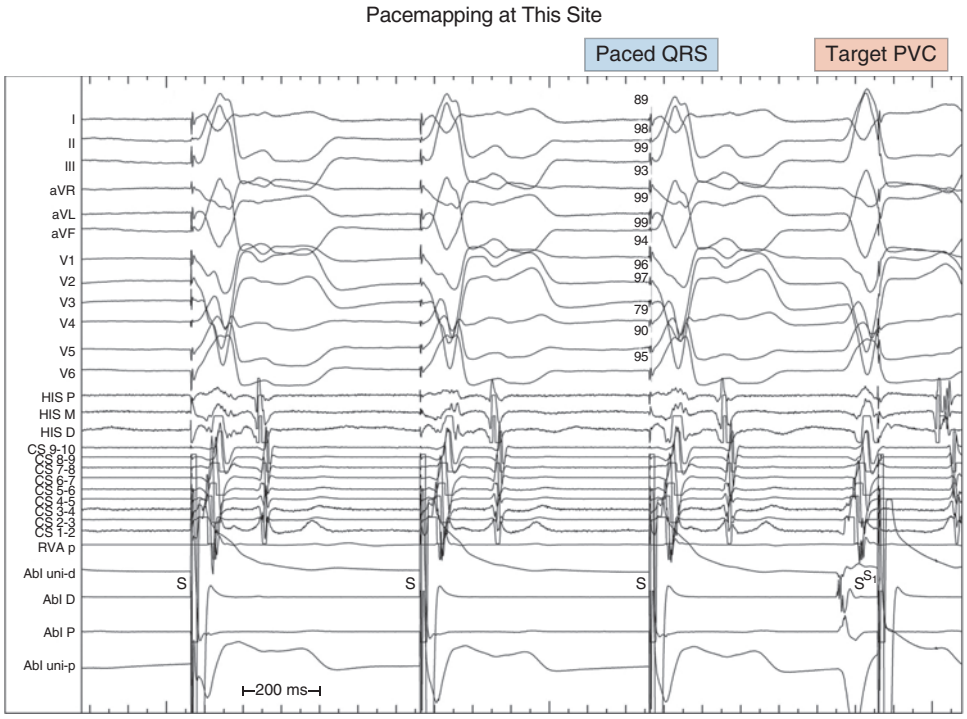

Figure 18-8

Pacing at this site (Fig. 18-8) yields a reasonable, but far from perfect, match. Ablation was not attempted here. Numbers to the left of each QRS complex on the 3rd paced cycle indicate percentage of morphology match (aggregate, 94%), using an algorithm in the recording system.

Algorithm Says 92% Match. Ablate Here?

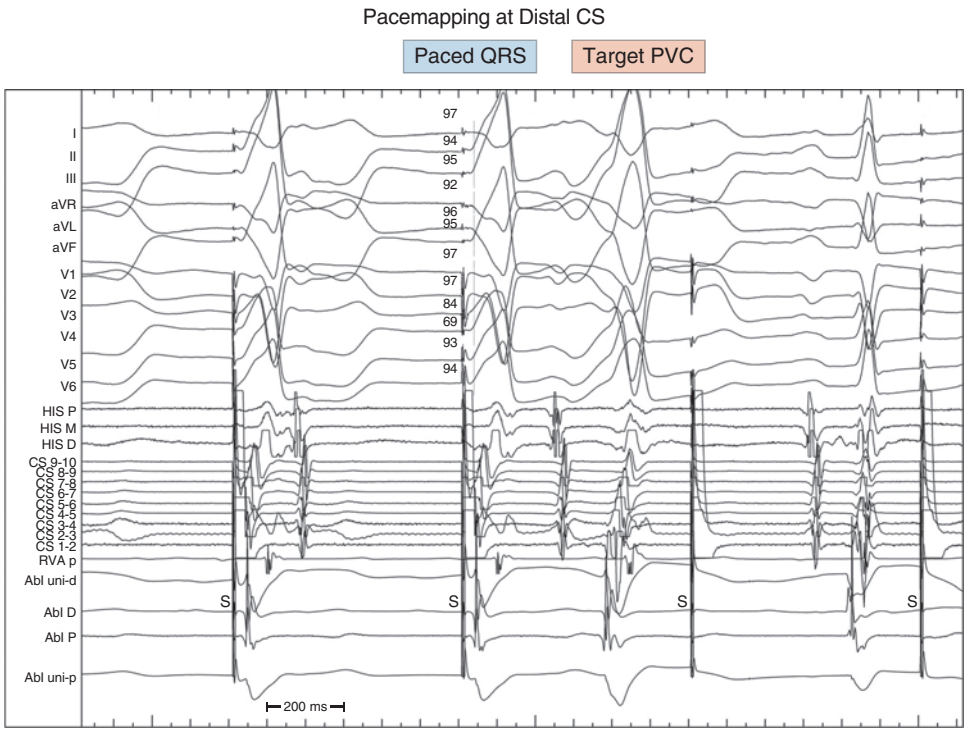

Figure 18-9

Pacing from the distal CS electrode pair yields a reasonable, but inexact, match with the PVC (Fig. 18-9). Ablation was not attempted here.

Is This a Good Site?

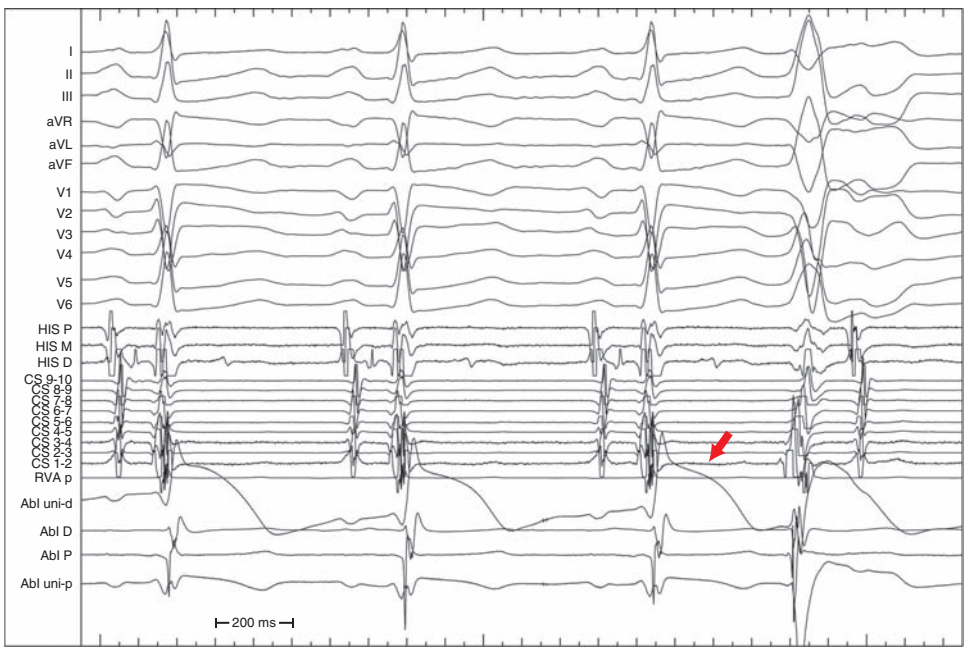

Figure 18-10

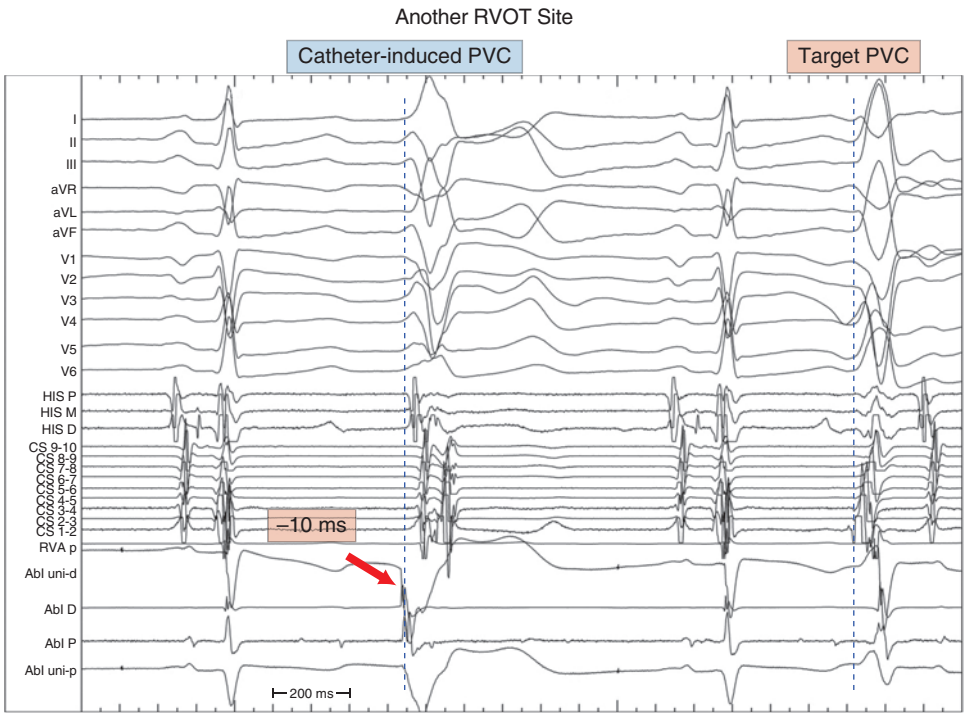
Mapping is continued back in the RV outflow tract. ST elevation on the unipolar recording (Fig. 18-10, *red arrow*) indicates too-good contact, threatening perforation. The catheter tip should be withdrawn somewhat from this point.

Is This a Good Site?

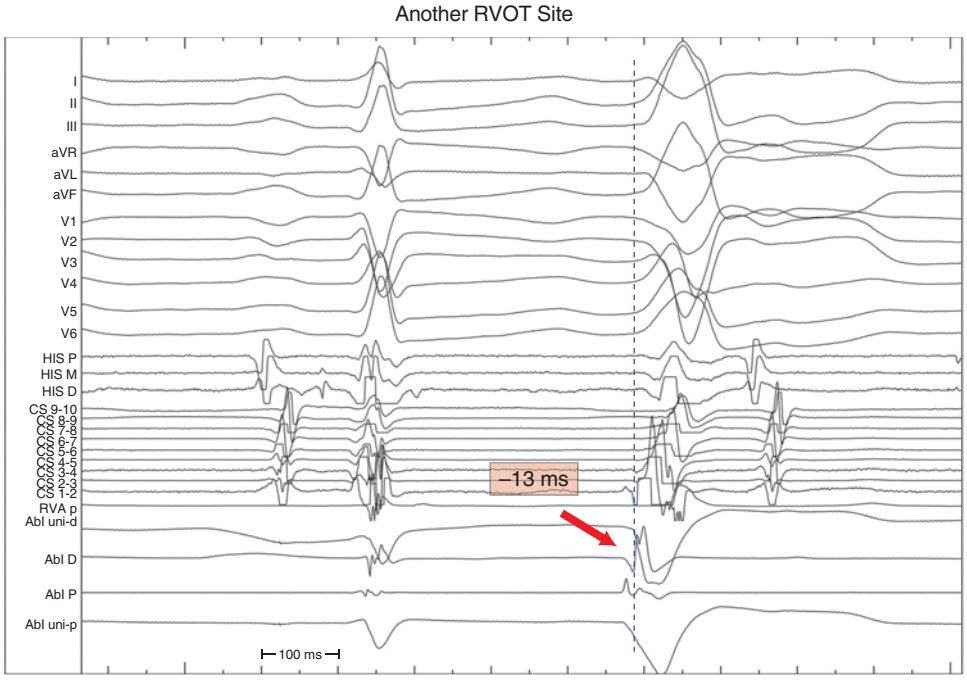
Figure 18-11



Mapping continues; in Fig. 18-11, a reasonably good site is shown; the unipolar recording has no R wave, and it is reasonably early. However, this is a catheter-induced PVC. The beginning of the QRS is difficult to see because of partial obscuration by the P wave. This site is not early during the real PVC (at right).

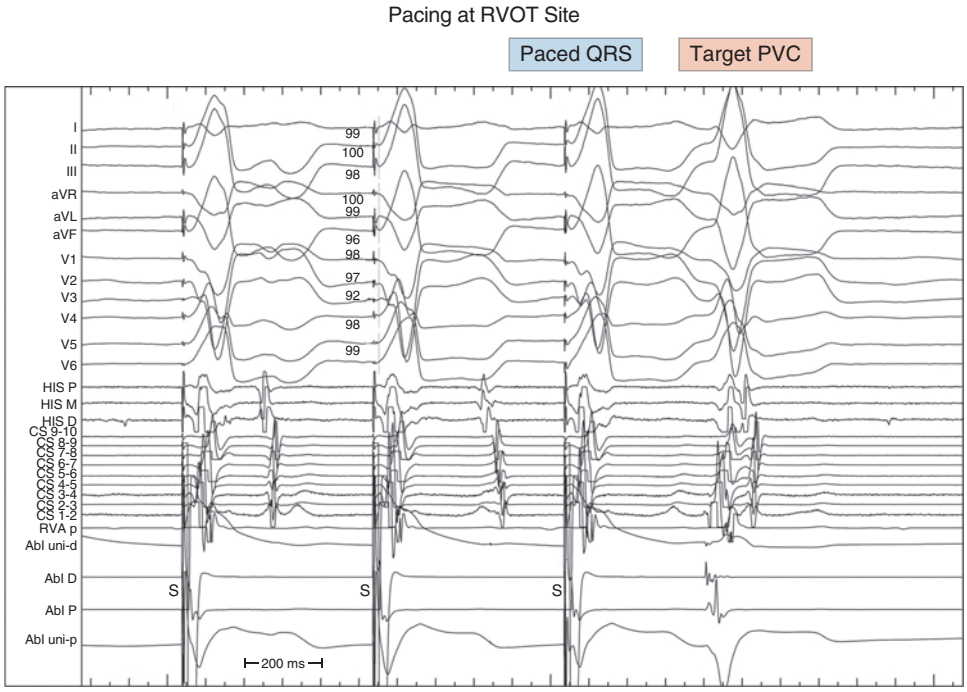
Is This a Good Site?

Figure 18-12



Additional mapping in the RV outflow tract shows another reasonably good site in Fig. 18-12; the unipolar has no R wave, and it is reasonably early. However, the proximal bipolar is almost as early as the distal, and distal unipolar and bipolar do not "agree." This was very near the "bump" site and directly across from the CS tip electrode.

Pacemapping to Corroborate Activation Mapping Data



Algorithm Says 94% Match. Ablate Here?

Figure 18-13

In Fig. 18-13, pacing at the site shown in Fig. 18-12 yields the best match yet, which visually/qualitatively seemed better than the 94% match calculated by machine reading. Ablation was attempted here.

First Ablation Attempted

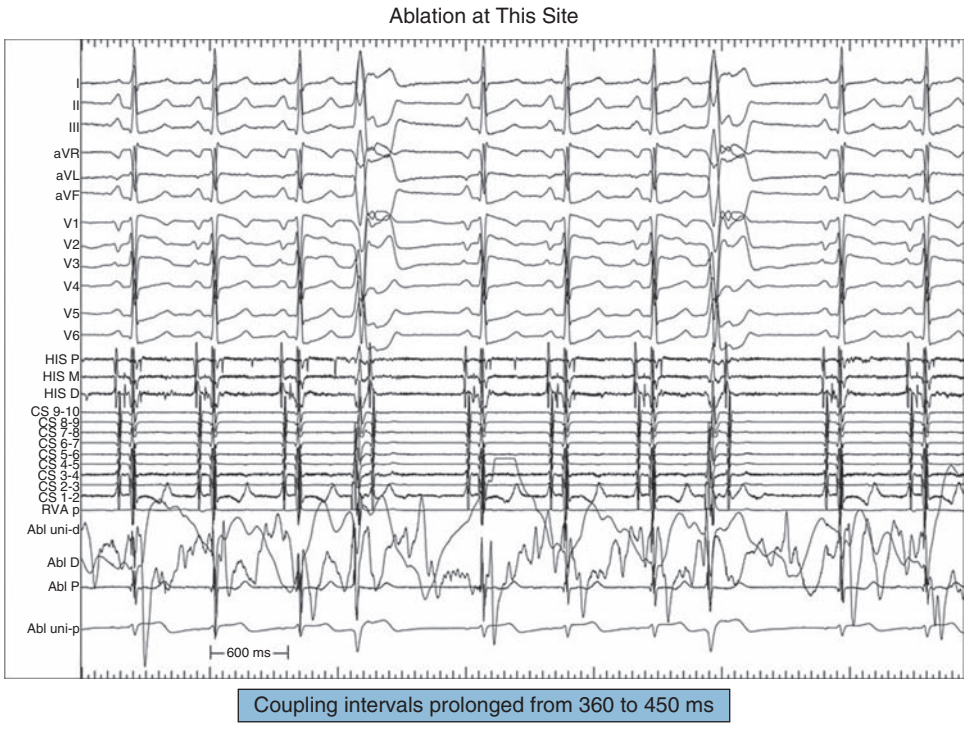


Figure 18-14

As a result of ablation, the coupling intervals of the PVCs from prior complexes increased substantially (Fig. 18-14); nevertheless, PVCs persisted. This probably indicates that the ablation site was near enough to the focus to have an effect on it, but not eliminate it.

Status Update

- RVOT has been thoroughly explored; no better sites were found
- Distal coronary sinus (CS)/great cardiac vein (GCV) has early potential, but we cannot advance the catheter further and cannot get the ablation catheter close to the same site in GCV
- What next?
  - Pericardial access and epicardial mapping?
  - Aortic sinus of Valsalva/left ventricular mapping?
  - Try harder to get the ablation catheter out the CS/GCV?

Mapping Other Sites

Is This a Good Site? [Fig. 18-15]

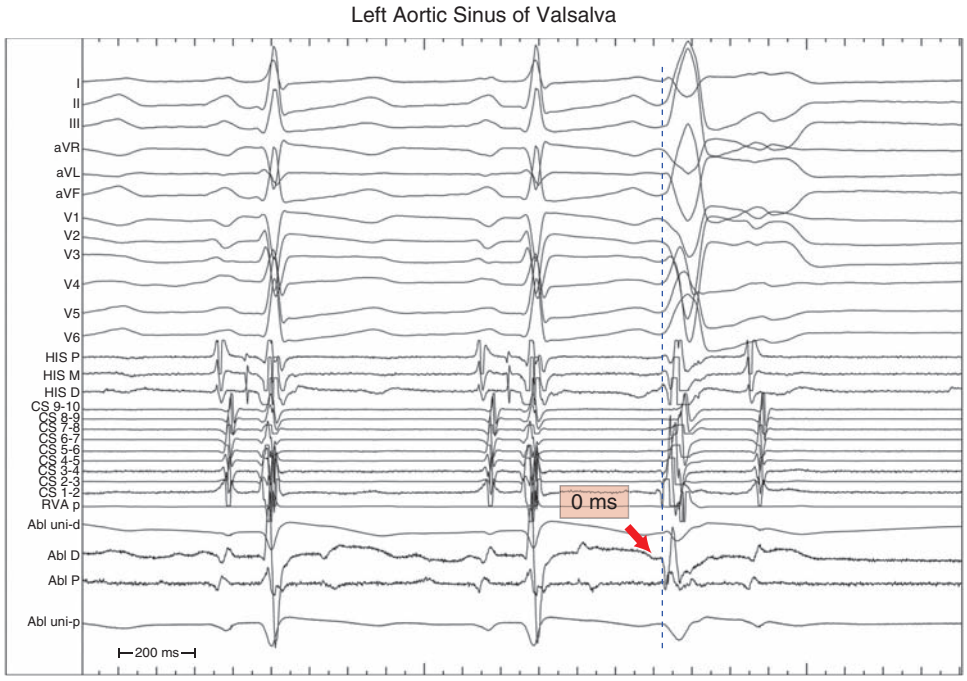

Figure 18-15

Mapping in the left aortic sinus of Valsalva (SOV) shows a site with poor features (Fig. 18-15); timing is not good at all. Because LV myocardium is some distance away, the unipolar signal is less helpful in the left SOV than when in contact with ventricular myocardium.

Algorithm Says 85% Match. Ablate Here?

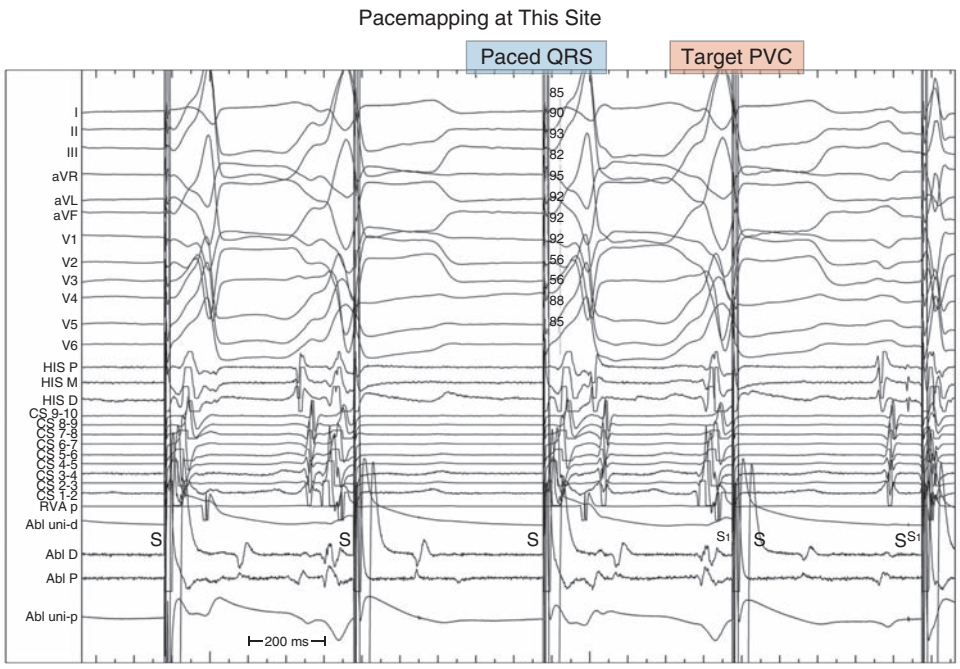

Figure 18-16

Pacing at the site shown in Fig. 18-16 (left aortic SOV) yields the poorest match yet; however, some PVCs can be ablated from this site with poor electrogram and pacemap features. Ablation was attempted here after left coronary arteriography showed >6 mm from this site to the left main ostium. PVCs continued unaffected by a 30-second application of ablation energy.

Is This a Good Site?

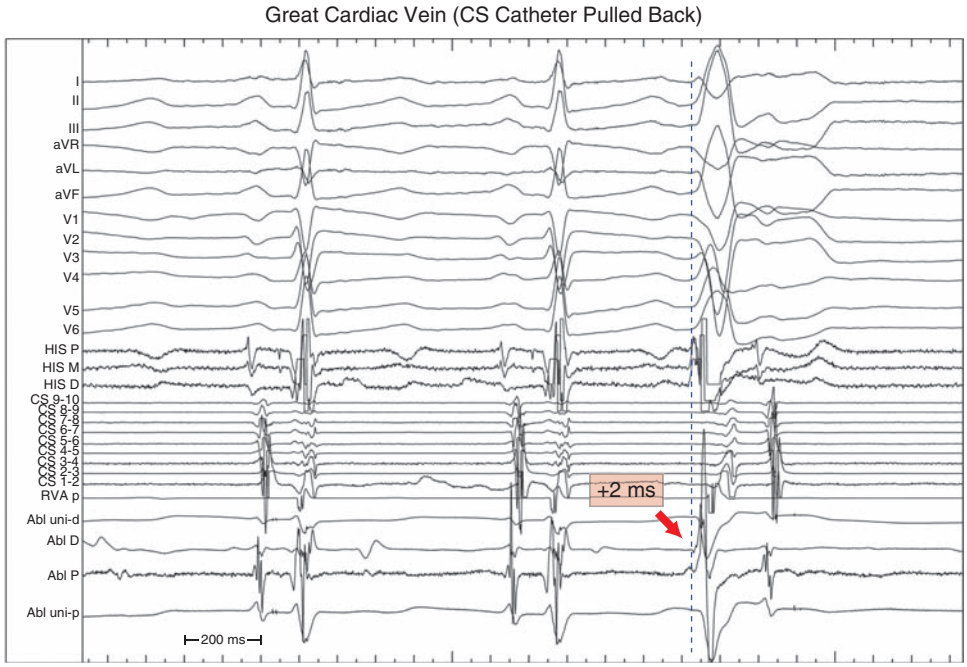

Figure 18-17

Next, the ablation catheter was inserted into the CS and advanced to the great cardiac vein (required partial withdrawal of the CS catheter to fit). Mapping here (Fig. 18-17) showed a poor site; the catheter tip could not be advanced further. The proximal recording has a far-field signal suggesting that something nearby is early (very gained up).

Algorithm Says 79% Match. Ablate Here?

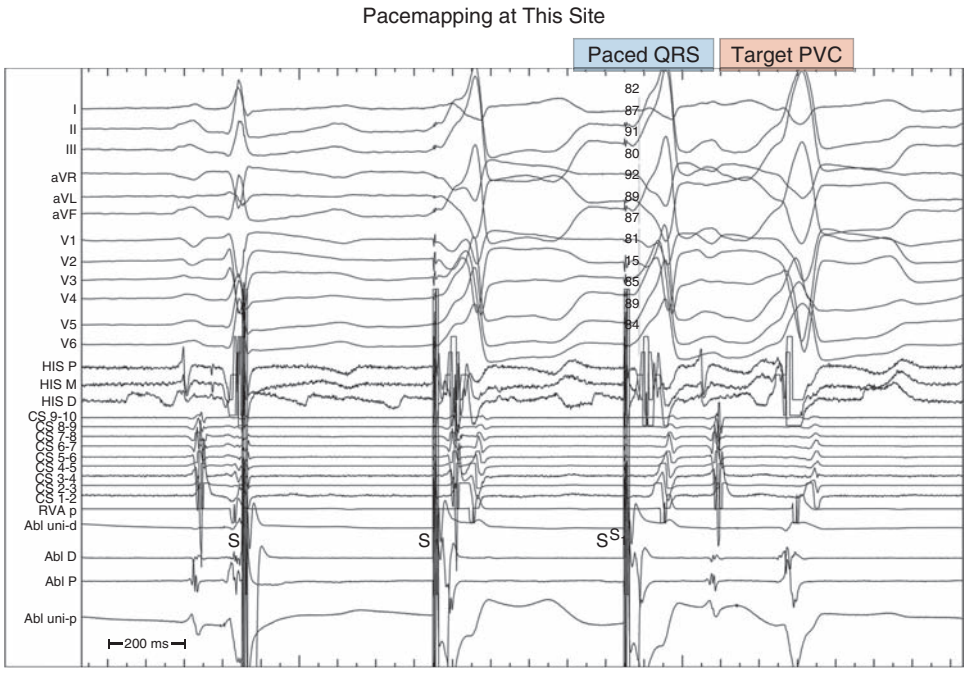

Figure 18-18

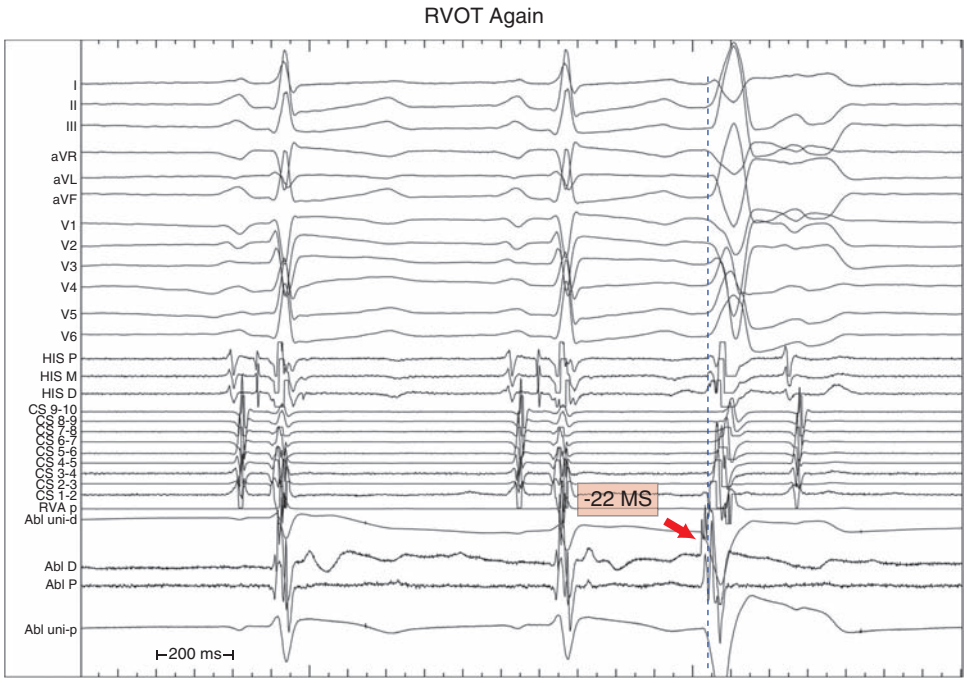
Pacing at this site (Fig. 18-18) in the distal CS yields the poorest match of all (aggregate match 79%); there is no point in attempting ablation in this small vessel with such poor mapping features.

Status Update

- RVOT has been thoroughly explored; no better sites were found
- Aortic sinuses of Valsalva showed poor sites
- Distal CS/GCV was even less promising
- What next?
  - Pericardial access and epicardial mapping?
  - Go back to RVOT where best sites were, and where "bump" mapping was observed?

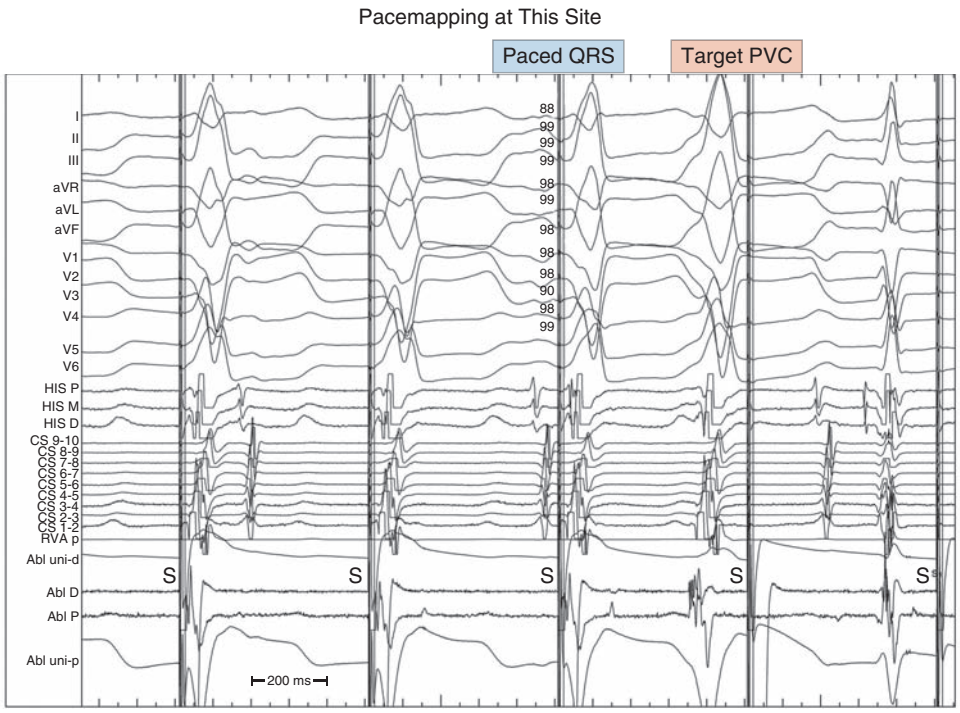
Repeat Right Ventricular Mapping and Ablation



Is This a Good Site?

Figure 18-19

Back in the right ventricular outflow tract again, a very good site is encountered in Fig. 18-19; all good target site features are fulfilled.



Algorithm Says 97% Match. Ablate Here?

Figure 18-20

Pacing at this site (Fig. 18-20) yields a very good pace-match (aggregate, 97%) with the spontaneously occurring PVC. The pacing output is only 2 mA; the lower the output, the more specific this finding is.

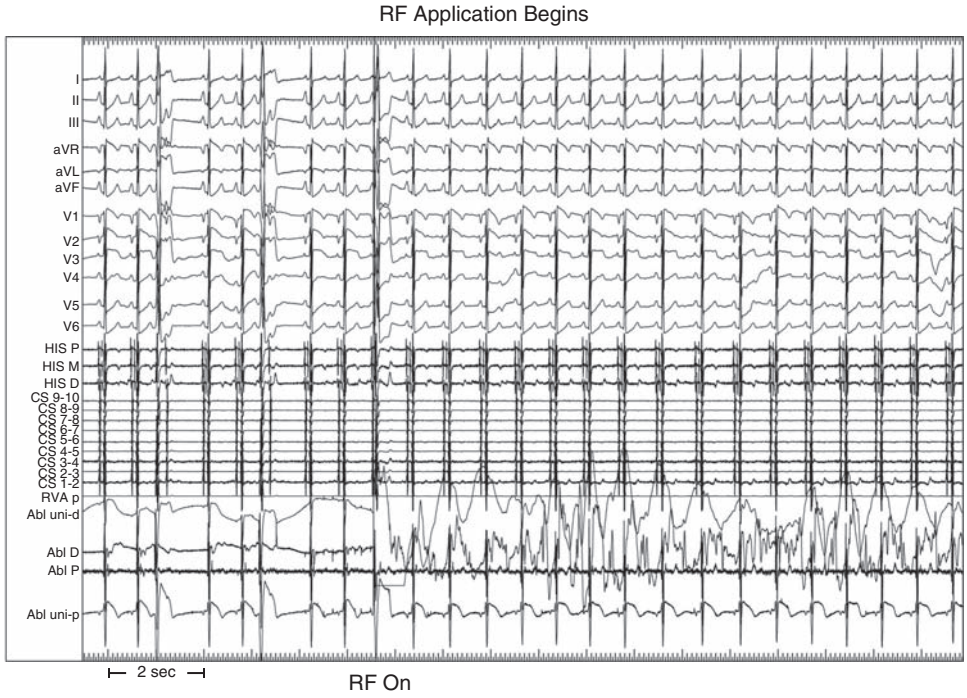


Figure 18-21

Immediately upon beginning radiofrequency (RF) energy delivery at this site in the RVOT, PVCs ceased and did not recur for the remainder of the procedure (Fig. 18-21).

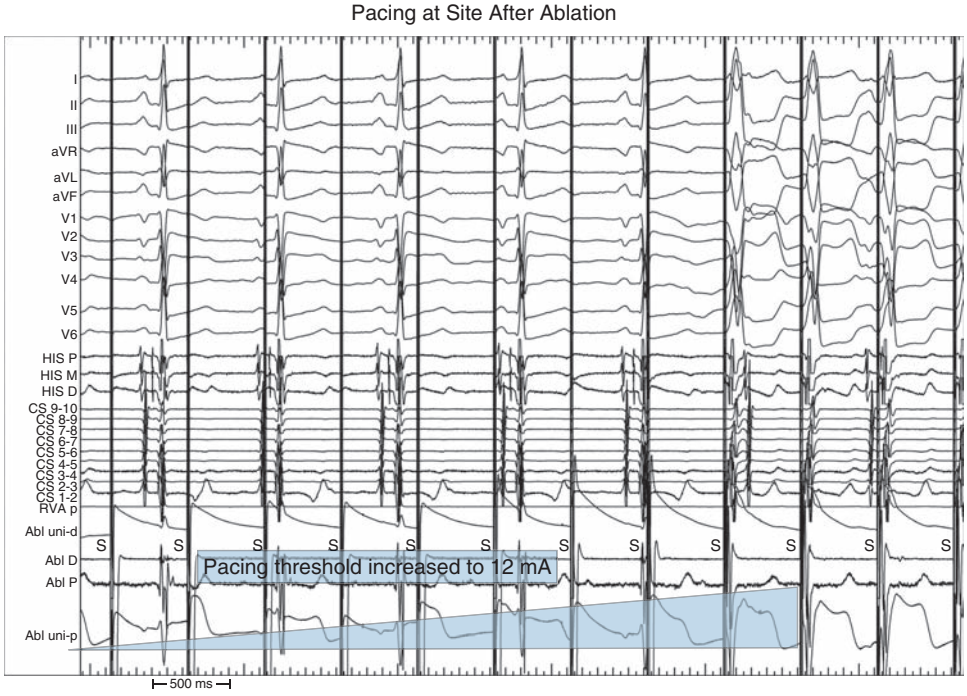

Figure 18-22

After RF application that eliminated ventricular ectopy, pacing at that site has a markedly elevated capture threshold (Fig. 18-22), indicative of substantial damage to the area. In addition, especially evident on the last two complexes on the right, ST elevation in the unipolar recording is seen, corroborating damage.

Images of Catheters and Maps

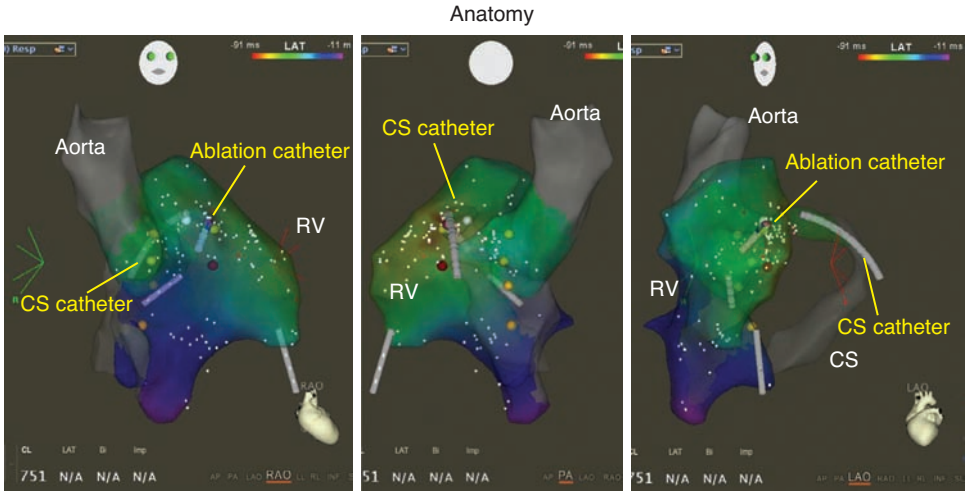

Figure 18-23

Fig. 18-23 displays electroanatomic mapping views of activation timing obtained during PVCs. Different chambers mapped are shown with labels (aorta [root], RV = right ventricle, CS = coronary sinus). In the left anterior oblique view, it is easy to see how the distal CS recordings could have early activation and yet the arrhythmia originates in the leftward aspect of the right ventricular outflow tract, with the two catheters (CS and ablation) nearly touching.

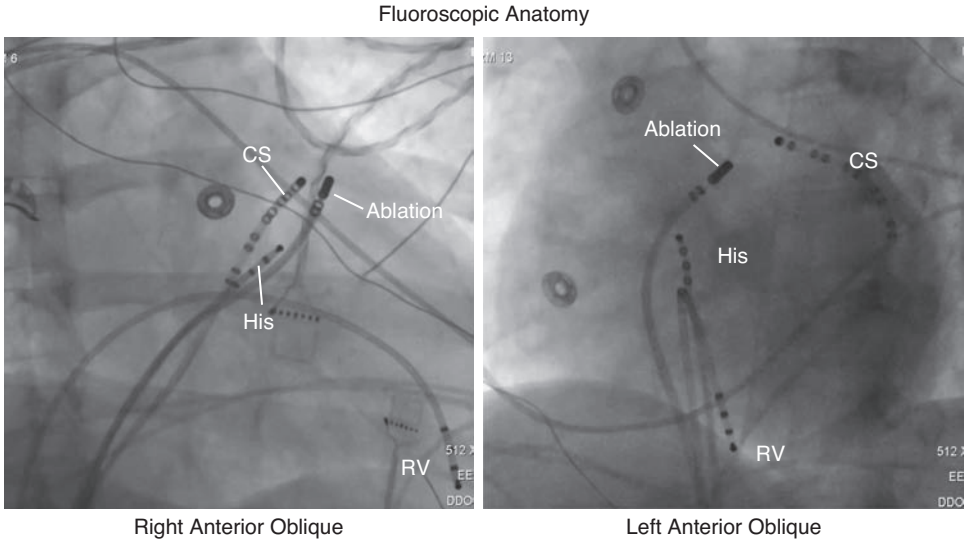

Figure 18-24

Right and left anterior oblique fluoroscopic views of catheter positions, noting especially successful ablation site in the right ventricular outflow tract, are shown in Fig. 18-24.

Final ECG

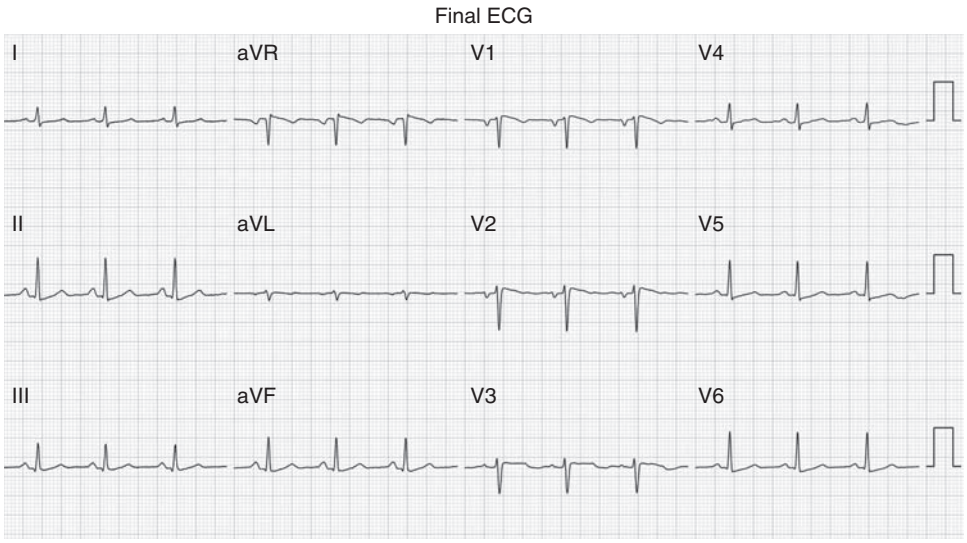

Figure 18-25

The final sinus rhythm ECG (Fig. 18-25) shows no ventricular ectopy. The patient was discharged the next morning, having had no palpitations or ectopy overnight, or on follow-up as an outpatient.

Mapping Sites Compared

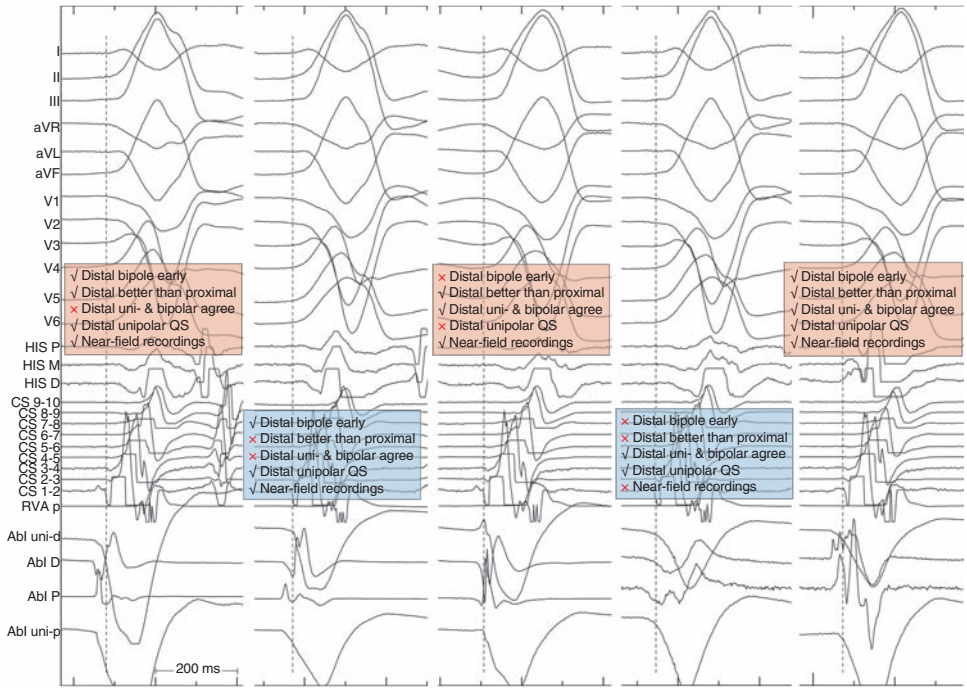

Figure 18-26

Fig. 18-26 provides a summary of electrogram features at different mapping sites, noting good and bad features.

Summary

- LBBB-inferior axis PVCs and VT may arise from:
  - RVOT/pulmonary artery
  - Right aortic sinus of Valsalva
  - LV or RV endocardium
  - LV or RV epicardium
  - Left aortic sinus of Valsalva/great cardiac vein (rare)
- Preprocedure ECG is an indicator of probability of location, but is not entirely specific
- After disappointing mapping and ablation in other areas, it is worth revisiting areas that had reasonable target features earlier
- Electrogram features of successful ablation sites:
  - Pre-QRS timing 15 to 40 ms
  - Unipolar "QS" configuration
  - "Agreement" between unipolar and bipolar recordings
  - Near-field characteristics (high amplitude, high frequency)
  - Consistent appearance from beat to beat (contact)

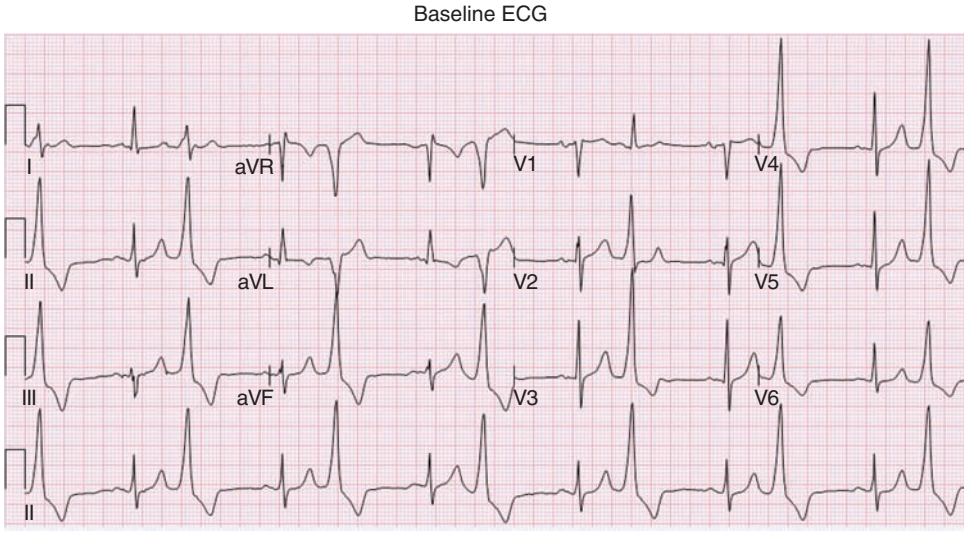
19 Coronary Sinus Ventricular Ectopy

Case Presentation

A 65-year-old man experienced symptomatic premature ventricular complexes (PVCs) for years. He initially sought evaluation 5 years ago because of palpitations: he was found to have an irregular pulse and a soft systolic murmur; ECG showed frequent PVCs; stress test was equivocal for ischemia and had no effect on PVCs; coronary arteriography showed normal epicardial arteries. After all this, he preferred no treatment. However, he developed increasing fatigue in the last few months. Ambulatory ECG showed very frequent PVCs and nonsustained ventricular tachycardia (~57% of complexes were ventricular in origin). Echocardiogram showed ejection fraction of 28% and moderate to severe valvular aortic stenosis. He was referred for consideration of transcutaneous aortic valve replacement (TAVR) and electrophysiologic evaluation and possible ablation.

Baseline ECGs

Figure 19-1



In Fig. 19-1, bigeminal ventricular ectopy is present with fixed coupling to the prior normal QRS.

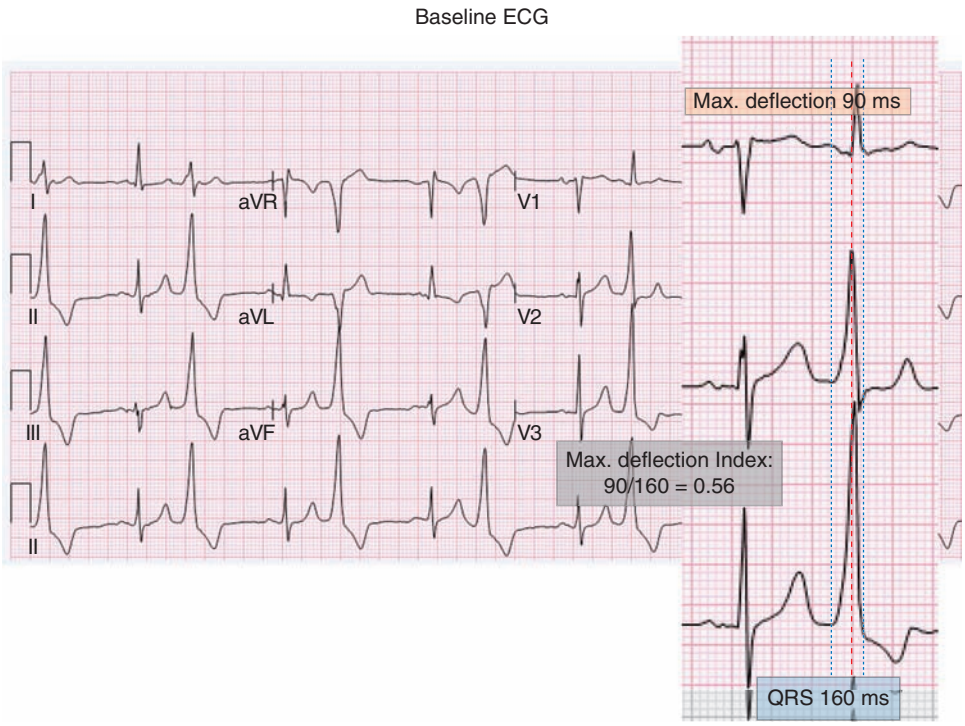


Figure 19-2

The QRS configuration in Fig. 19-2 suggests a possible epicardial source of ventricular ectopy because of the maximum deflection index (0.56). Another potential source, the left aortic sinus of Valsalva, might well become difficult to access (or be completely inaccessible) if he underwent TAVR or surgical valve replacement. Thus EP evaluation and potential ablation before an aortic procedure were reasonable.

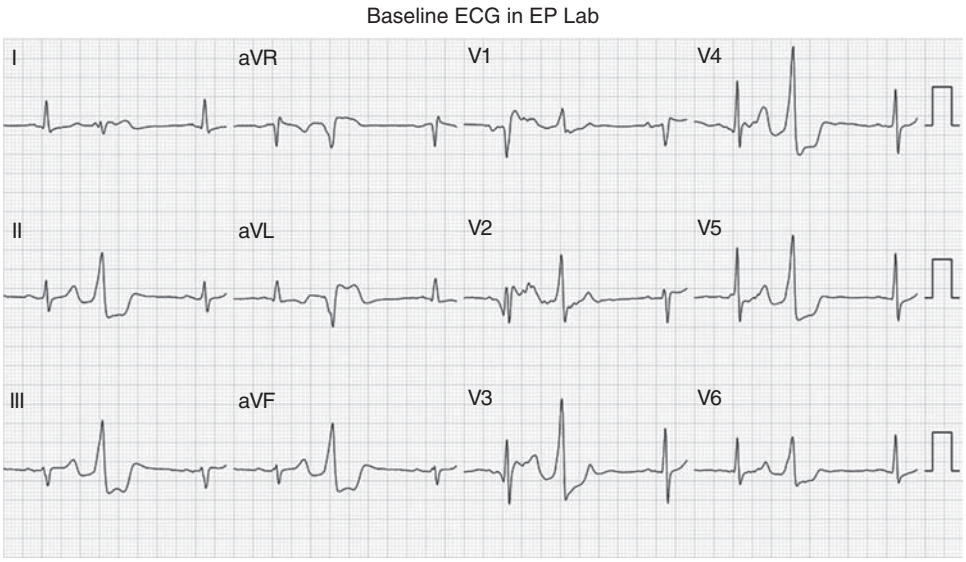

Figure 19-3

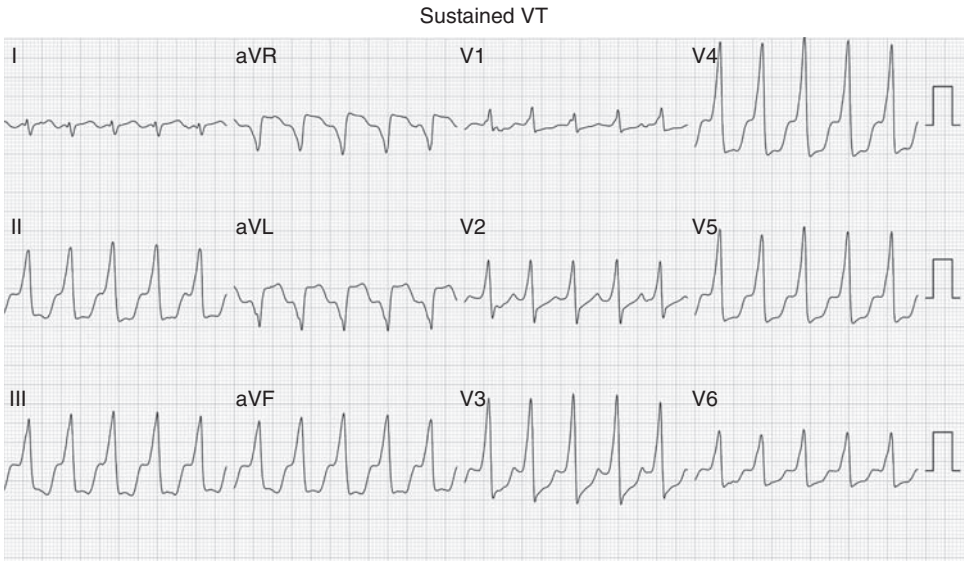
PVCs have a slightly different configuration in lead 1 of Fig. 19-3 compared with the office ECG, likely because of lead placement variation. This is a significant limitation of matching ECG morphologies (ventricular tachycardia [VT], Wolff-Parkinson-White syndrome [WPW] of spontaneously recorded episodes with those recorded in the EP laboratory; the ECG leads are typically the last things to go on the patient's chest when they are being prepared for the procedure (defibrillation pads and mapping system surface patches claim their territory first, with whatever skin is left over available for precordial ECG lead placement). It is well-known that differences in limb lead position can influence frontal plane ECG lead appearance.

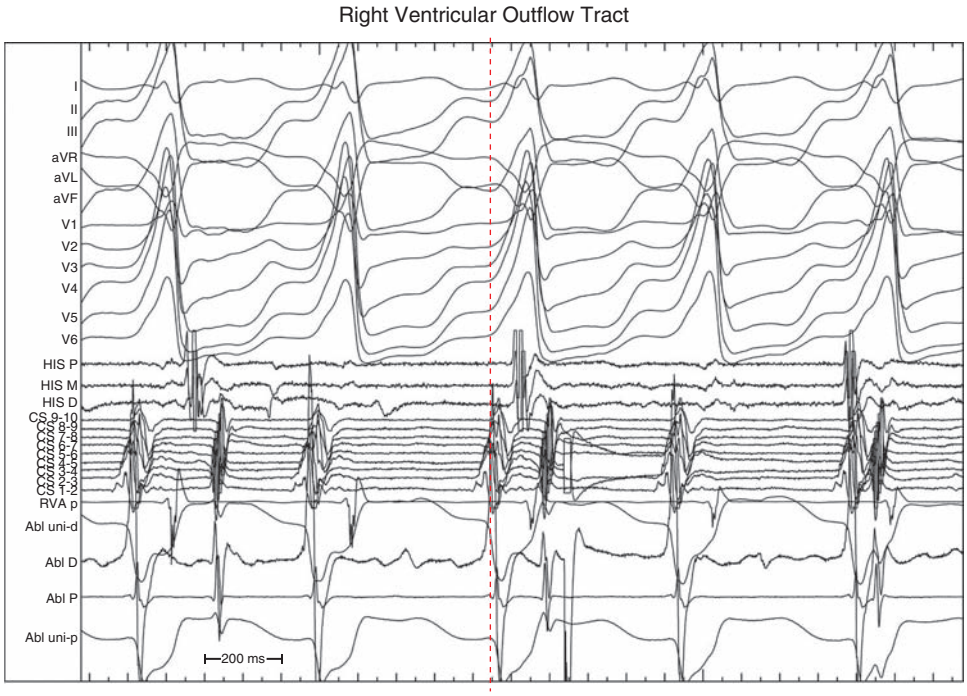
Figure 19-4



Sustained VT developed while operators were getting vascular access (no catheters in the heart at this time). See Fig. 19-4. This was hemodynamically tolerated and came and went during the procedure (went back to sinus with bigeminy, then VT intermittently).

Mapping Various Sites

Figure 19-5



A coronary sinus (CS) catheter, positioned as distally as possible, can often show early activation times and provide clues as to whether the origin is likely to be remote from the recording site (endocardial or aortic sinus of Valsalva, indicated by late activation in the CS), nearby on the epicardial surface (presystolic but far-field appearing), or associated with the coronary venous system (presystolic and near-field). In Fig. 19-5, the distal CS recording occurs well before the QRS onset *(dotted line)* and is relatively sharp, suggesting a nearby source (epicardial, coronary venous, or possibly aortic sinus of Valsalva depending on how close this is to the recording site). Mapping usually starts in the right ventricular outflow tract because, though an unlikely source in this case, it is nonetheless easy to reach. The ablation recording is just at the QRS onset so no ablation was performed.

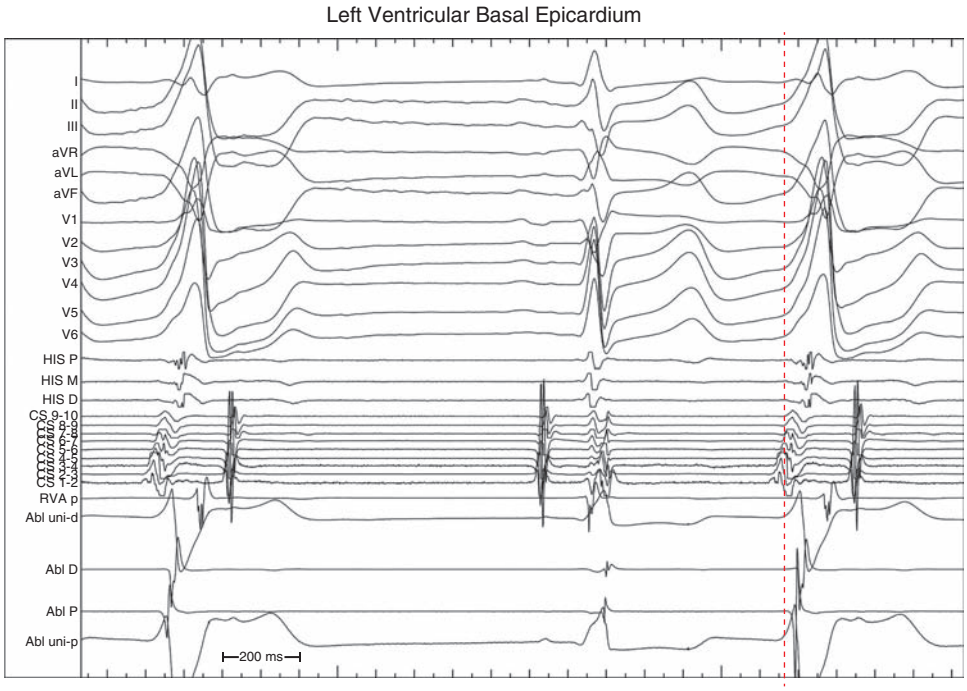


Figure 19-6

Because no attractive ablation sites were found in the right ventricular outflow tract and ECG and electrogram features suggested a possible epicardial source, pericardial access was obtained. In Fig. 19-6, mapping the epicardial surface near the distal CS recording site shows a late activation time, not suitable for ablation. Pacing here (not shown) yielded a poor match with PVCs.

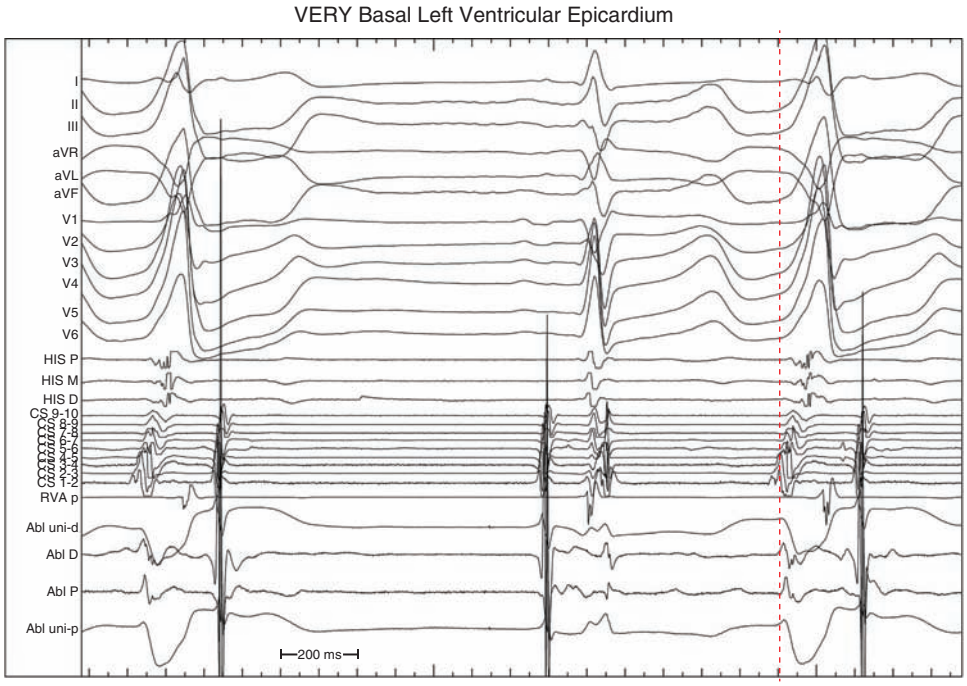

Figure 19-7

A site on the left ventricular epicardial surface even more basal than the prior site (Fig. 19-7, indicated by the large atrial signal) has an electrogram with very minimal presystolic activation with a "QS" in the unipolar recording; the distal bipolar recording precedes the proximal bipolar recording. These features would ordinarily suggest a reasonable ablation site, but earlier recordings remain in the distal CS. Thus this is not an attractive ablation site. Full exploration of areas around this site (that had the best recordings) failed to show any sites more suitable for ablation.

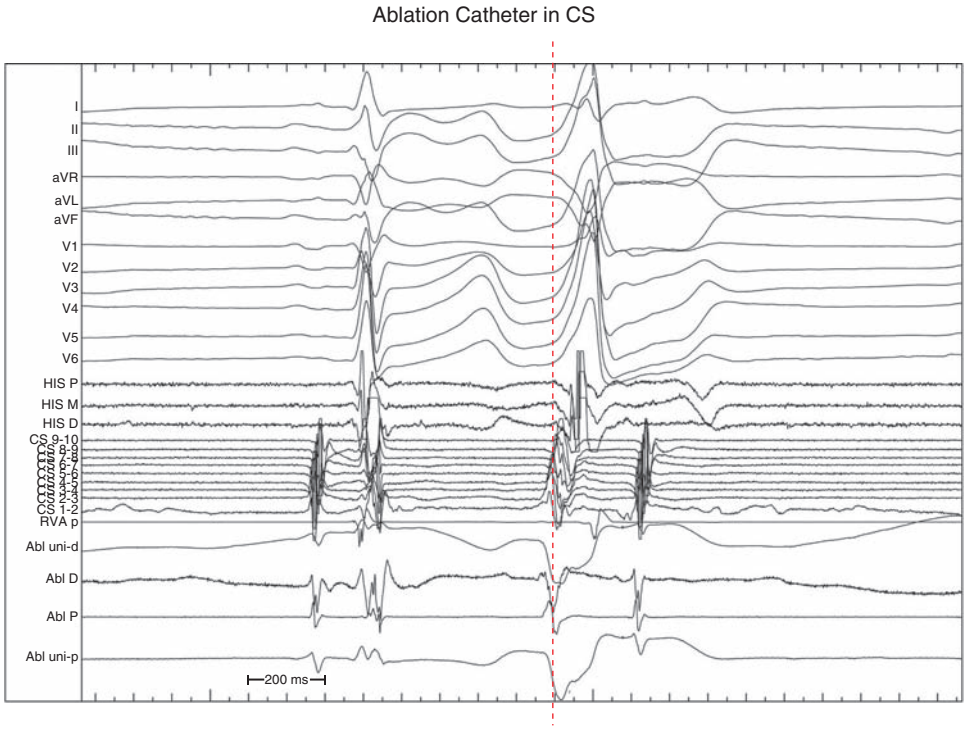

Figure 19-8

The ablation catheter was removed from the pericardial sheath (and replaced with the dilator and guidewire), and mapping of the aortic root and sinuses of Valsalva was performed. No sites with either presystolic activation or reasonable pace-matches were observed (Fig. 19-8). The catheter was then removed from the arterial system and positioned in the CS alongside the CS catheter. Now, the distal bipolar recording has a timing equivalent to the distal CS recording.

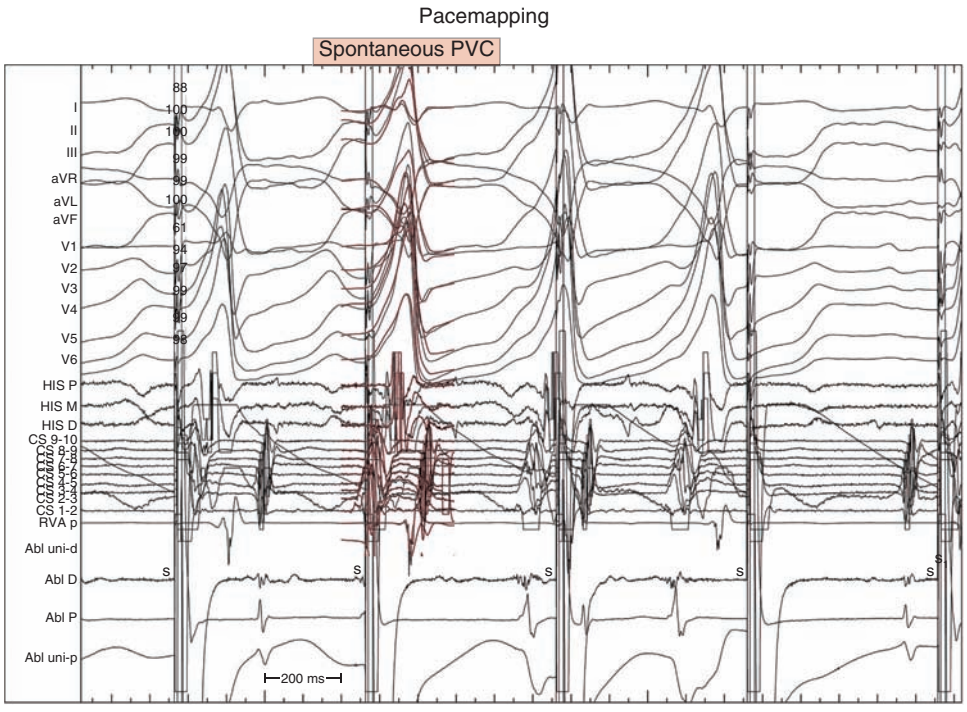

Figure 19-9

Pacing from the ablation catheter at this site yields at 98% electronic pace-match with the spontaneous PVC (Fig. 19-9, superimposed in *red*). This corroborates the early activation in the distal ablation electrode within the distal CS.

Imaging (Fluoroscopy, Electroanatomic Mapping)

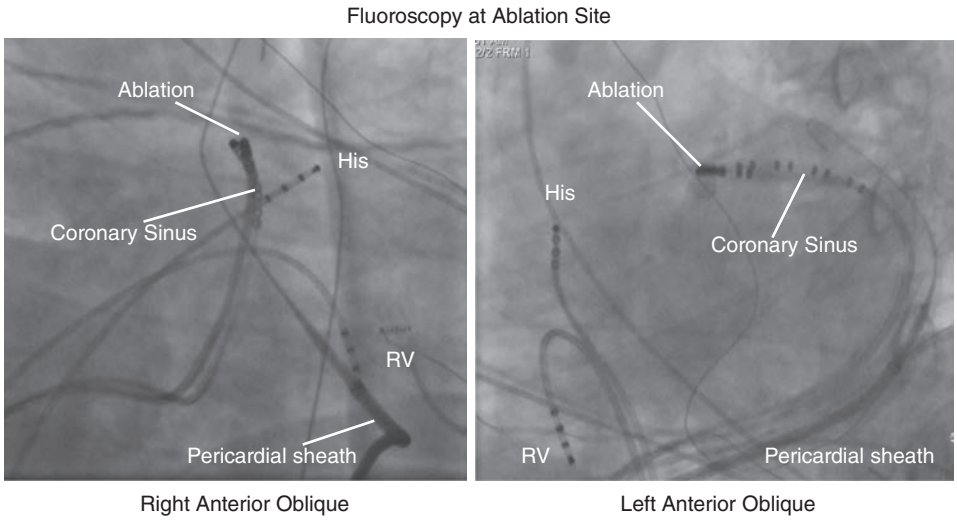

Figure 19-10

Catheter positions during ablation are displayed in Fig. 19-10; note that the ablation catheter tip is slightly distal to the CS catheter (which was pulled back somewhat to allow further advancement of the ablation catheter in the CS). Injection of a diluted solution of radiographic contrast through the irrigation ports of the ablation electrode showed that it was at the junction of the anterior interventricular vein and great cardiac vein. Coronary arteriography showed that the distance to the diagonal artery (closest branch) was about 0.8 cm.

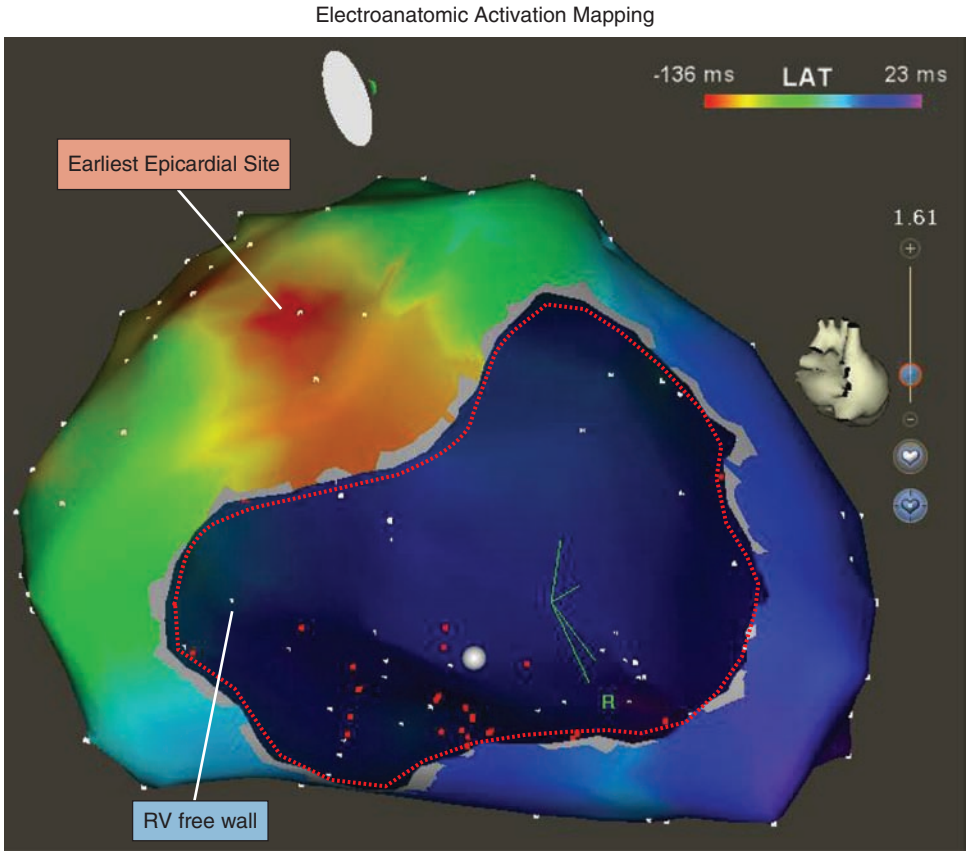

Figure 19-11

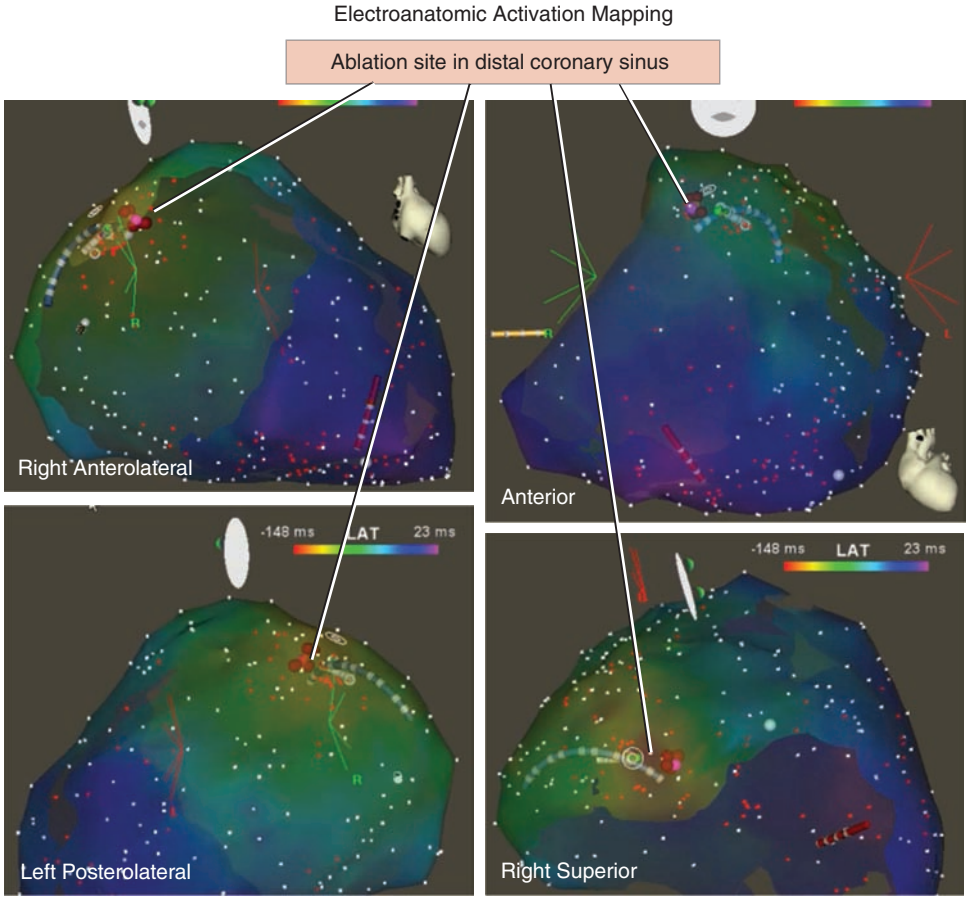
Fig. 19-11 provides an activation map of the PVCs on the epicardial surface. The earliest site *(red)* is surrounded by progressively later sites, typical of a focal process. This was at the junction of the great cardiac vein (distal CS) and anterior interventricular vein. Attempts at ablation here would likely have no effect on the ectopy, because of epicardial fat that is always relatively thick in this area.

Figure 19-12



Electroanatomic activation mapping from coronary venous system and epicardium combined is shown in Fig. 19-12. The epicardial map shown previously has been made slightly transparent to allow visualization of the coronary venous mapping sites. *Red dots* indicate ablation sites in the distal portion of the CS, whereas the *purple dot* indicates the site at which ablation eliminated PVCs. It is evident that this site is fundamentally identical to the epicardial site of earliest activation during the PVC.

Ablation

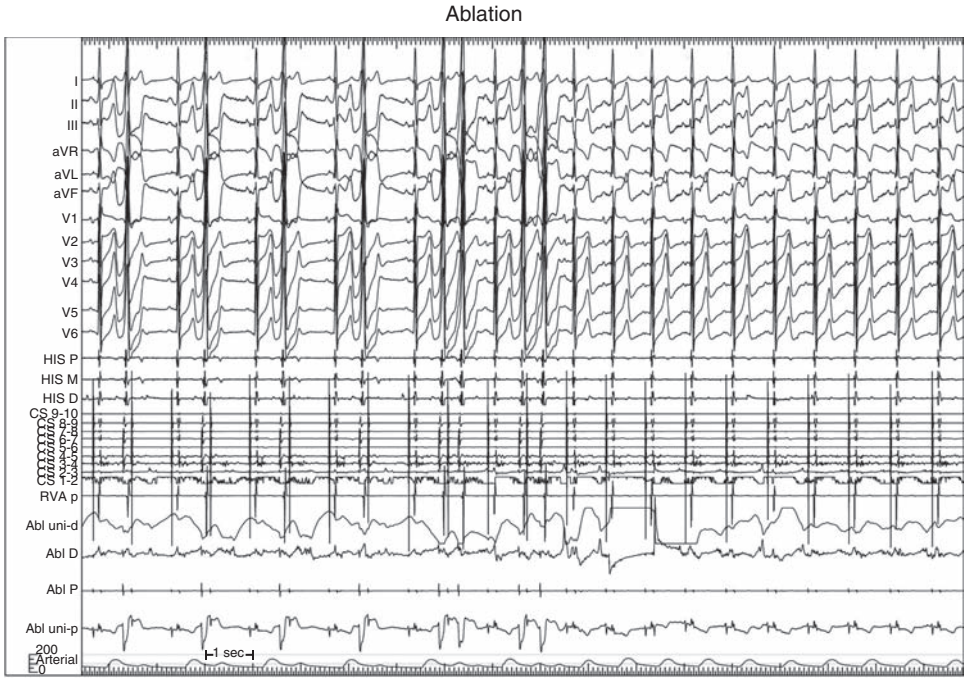


Figure 19-13

Ablation at this site (Fig. 19-13) in the distal CS (15 W) eliminates ventricular ectopy shortly after starting energy delivery. The amount of power delivered in this area should be as little as is needed to achieve the desired effect, because coronary arteries are nearby (left anterior descending, circumflex, or even left main artery). Because the distal CS (actually, great cardiac vein/anterior interventricular vein) is a relatively small vessel, with a relatively small amount of blood to cool an ablation electrode, ablating with a standard (nonirrigated) ablation electrode may not be successful because of rapid heating of the electrode with relatively little power delivery. Using an irrigated electrode overcomes this limitation, allowing greater power delivery without electrode overheating. This does not prevent tissue overheating and steam pops, however. After this RF application, no further ventricular ectopy was observed either spontaneously or after isoproterenol provocation. If this effort had been unsuccessful, ablation in the left aortic sinus of Valsalva would have been attempted.

Hemodynamic Study

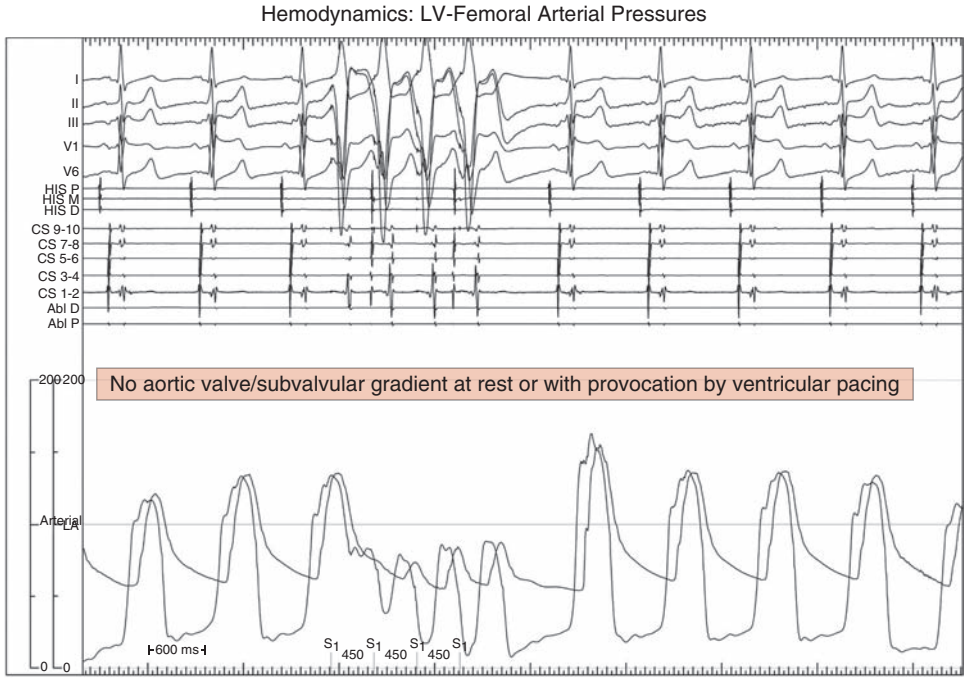

Figure 19-14

A short hemodynamic study after the ablation procedure showed no valvular or subvalvular left ventricular outflow gradient. A burst of ventricular pacing is used to try to provoke a gradient (Fig. 19-14).

Final ECG

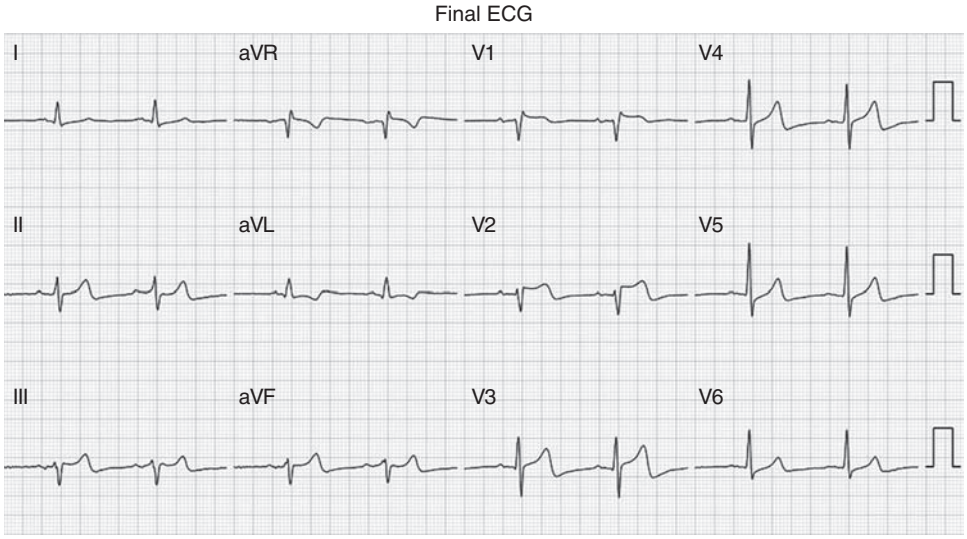

Figure 19-15

The ECG (Fig. 19-15) has entirely normalized, with no residual ectopy. The patient was monitored overnight to ensure no complications related to either pericardial access or ablation in the region of the coronary arteries. Repeat echocardiogram about 10 weeks after the procedure showed ejection fraction 52% and minimal aortic valve gradient.

Summary

- PVCs and ventricular tachycardia that have a configuration that suggests an epicardial source may arise from the actual epicardial surface, or the coronary venous system or aortic sinuses of Valsalva
- Ablation within the coronary venous system is feasible, sometimes necessary, and generally safe, but the veins restrict catheter movement to their lumens; epicardial mapping offers greater versatility, but a layer of epicardial fat interposed between the epicardial surface and catheter in the pericardial space may limit ablation efficacy
- The appearance of abnormal hemodynamics may be related to frequent ventricular ectopy (or other causes of irregular ventricular filling, such as atrial fibrillation)

20 Papillary Muscle Ventricular Ectopy

Case Presentation

A 63-year-old man without prior cardiac history was referred for evaluation of frequent premature ventricular complexes (PVCs). His initial complaint was dizziness and fatigue; finding an irregular pulse led to obtaining an ECG that showed frequent monomorphic PVCs. An ambulatory monitor showed monomorphic PVCs comprising 18% of all complexes. Echocardiogram showed mildly decreased left ventricular ejection fraction (43%). He was referred for electrophysiology study and possible catheter ablation.

Baseline Recordings

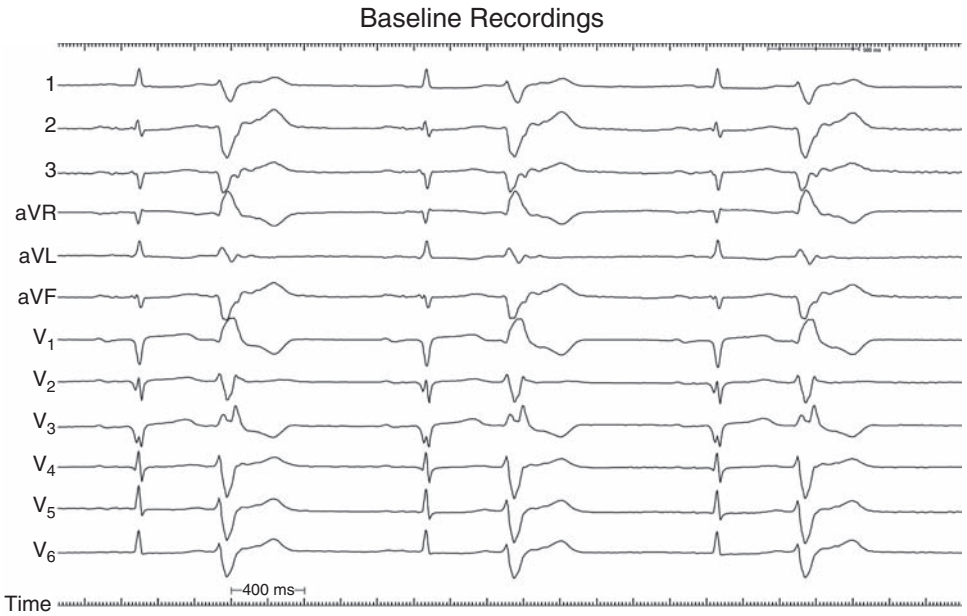

Figure 20-1

Baseline recordings made at the time of EP study (Fig. 20-1) show bigeminal PVCs with a right bundle branch block, rightward superior axis morphology. In a structurally normal heart such as his, the morphology overall suggests an inferolateral, somewhat apical left ventricular (LV) origin (negative in leads 1, 2, and 3 and relatively early R-wave regression in precordial leads). There is a tiny Q wave in lead V1; sometimes this points to a papillary muscle as the origin of the PVC. It is important to make recordings of the spontaneous PVCs before inserting catheters into the heart so that the true target is known, because catheters can themselves cause ectopic complexes that can confuse mapping.

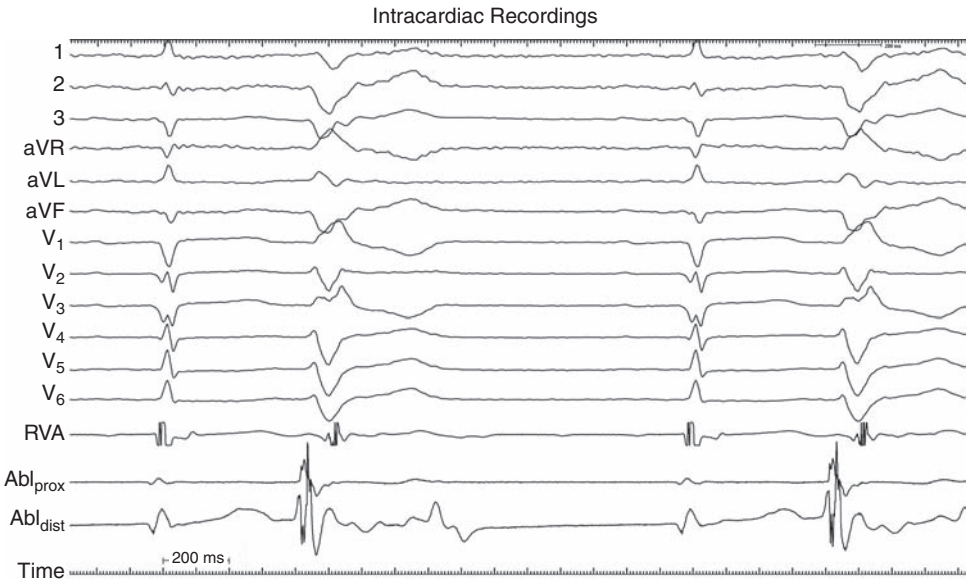

Figure 20-2

Intracardiac recordings from right ventricle and a catheter in the left ventricle (Abl) are shown in Fig. 20-2 during sinus rhythm with ventricular bigeminy.

Mapping

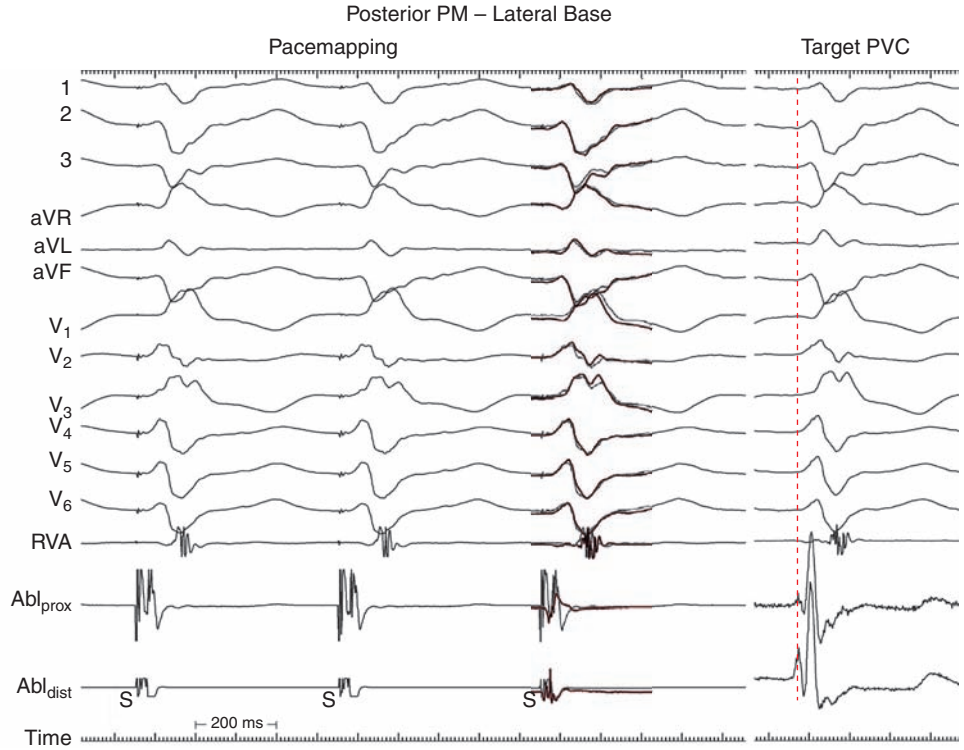

Figure 20-3

The process of mapping in this case consisted of activation mapping (manipulating the ablation catheter to various locations in the heart seeking earliest presystolic activation) corroborated by pacemapping (pacing at candidate sites to see how closely the resulting QRS complex corresponds to the native PVC). For either purpose, it is important to have adequate gain of surface ECG leads to be able to determine (1) the true QRS onset, because this will serve as a point of reference for determining whether a mapping site is early or late, and (2) being able to compare subtle differences in paced versus target PVC complexes. In Fig. 20-3, the activation time at a site on the lateral base of the posterior papillary muscle is shown at right; a *dashed line* indicates the onset of the QRS complex. Pacing at this site for three complexes is also shown. A single beat of the target PVC is superimposed on the last paced complex. The activation time at this site is about −15 ms, with distal electrode earlier than proximal, but the paced morphology is not a very good match. Mapping will continue.

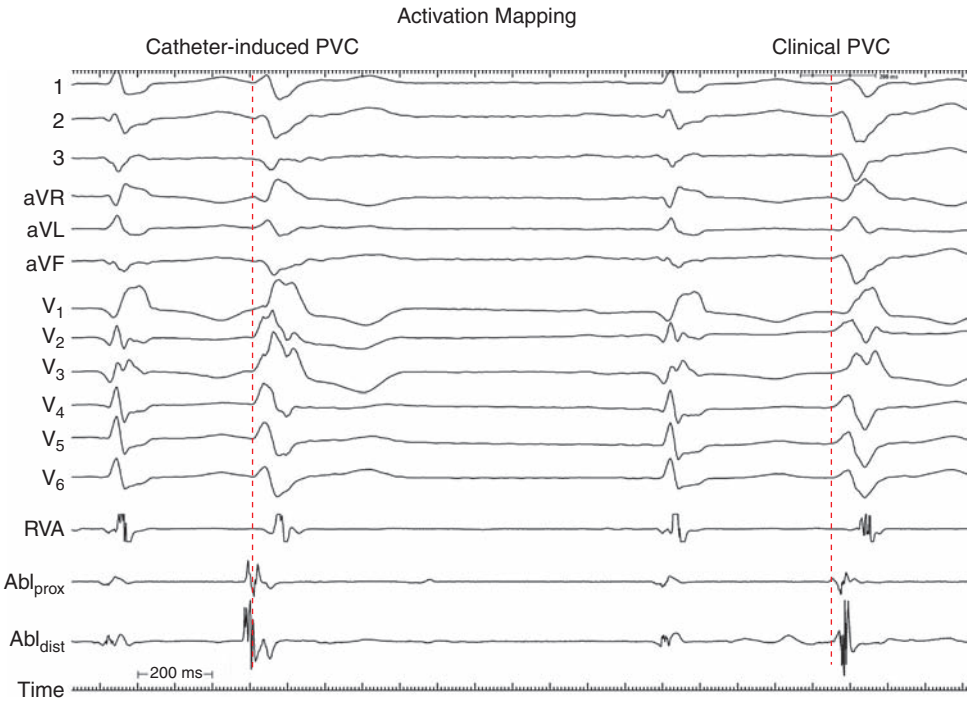

Figure 20-4

At another site, the PVC on the left has an activation time about −33 ms, with the distal electrode earlier than proximal (Fig. 20-4). This looks like a great ablation site, but careful inspection shows that the PVC morphology is different from the target PVC at right (where the activation time is not good at all). The PVC on the left is thus catheter-induced ectopy and illustrates one of the hazards of mapping in such cases. Catheter–tissue contact is important for both mapping and ablation, but can cause PVCs that look like good ablation targets, but are not.

It is no surprise that the activation time is so early, because the catheter tip (where this distal recording is made) caused the ectopy. Of note, catheter-induced right bundle branch block (RBBB) is now present during sinus complexes.

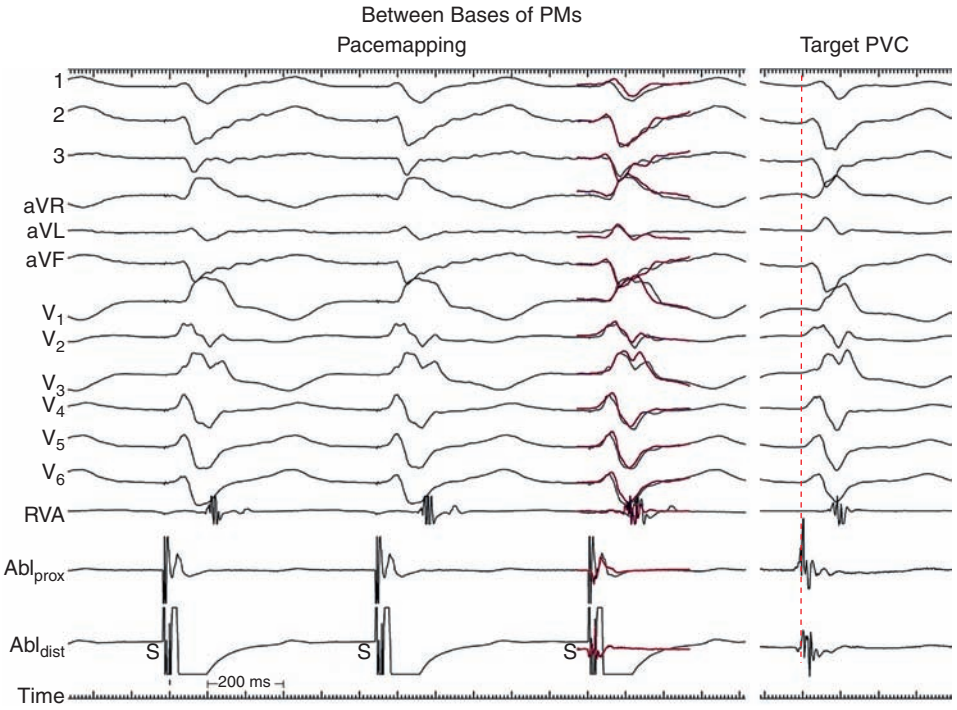

Figure 20-5

At a site between the bases of the anterior and posterior papillary muscles (Fig. 20-5), the activation time is about −15 ms; however, the proximal and distal electrodes have similar timing, and for ablation, the distal should be earlier. Pacing at this site again shows a good, but not exact, match with the target PVC. Mapping will continue.

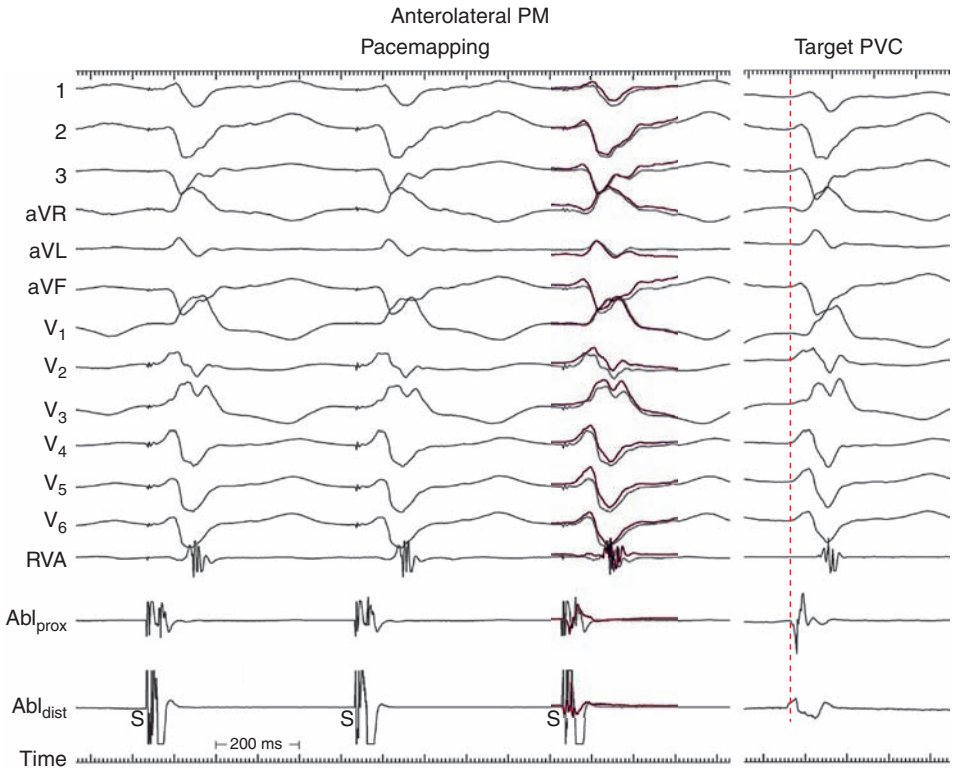

Figure 20-6

A site on the anterolateral papillary muscle (Fig. 20-6) has an activation time at the distal electrode of about −15 ms, but the proximal electrode is even earlier; pacing was performed at the site (even though it would not serve as a good ablation site because of the timing of activation), and again was not a very good match with the target PVC.

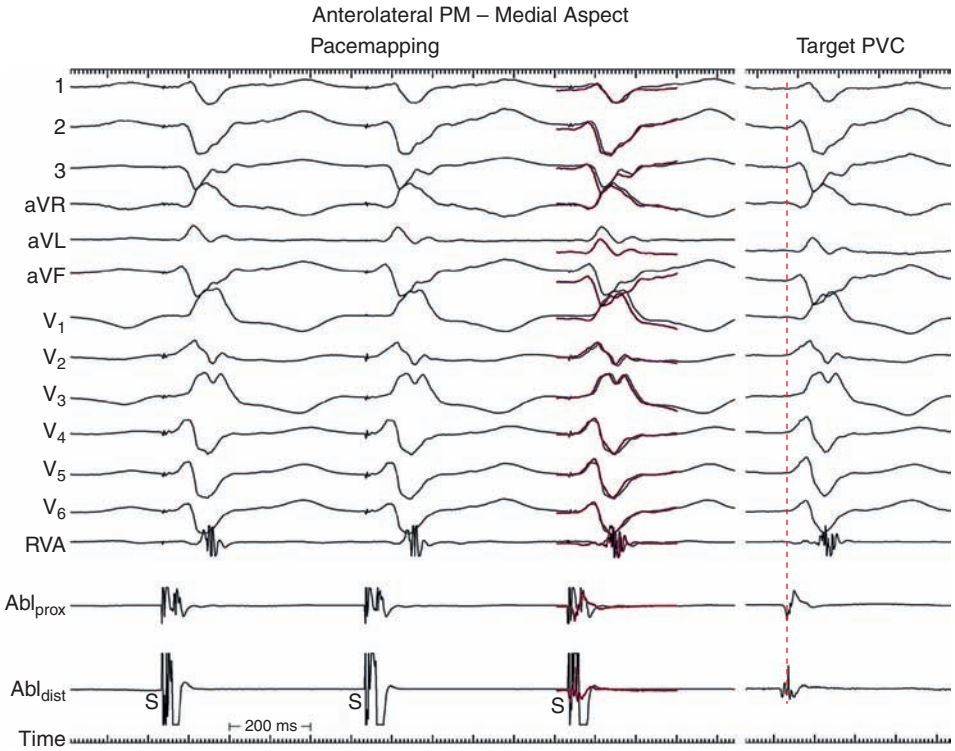

Figure 20-7

In Fig. 20-7, a site on the medial aspect of the anterolateral papillary muscle shows an activation time about −25 ms; this is the earliest that has been found thus far. The location is away from where the Purkinje network should be and the electrogram does not suggest Purkinje tissue (typically a very sharp potential preceding and often separated from a larger ventricular signal by 5 to 10 ms). Thus this seems to be myocardial in origin. Pacing at this site exactly replicates the target PVC. This should hopefully serve as a good ablation site.

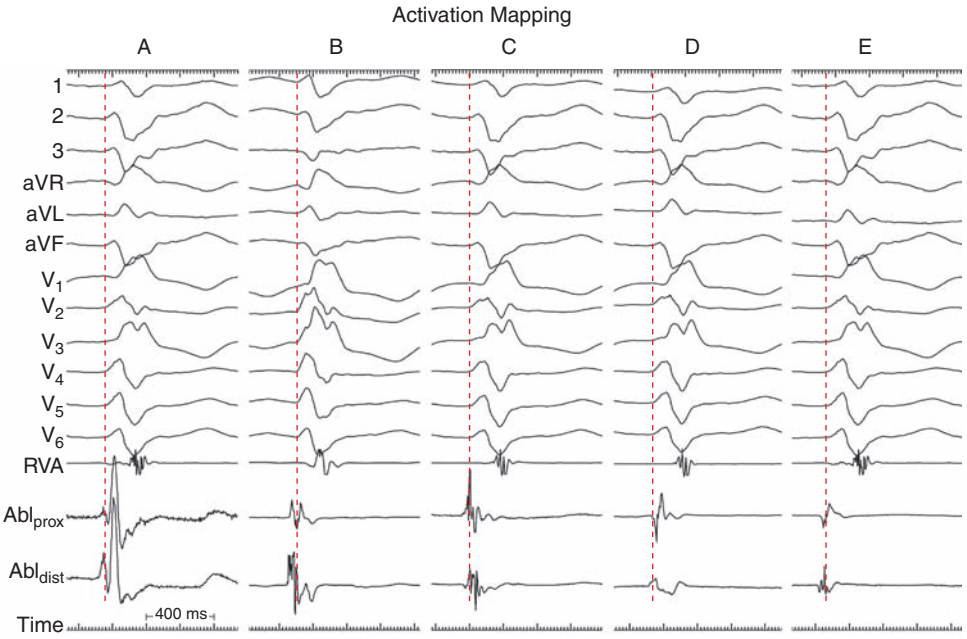

Figure 20-8

Fig. 20-8 is a compilation of activation times from five different LV sites. At site A, the distal electrogram is somewhat early relative to the QRS onset (−15 ms) and precedes the proximal electrogram, but its timing is not particularly early. At site B, the activation time looks great at −33 ms, but the QRS complex is different from the target PVC (our catheter-induced PVC from earlier). Site C has a relatively early electrogram timing (−15 ms), but the proximal electrode is earlier (−20 ms). At site D, the timing of the distal electrogram is about −20 ms, but its shape is rounded rather than sharp, indicating relatively poor contact. None of these candidate sites are suitable for attempting ablation. At site E, a sharp electrogram precedes the QRS complex by about 25 ms and is earlier than the proximal electrode. This is the site at which the perfect pace match was obtained.

Ablation

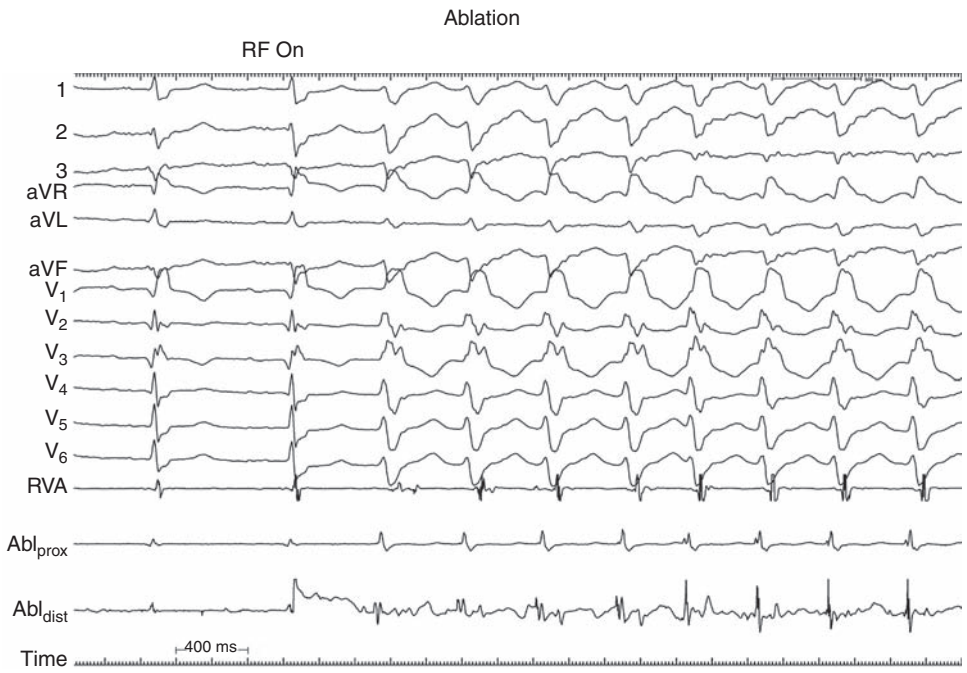

Figure 20-9

In Fig. 20-9, radiofrequency (RF) ablation is begun at the site shown in Fig. 20-7. The first thing to notice is that the first two complexes at left are sinus complexes with RBBB; the

previously bigeminal PVCs have been transiently suppressed by catheter pressure at the site. Almost as soon as RF energy is turned on, a flurry of ventricular tachycardia (VT) with the same morphology as the target PVCs occurs. This is a common finding with focal arrhythmias, so much so that if one does not see RF-induced ectopy during the first few seconds of ablation in such cases, it is worth considering stopping energy delivery and mapping elsewhere or getting better contact on the site.

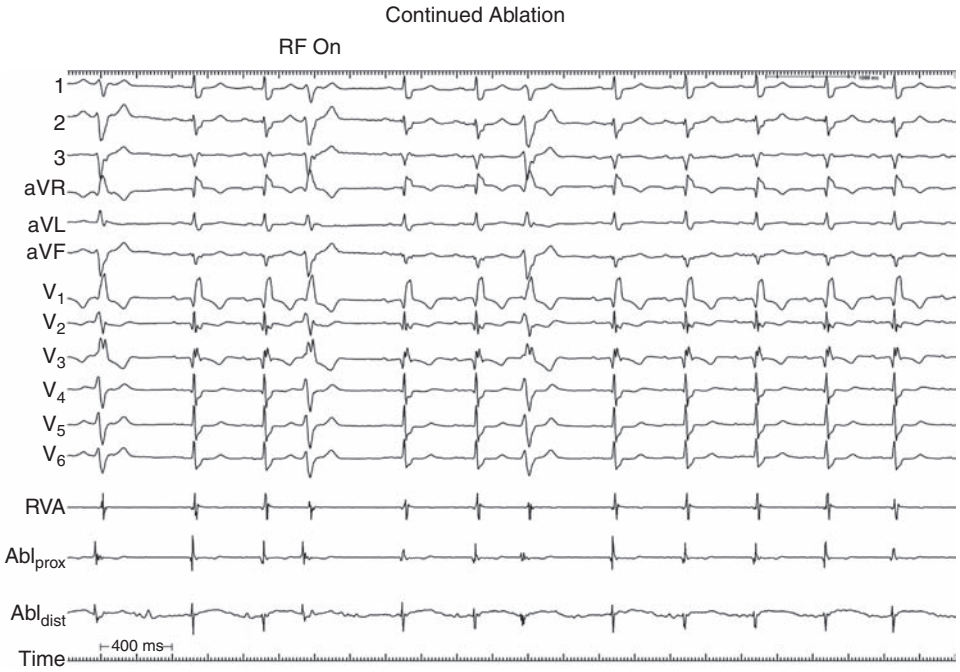

Figure 20-10

After stopping RF delivery at the site, rare PVCs persisted. Here (Fig. 20-10), PVCs have become trigeminal. Additional RF energy is delivered that results in sudden cessation of ectopy. Several more RF applications were delivered in the same general area, because foci of ectopy are sometimes deep and/or diffuse. Despite extensive ablation, papillary muscle dysfunction with mitral regurgitation is rare.

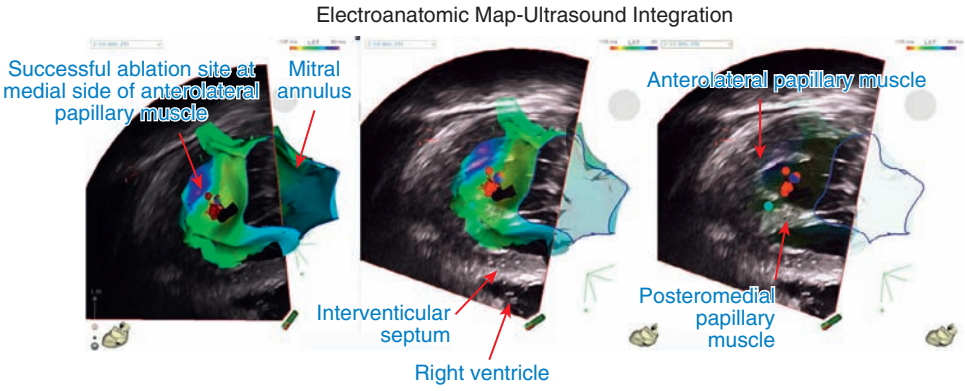

Figure 20-11

Intracardiac echocardiography is often useful for delineation of structures, such as papillary muscles, and stabilization of catheters especially in cases such as this. Stability of catheter contact on papillary muscles is notoriously difficult to achieve. Here (Fig. 20-11), integration of electroanatomic mapping and intracardiac echocardiography shows where ablation was performed (*red dots*, medial aspect of anterolateral papillary muscle).

Summary

- PVCs and VT arising from a papillary muscle are relatively rare and must be distinguished from fascicular ectopy as well as verapamil-sensitive VT
- PVCs more commonly originate from the posterior than anterior papillary muscle, but can arise in a right ventricular papillary muscle as well
- Intracardiac echocardiography may help in localizing the anatomic site of origin of the PVC/VT and aid in stabilization of the ablation catheter, but is not mandatory
- Ectopic foci from papillary muscles may be difficult to ablate because of catheter stability and depth of penetration needed

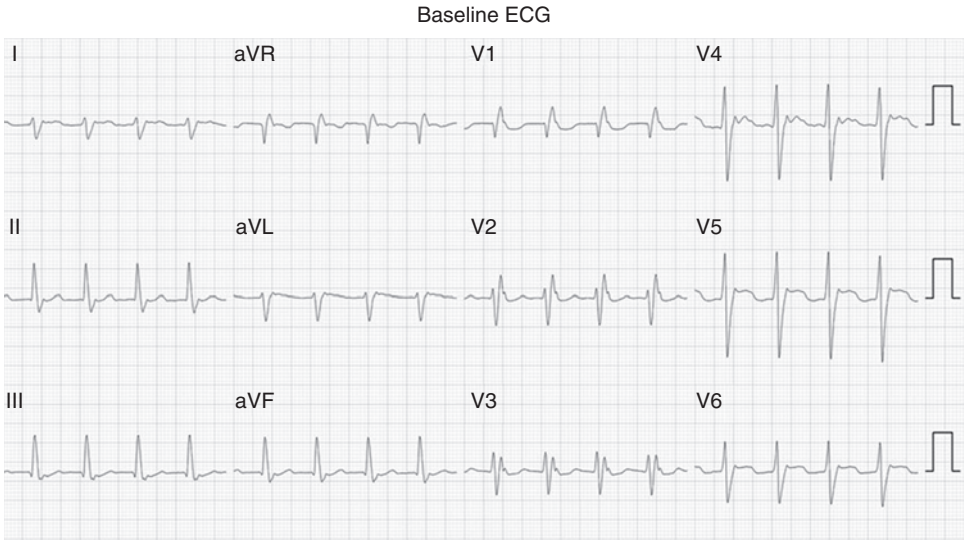
Focal Fascicular Ventricular Tachycardia

21

Case Presentation

The patient was a 37-year-old man with palpitations for many years and had occasional lightheaded episodes. ECG showed right bundle branch block (RBBB) and rightward inferior axis QRS. The rhythm was incessant (present 100% of the time) and atrioventricular (AV) dissociation was evident. Echocardiogram revealed low-normal left ventricle (LV) systolic function (ejection fraction [EF] 40%). He had undergone three catheter ablation attempts in the past, without noteworthy benefit. He was referred for repeat electrophysiology (EP) study and possible ablation, but he expressed skepticism about whether it was worth it to proceed in light of prior failures.

Baseline ECG and Intracardiac Recordings



What Is the Rhythm?

- Ventricular tachycardia (VT)?
- Supraventricular tachycardia (SVT) with aberration?
- Fascicular? [Fig. 21-1]

Figure 21-1

The ECG in Fig. 21-1 shows a wide-complex tachycardia with RBBB-rightward inferior axis. P waves are not clearly seen. Using standard morphologic criteria, most suggest that this is a supraventricular (SVT) QRS complex rather than ventricular in origin (QRS duration, axis, precordial QRS onset to S nadir <100 ms, time to peak in lead 2 <50 ms, sharp Q in aVR). However, an arrhythmia from the infranodal conduction system (junctional with aberration, or fascicular) could look like this and meet the same criteria (suggesting SVT with aberration).

What Does This Say About the Nature of the Arrhythmia? How Can the Mechanism Be Assessed?

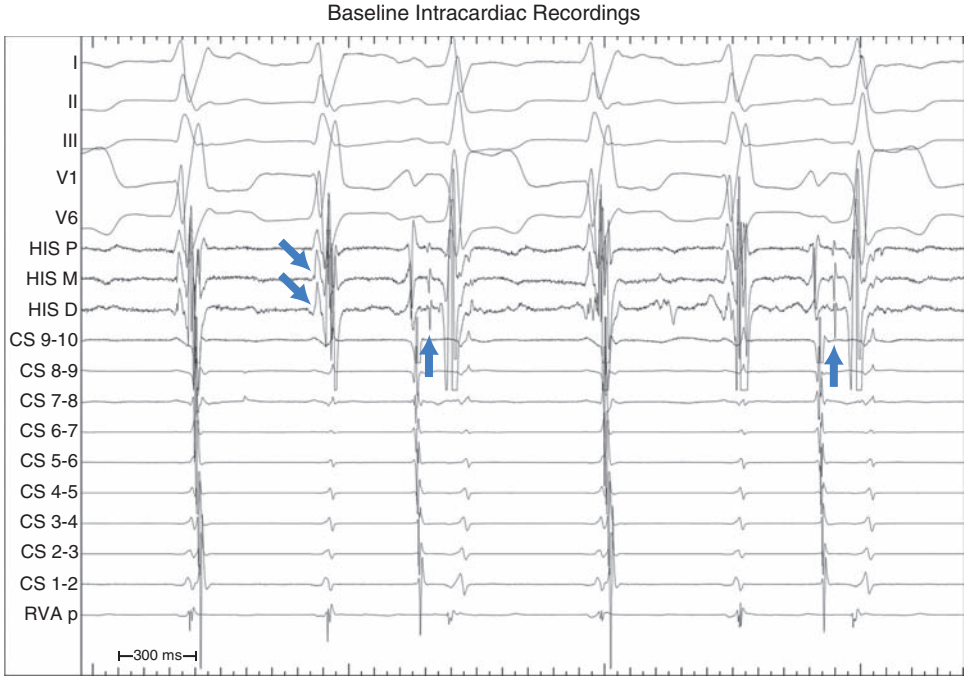


Figure 21-2

Baseline intracardiac recordings (Fig. 21-2) show AV dissociation during the wide-complex tachycardia; the third and sixth QRS complexes are different from the others, being either fusion complexes or complete capture complexes as a result of fortuitous timing of a P wave at such a time that anterograde conduction over the normal conduction system is possible. Both of these QRS complexes have His potentials (inscribed anterogradely; *slanted arrows*) before the QRS complex, identifying them as fusion/capture complexes. The His potential during tachycardia complexes is not as easily seen; *vertical blue arrows* point to possible retrograde His potentials. This also shows that the baseline rhythm is fascicular in origin rather than junctional with RBBB/left posterior fascicular block; in the latter case, conducted complexes should also show RBBB/right axis.

Effects of Right Ventricular Overdrive Pacing

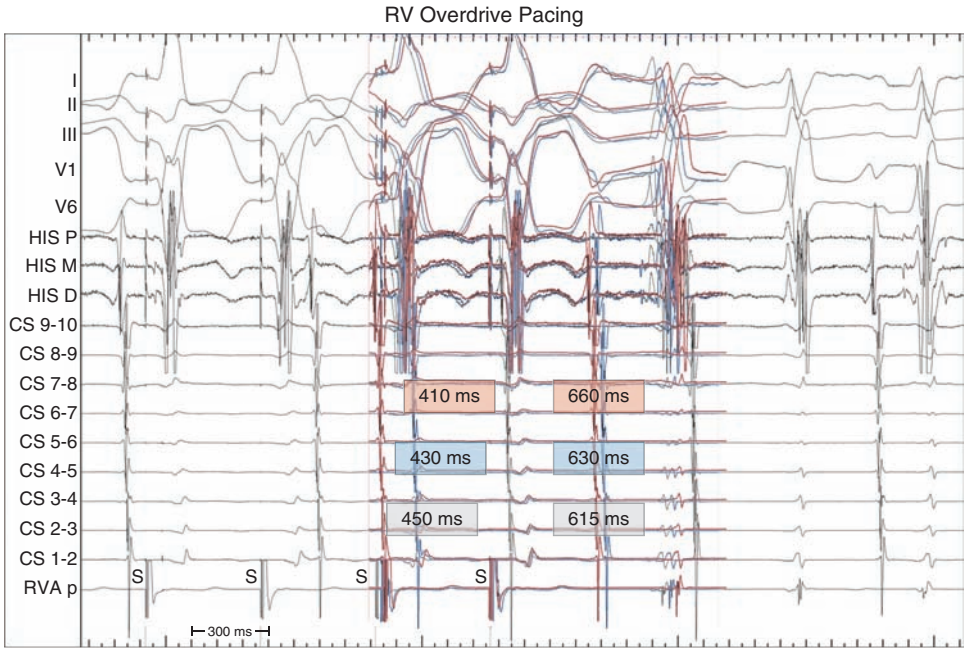

Figure 21-3

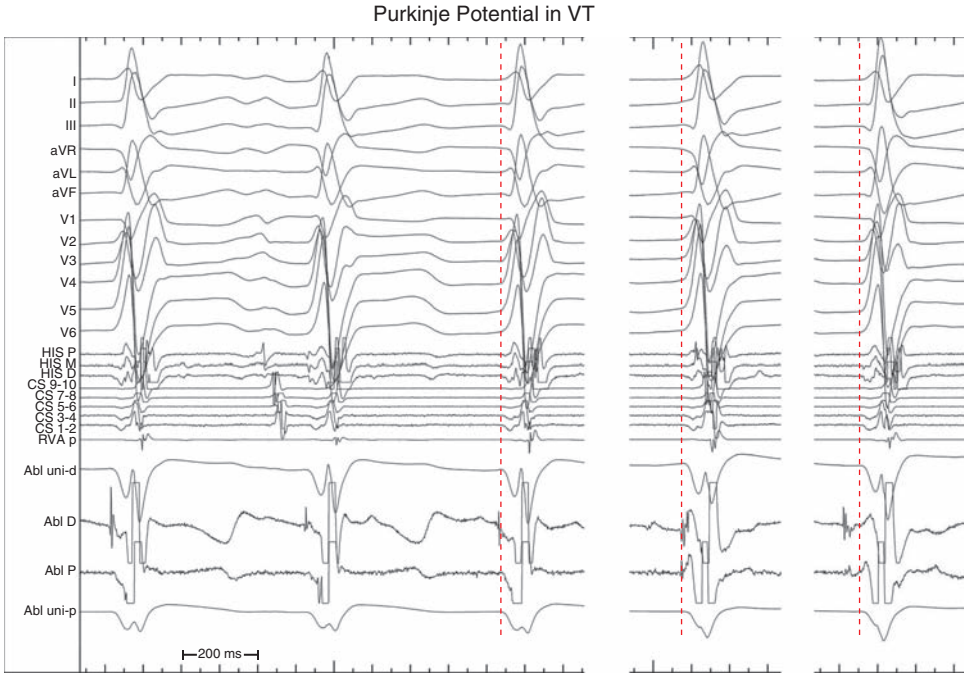
To determine whether the tachycardia mechanism was macroreentry or a focus (most likely automatic), overdrive pacing was performed at progressively more rapid rates and the timing of the first return VT cycle measured. In Fig. 21-3, for pacing at cycle length (CL) 450 ms, the first VT complex returns after 615 ms; for pacing at 430 ms (in *blue*), the VT returns at 630 ms; and for pacing at 410 ms (in *red*), the VT returns at 660 ms. This response shows overdrive suppression, a characteristic of automatic foci. In reentrant rhythms, the return cycle is typically relatively constant over a wide range of overdrive paced CLs, whereas in tachycardias due to classical triggered activity related to delayed afterdepolarizations, the first complex of the resumed arrhythmia returns progressively sooner following more rapid paced rates.

Different Mapping Sites ("Purkinje Potential")



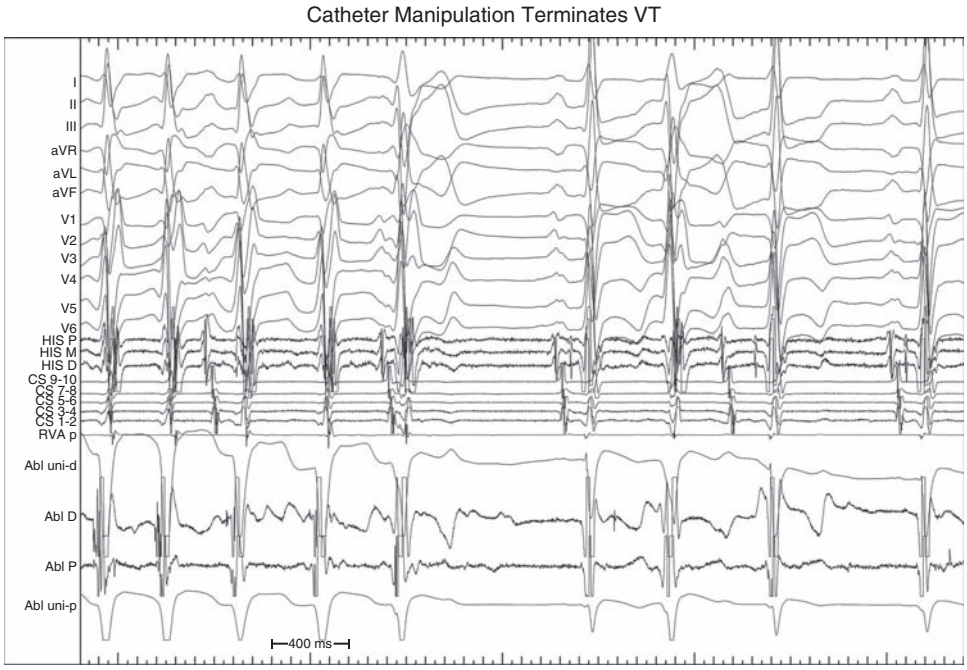
Is There a Good Ablation Site Shown? [Fig. 21-4]

Figure 21-4

Based on the foregoing tests, a diagnosis of a focal, automatic fascicular tachycardia has been made and its origin will be sought. In Fig. 21-4, multiple sites are mapped during the arrhythmia, seeking the earliest Purkinje recording; this should be 15 to 40 ms before QRS onset *(dashed red line)*. Ablation at a site other than that of earliest activation (the focus) will have no effect on the focus but may alter its exit (QRS morphology); see below (Fig. 21-12). Thus it is important to take the time to carefully map and determine the earliest site, from which all other recordings emanate. While each panel shows a Purkinje spike in Abl D recordings, only in the far right panel is it significantly prior to the QRS onset; this was the very earliest site found of about 90 sites sampled during tachycardia.

Catheter Manipulation Terminates VT

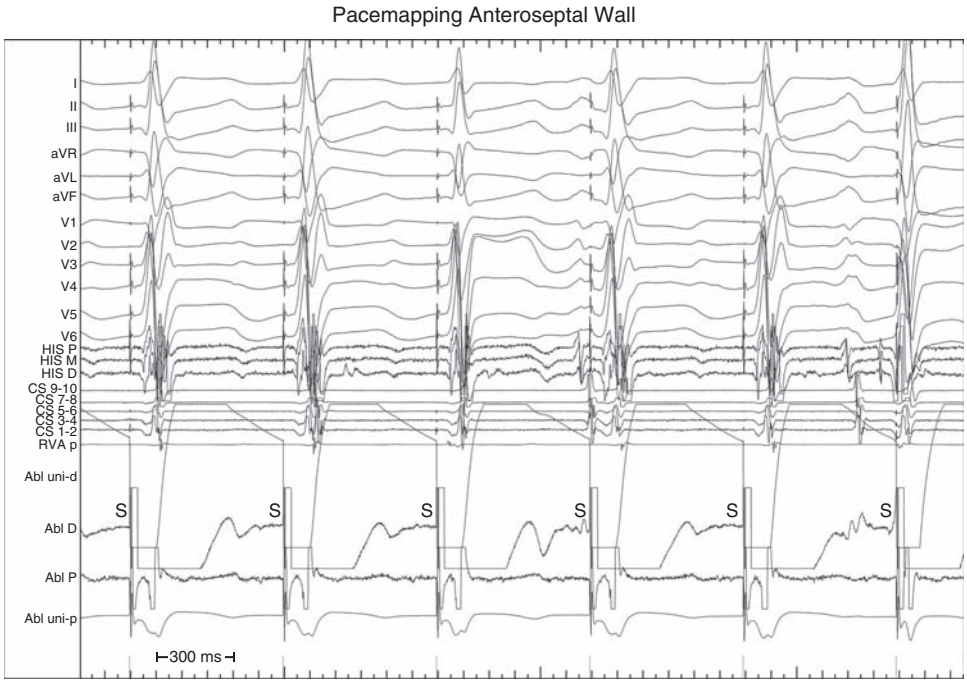
Figure 21-5



The focus is often very superficial on the endocardial surface and thus susceptible to catheter-induced trauma, resulting in arrhythmia termination (as shown in Fig. 21-5) and subsequent quiescence for prolonged periods. In many (but not all) cases, the focus recovers within minutes and mapping can continue. Careful mapping (minute catheter movements) allows logging of the site on an electroanatomic mapping system at the moment of catheter-related arrhythmia termination so that it can still be targeted for ablation even if the arrhythmia remains quiescent. This so-called "bump-mapping" implies a very small discrete target that is superficial (ie, not in deeper layers) and furthermore has been encountered by the catheter (it was "bumped").

Pacemapping Anteroseptal Wall, Superimposed on Baseline VT ECG

Figure 21-6



Pacemapping can corroborate activation mapping data; in Fig. 21-6, pacing at a site with an early Purkinje potential during VT perfectly replicates the arrhythmia on 12-lead ECG with an electrocardiographically quiet, discrete interval from stimulus-QRS that correlates with the interval from the Purkinje potential to QRS onset during VT.

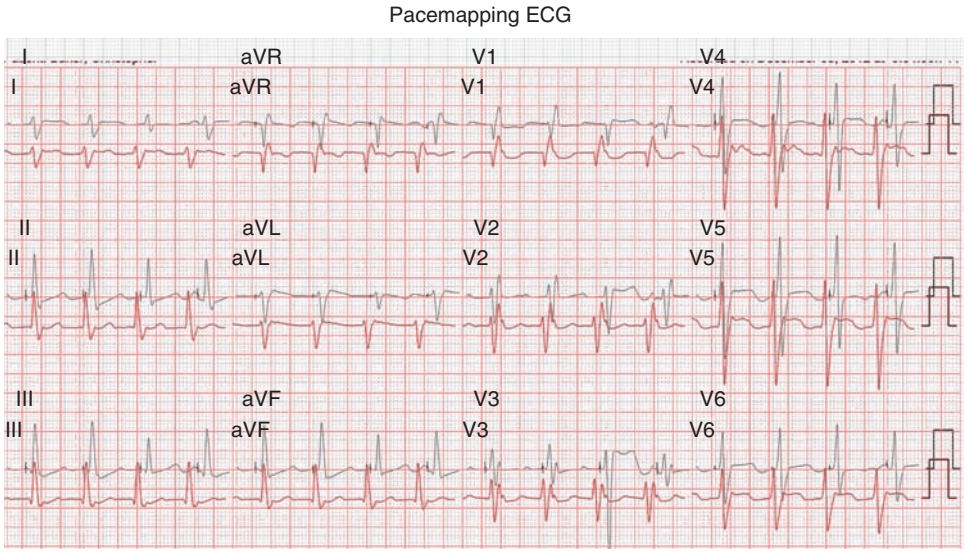


Figure 21-7

Superimposition of the VT ECG atop the pacemapping ECG (in red, aligning the first complex in each panel) shows a perfect match with VT (Fig. 21-7).

RF Energy Delivery

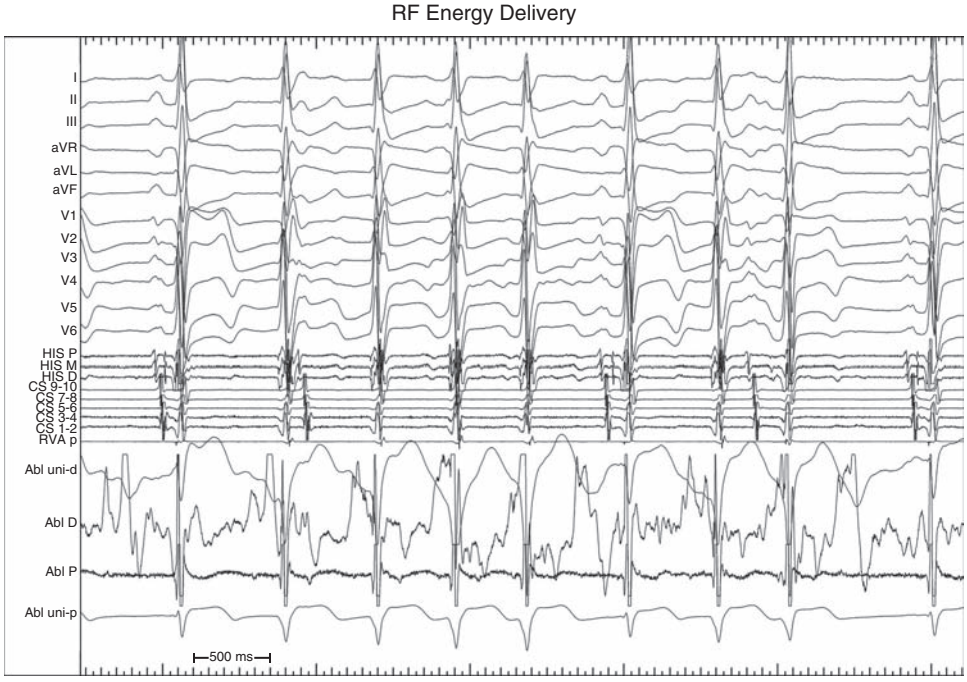

Figure 21-8

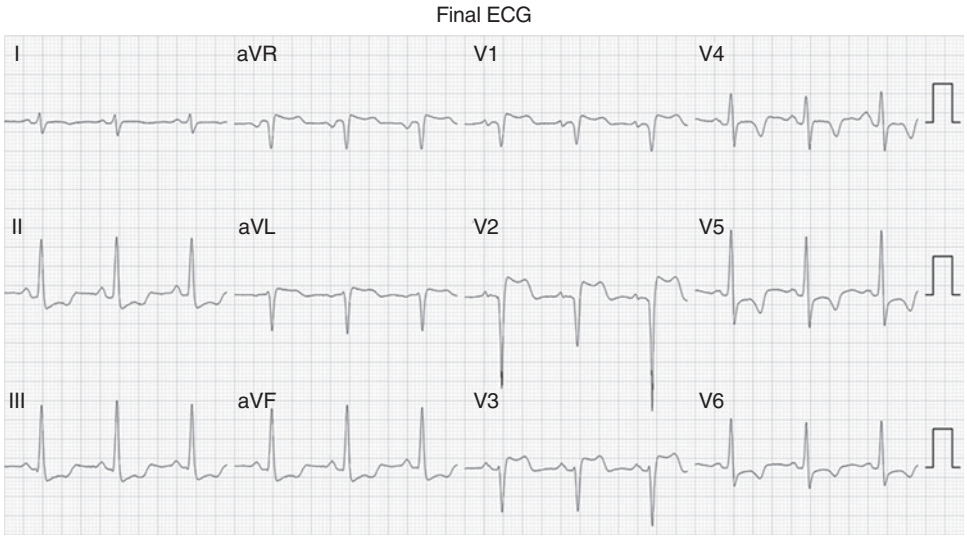
During RF delivery at the site of earliest Purkinje activation during VT, a flurry of activity with the same QRS complex occurs followed by termination to sinus rhythm (Fig. 21-8). This effect is characteristic of focal emanation (in contrast, reentrant VTs typically slow before termination).

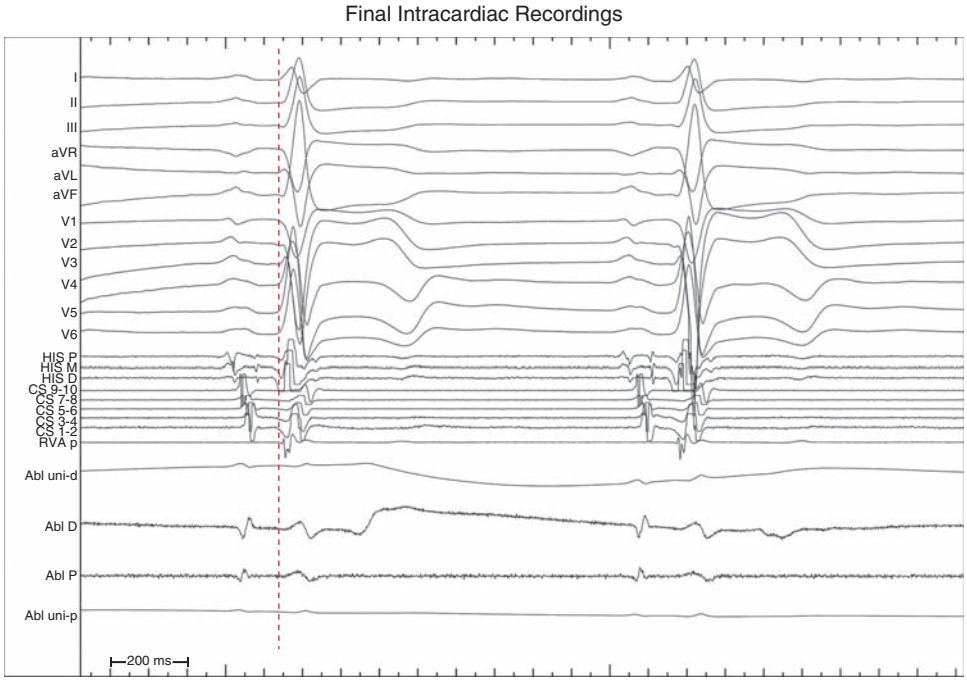
Final ECG and Intracardiac Recordings

Figure 21-9



The final ECG (Fig. 21-9) shows sinus rhythm without bundle branch block or axis deviation; ST-T wave abnormalities are an artifact of the recording system.

Figure 21-10



The final intracardiac recordings (Fig. 21-10) show sinus rhythm without bundle branch block or axis deviation.

Electroanatomic Maps

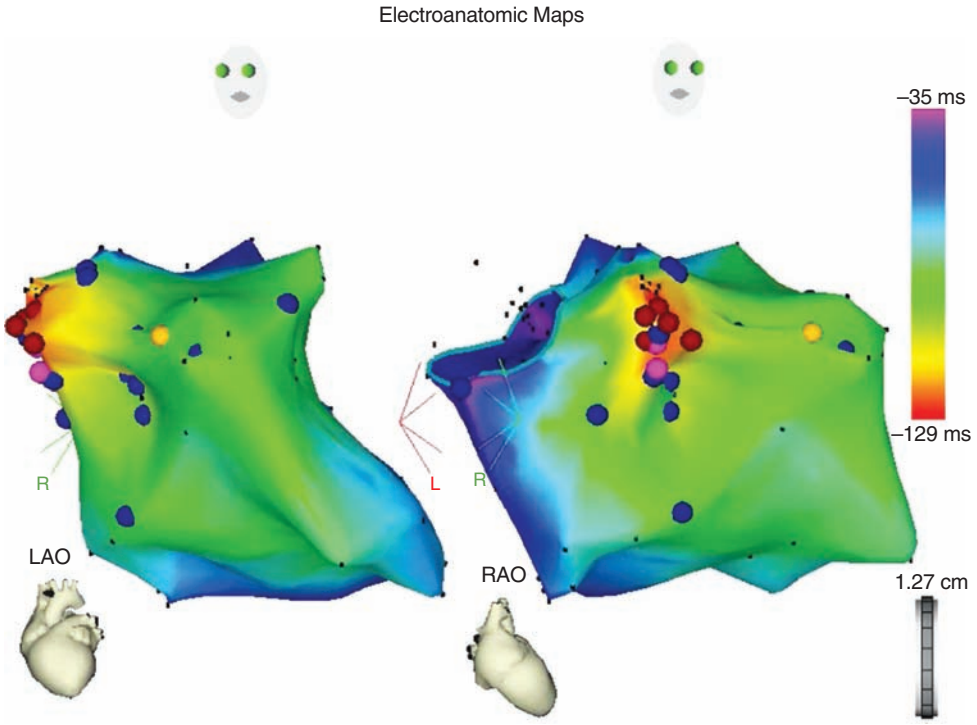


Figure 21-11

Fig. 21-11 displays the right and left anterior oblique views of the left ventricular activation during VT. The *purple dots* signify where perfect pace-matches were obtained as well as ablation sites where tachycardia terminated; *red dots* are consolidation ablation sites; *blue dots* denote where other Purkinje potentials were identified. The activation map shows earliest recordings during VT at the upper basal septal/anterior wall junction, with all other activations proceeding centrifugally from this region (consistent with a focal process).

Points on Mapping Fascicular VTs

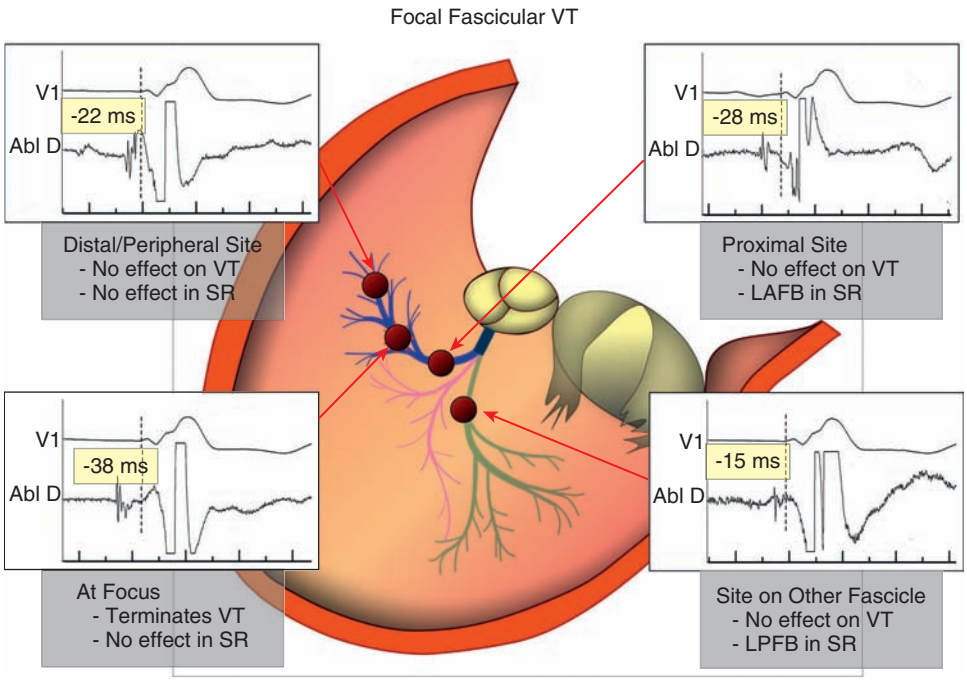

Figure 21-12

Fig. 21-12 shows the importance of ablation at the best site and implications of ablation at incorrect sites. SR, sinus rhythm; LAFB, left anterior fascicular block; LPFB, left posterior fascicular block.

Follow-up

- No further arrhythmias overnight, discharged the following morning
- Seen in follow-up 3 months later:
  - Sinus rhythm, no ectopy
  - Energy significantly improved
  - Very glad now that he had the procedure

Summary

- Fascicular tachycardias can be reentrant or focal (as in this case); overdrive pacing can differentiate these two causes
- It is important to determine whether the arrhythmia is junctional with bundle branch block/fascicular block or fascicular rhythm
- "Bump-mapping" can be useful but has limitations
- Correct targeting of the focus is critical for eliminating it and not causing unwanted "collateral damage" to other areas

Reentrant Fascicular Ventricular Tachycardia

22

Case Presentation

The patient is a 30-year-old man with four episodes of severe palpitations. In the first episode, the patient had palpitations and near-syncope while playing basketball. He was taken to the local ER, and his blood pressure was 110/80 mm Hg and wide complex tachycardia was 200/min. He was given adenosine, metoprolol, and diltiazem, but there was no effect. Arrhythmia was ultimately slowed and terminated. He was hospitalized and underwent an electrophysiology (EP) study; no arrhythmia was initiated. He was diagnosed with probable atrial tachycardia and treated with metoprolol, and subsequently discharged. Subsequent episodes were with and without exertion and stopped spontaneously after 15 to 40 min. He was found to have normal exercise capacity, and findings of physical examination and echocardiogram were normal; baseline ECG was normal too. The EP study found no inducible arrhythmias, and he was referred for a repeat EP study and possible ablation.

Baseline ECGs

What Is the Rhythm? [Fig. 22-1]

- VT?
- SVT with aberration?
- Fascicular?

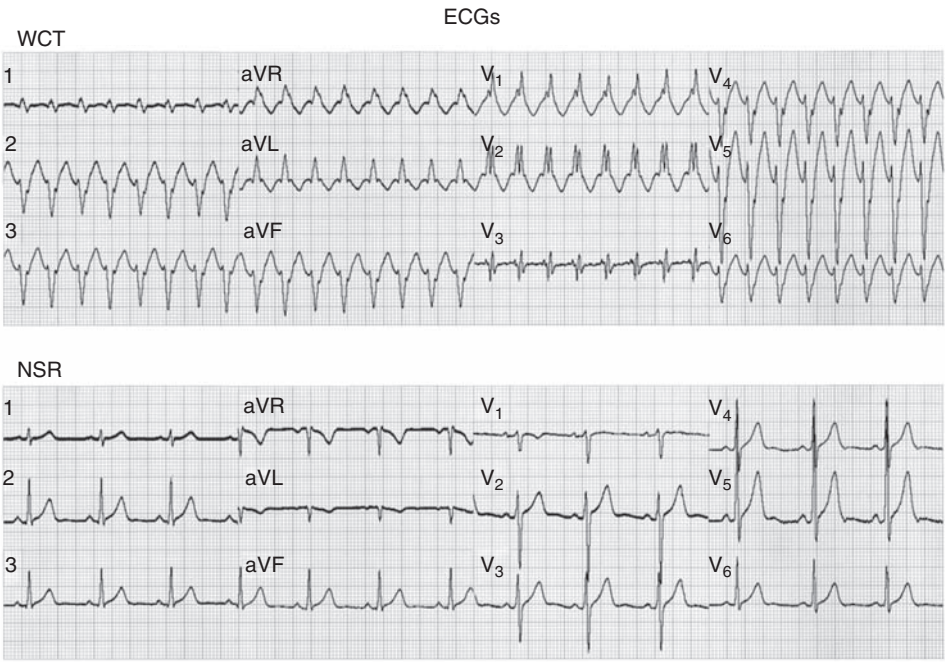

Figure 22-1

As shown in Fig. 22-1, the QRS during the wide complex tachycardia (WCT) is about 130 ms in duration and has RBBB pattern that in V1 and V6 is more consistent with ventricular tachycardia (VT; the rR′ in V1, R/S ratio <1 in V6), but the R-wave peak time in lead 2 (<50 ms), rS interval in a precordial lead <100 ms (Brugada criterion), qR pattern in aVR, and ventricular activation velocity index in V2 and V3 (>1) favor supraventricular tachycardia (SVT). P waves are not clearly evident (thus one cannot determine dissociation of atrial activity). There are no pathologic Q waves during the WCT or sinus rhythm to suggest old infarction. There is no preexcitation or any other abnormality of the QRS or repolarization to suggest a cardiomyopathy. Thus the WCT is either an atypical form of aberration during SVT or it is VT in the absence of structural heart disease. It is notable that no arrhythmias could be initiated at the prior EP study, but some VT in normal hearts as well as some focal atrial tachycardias may be difficult to initiate.

Baseline Atrial Pacing and Arrhythmia Induction

What's Going on Here? [Fig. 22-2]

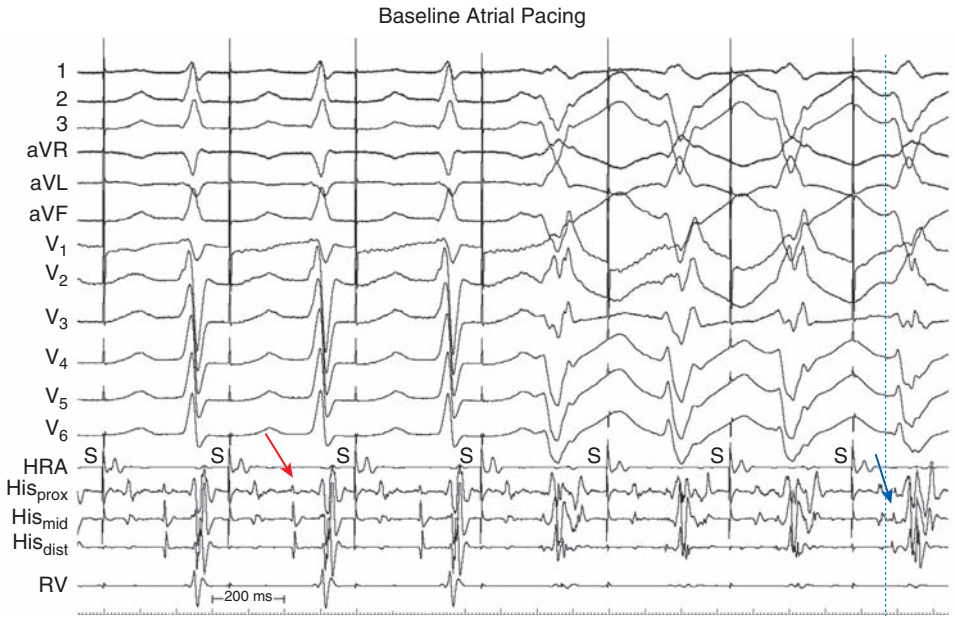

Figure 22-2
